The **IgM-IFA test** is useful for the diagnosis of acute acquired infection with *T. gondii* in the older child because IgM antibodies appear earlier, often by 5 days after infection, and diminish more quickly than IgG antibodies. In most instances, IgM antibodies rise rapidly (1 : 50 to <1 : 1,000) and then fall to low titers (1 : 10 or 1 : 20) or disappear after weeks or months. However, some patients continue to have positive IgM results with low titers for several years. The IgM-IFA test detects *Toxoplasma* -specific IgM in only approximately 25% of congenitally infected infants at birth. IgM antibodies may not be present in sera of immunocompromised patients with acute toxoplasmosis or in patients with reactivation of ocular toxoplasmosis. The IgM-IFA test may yield false-positive results as a result of rheumatoid factor.

The **double-sandwich IgM enzyme-linked immunosorbent assay (IgM-ELISA)** is also useful for detection of *Toxoplasma* IgM antibodies. In the older child, serum IgM-ELISA *Toxoplasma* antibodies of >2 (a value of one reference laboratory; each laboratory must establish its own value for positive results) indicates that *Toxoplasma* infection most likely has been acquired recently. The IgM-ELISA identifies approximately 50–75% of infants with congenital infection. IgM-ELISA avoids both the false-positive results from rheumatoid factor (RF) and the false-negative results from high levels of passively transferred maternal IgG antibody in fetal serum, as may occur in the IgM-IFA test. Results obtained with commercial kits must be interpreted with caution, because false-positive reactions can occur. Care must also be taken to determine whether kits have been standardized for diagnosis of infection in specific clinical settings, such as in the newborn infant. The **IgA-ELISA** also is a sensitive test for detection of maternal and congenital infection, and results may be positive when those of the IgM-ELISA are not.

The **immunosorbent agglutination assay (ISAGA)** combines trapping of a patient's IgM to a solid surface and use of formalin-fixed organisms or antigen-coated latex particles. It is read as an agglutination test. There are no false-positive results from RF or antinuclear antibodies (ANAs). **IgM-ISAGA** is more sensitive than and may detect specific IgM antibodies before and for longer periods than IgM-ELISA.

At present, IgM-ISAGA and IgA-ELISA are the most useful tests for diagnosis of congenital infection in the newborn but are not positive in all infected infants. The IgE-ELISA and IgE-ISAGA are also sometimes useful in establishing the diagnosis of congenital toxoplasmosis or acute acquired *T. gondii* infection. The presence of IgM antibodies in the older child or adult can never be used alone to diagnose acute acquired infection.

The **differential agglutination test (HS/AC)** compares antibody titers obtained with formalin-fixed tachyzoites (**HS antigen**) with titers obtained using acetone-fixed tachyzoites (**AC antigen**) to differentiate recent and remote infections in adults and older children. This method may be particularly useful in differentiating remote infection in pregnant women, because levels of IgM and IgA antibodies detectable by ELISA or ISAGA may remain elevated for months to years in adults and older children.

The **avidity test** can be helpful to establish time of acquisition of infection. A high-avidity test result indicates that infection began >12-16 wk earlier, which is especially useful in determining time of acquisition of infection in the 1st or final 16 wk of gestation. A low-avidity test result may be present for many months or even years and does not definitively identify recent acquisition of infection.

A relatively higher level of *Toxoplasma* antibody in the aqueous humor or in CSF demonstrates local production of antibody during active ocular or CNS toxoplasmosis. This comparison is performed, and a coefficient [C] is calculated as follows:

$$C = \frac{\text{Antibody titer in body fluid}}{\text{Antibody titer in serum}} \times \frac{\text{Concentration of IgG in serum}}{\text{Concentration of IgG in body fluid}}$$

Significant coefficients [C] are >8 for ocular infection, >4 for CNS for congenital infection, and >1 for CNS infection in patients with AIDS. If the serum dye test titer is >300 IU/mL, it is not possible to demonstrate significant local antibody production using this formula with either the dye test or the IgM-IFA test titer. IgM antibody may be detectable in CSF.

Comparative **Western immunoblot** tests of sera from a mother and infant may detect congenital infection. Infection is suspected when the mother's serum and her infant's serum contain antibodies that react with different *Toxoplasma* antigens.

The **enzyme-linked immunofiltration assay** using micropore membranes permits simultaneous study of antibody specificity by immunoprecipitation and characterization of antibody isotypes by immunofiltration with enzyme-labeled antibodies. This method able to detect 85% of cases of congenital infection in the 1st few days of life.

Serologic tests in development include multiplex antibody tests for IgG, IgM, and IgA-specific antibodies, as well as point-of-care tests designed to provide accurate and rapid identification of recent infection or seroconversion in pregnant women.

PCR is used to amplify the DNA of *T. gondii,* which then can be detected by using a DNA probe. Detection of repetitive *T. gondii* genes, the B1 or 529 bp, 300 copy gene, in amniotic fluid is the PCR target of choice for establishing the diagnosis of congenital *Toxoplasma* infection in the fetus. Sensitivity and specificity of this test in amniotic fluid obtained to diagnose infections acquired between 17 and 21 wk of gestation are approximately 95%. Before and after that time, PCR with the 529 bp, 300 copy repeat gene as the template is 92% sensitive and 100% specific for detection of congenital infection. PCR of vitreous or aqueous fluids also has been used to diagnose ocular toxoplasmosis. PCR of peripheral white blood cells, CSF, and urine has been reported to detect congenital infection.

Point-of-care tests such as the *Toxoplasma* ICT IgG-IgM test or a nanogold test will lower the cost of and increase the ease of rapid testing.

Lymphocyte blastogenesis to *Toxoplasma* antigens has been used to diagnose congenital toxoplasmosis when the diagnosis is uncertain and other test results are negative. However, a negative result does not exclude the diagnosis because peripheral blood lymphocytes of infected newborns may not respond to *T. gondii* antigens because of immune tolerance testing in specific circumstances.

Acquired Toxoplasmosis

Recent infection is diagnosed by seroconversion from a negative to a positive IgG antibody titer (in the absence of transfusion); a 2-tube increase in *Toxoplasma* -specific IgG titer when serial sera are obtained 3 wk apart and tested in parallel; or the detection of *Toxoplasma* -specific IgM antibody in conjunction with other tests, but never alone.

Ocular Toxoplasmosis

IgG antibody titers of 1 : 4 to 1 : 64 are usual in older children with active *Toxoplasma* chorioretinitis. Even the presence of antibodies measurable only when serum is tested undiluted is helpful in establishing the diagnosis. The diagnosis is likely with characteristic retinal lesions and positive serologic tests. PCR of aqueous or vitreous fluid has been used to diagnose ocular toxoplasmosis but is infrequently performed because of the risks associated with obtaining intraocular fluid.

Immunocompromised Persons

IgG antibody titers may be low, and *Toxoplasma* -specific IgM is often absent in immunocompromised stem cell transplant recipients, but not in kidney or heart transplant recipients with toxoplasmosis. Demonstration of *Toxoplasma* DNA by PCR in serum, blood, and CSF may identify disseminated *Toxoplasma* infection in immunocompromised persons. Resolution of CNS lesions during a therapeutic trial of pyrimethamine and sulfadiazine has been useful to diagnose toxoplasmic encephalitis in patients with AIDS. Brain biopsy has been used to establish the diagnosis if there is no response to a therapeutic trial and to exclude other possible diagnoses such as CNS lymphoma.

Congenital Toxoplasmosis

Fetal ultrasound examination, performed every 2 wk during gestation, beginning at diagnosis of acute acquired infection in a pregnant woman, and PCR analysis of amniotic fluid are used for prenatal diagnosis. *T. gondii* may also be isolated from the placenta at delivery.

Serologic tests are also useful in establishing a diagnosis of congenital toxoplasmosis. Either persistent or rising titers in the dye test or IFA test, or a positive IgM-ELISA or IgM-ISAGA result, is diagnostic of congenital toxoplasmosis. The half-life of IgM is approximately 2 days, so if there is a placental leak, the level of IgM antibodies in the infant's serum decreases significantly, usually within 1 wk. Passively transferred maternal IgG antibodies may require many months to a year to disappear from the infant's serum, depending on the magnitude of the original titer. The half-life of passively transferred maternal IgG is approximately 30 days, so the titer diminishes by half each 30 days. Synthesis of *Toxoplasma* antibody is usually demonstrable by the 3rd mo of life if the infant is untreated, although the rate of IgG synthesis varies considerably in infants <1 yr old. If the infant is treated, synthesis may be delayed for as long as the 9th mo of life and, infrequently, may not occur at all. When an infant begins to synthesize IgG antibody, infection may be documented serologically even without demonstration of IgM antibodies by an increase in the ratio of specific serum IgG antibody titer to the total IgG, whereas the ratio will decrease if the specific IgG antibody has been passively transferred from the mother.

Newborns suspected of having congenital toxoplasmosis should be evaluated by general, ophthalmologic, and neurologic examinations; head CT scan; and some or ideally all of the following tests: an attempt to isolate *T. gondii* from the placenta and infant's leukocytes from peripheral blood buffy coat; measurement of serum *Toxoplasma* -specific IgG, IgM, IgA, and IgE antibodies, and the levels of total serum IgM and IgG; lumbar puncture, including analysis of CSF for cells, glucose, protein, *Toxoplasma* -specific IgG and IgM antibodies, and level of total IgG; and testing of CSF for *T. gondii* by PCR and inoculation into mice. Presence of *Toxoplasma* -specific IgM in CSF that is not contaminated with blood, or confirmation of local antibody production of *Toxoplasma* -specific IgG antibody in CSF, establishes the diagnosis of congenital *Toxoplasma* infection.

Many manifestations of congenital toxoplasmosis are similar to findings that occur in other perinatal infections, especially congenital cytomegalovirus infection. Since neither cerebral calcification nor chorioretinitis is pathognomonic, a negative urine culture or PCR for CMV soon after birth is a useful adjunctive test. The clinical picture in the newborn infant may also be compatible with sepsis, aseptic meningitis, syphilis, or hemolytic disease. Some children <5 yr old with chorioretinitis have postnatally acquired *T. gondii* infection.

Treatment

Pyrimethamine and **sulfadiazine** act synergistically against *Toxoplasma*, and combination therapy is indicated for many of the forms of toxoplasmosis. Use of pyrimethamine is contraindicated during the first trimester of pregnancy. **Spiramycin** should be used to attempt to prevent vertical transmission of infection to the fetus of acutely infected pregnant women. Pyrimethamine inhibits the enzyme dihydrofolate reductase, and thus the synthesis of folic acid, and therefore produces a dose-related, reversible, and usually gradual depression of the bone marrow. Neutropenia is most common, but rarely treatment has been reported to result in thrombocytopenia and anemia as well. **Reversible neutropenia** is the most common adverse effect in treated infants. All patients treated with pyrimethamine should have leukocyte counts twice weekly. Seizures may occur with overdosage of pyrimethamine. Potential toxic effects of sulfonamides (e.g., crystalluria, hematuria, rash) should be monitored. Hypersensitivity reactions occur, especially in patients with AIDS. Folinic acid, as calcium **leucovorin** , should always be administered concomitantly and for 1 wk after treatment with pyrimethamine is discontinued to prevent bone marrow suppression.

Acquired Toxoplasmosis

Patients with acquired toxoplasmosis and lymphadenopathy usually do not need specific treatment unless they have severe and persistent symptoms or evidence of damage to vital organs (see Table 316.2). If such signs and symptoms occur, treatment with pyrimethamine, sulfadiazine, and leucovorin should be initiated. Patients who appear to be immunocompetent but have severe and persistent symptoms or damage to vital organs (e.g., chorioretinitis, myocarditis) need specific therapy until these specific symptoms resolve, followed by therapy for an additional 2 wk. Therapy often is administered for at least 4-6 wk. The optimal duration of therapy is unknown. A loading dose of pyrimethamine for older children is 2 mg/kg/day divided twice daily (maximum 50 mg bid), given for the 1st 2 days of treatment. The maintenance dose begins on the 3rd day and is 1 mg/kg/day (maximum 50 mg/day). Sulfadiazine is administered at 100 mg/kg/day bid (maximum 4 g/day). Leucovorin is administered orally (PO) at 5-20 mg 3 times weekly (or even daily depending on the leukocyte count).

Ocular Toxoplasmosis

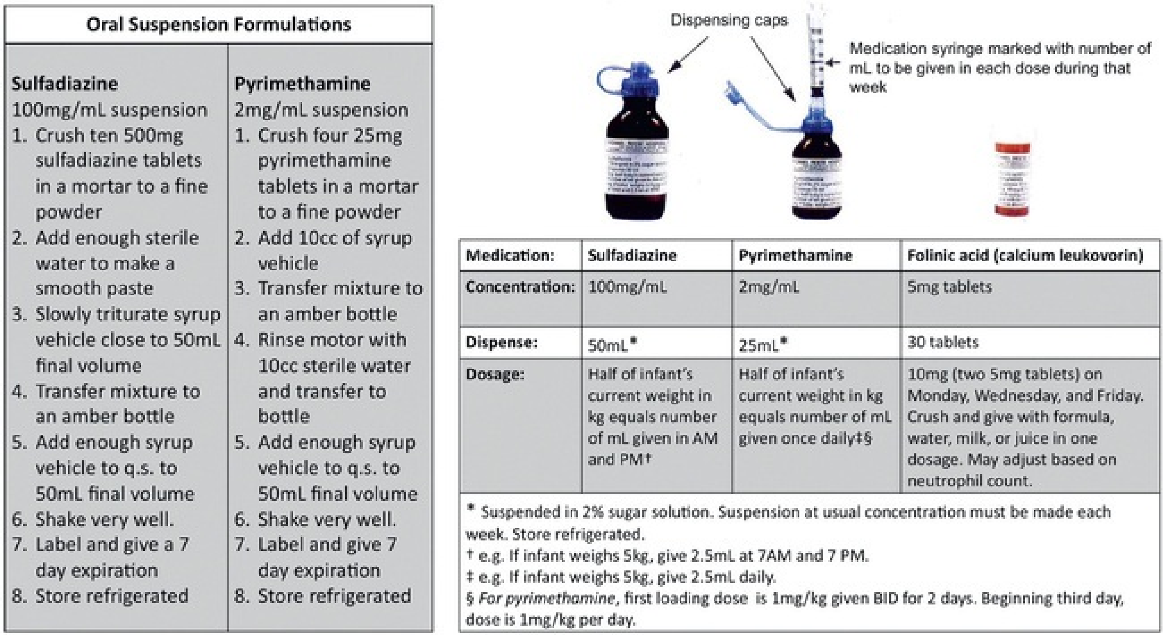
Patients with active ocular toxoplasmosis are treated with pyrimethamine, sulfadiazine, and leucovorin (see Table 316.2). They are treated while disease is active and then for approximately 1 wk after the lesion has developed a quiescent appearance (i.e., sharp borders, pigmentation at margins of the lesion, and resolution of associated inflammatory cells in the vitreous), which usually occurs in 2-4 wk when treatment is initiated promptly. Within 7-10 days, the borders of the retinal lesions sharpen, and visual acuity usually returns to that noted before development of the acute lesion. Systemic corticosteroids have been administered concomitantly with antimicrobial treatment when lesions involve the macula, optic nerve head, or papillomacular bundle. Corticosteroids must never be given alone but may be initiated after loading doses of pyrimethamine and sulfadiazine have been administered (2 days). With recurrences, new lesions often appear contiguous to old ones. Very rarely, vitrectomy and removal of the lens are needed to restore visual acuity. Active choroidal neovascular membranes as a result of toxoplasmic chorioretinitis have been treated successfully in children with intravitreal injection of antibody to vascular endothelial growth factor in addition to oral anti-*Toxoplasma* medicines. Suppressive treatment has prevented frequent recurrences of vision-threatening lesions.

Immunocompromised Persons

Serologic evidence of acute infection in an immunocompromised patient, regardless of whether signs and symptoms of infection are present or tachyzoites are demonstrated in tissue, are indications for therapy similar to that described for immunocompetent persons with symptoms of organ injury (see Table 316.2). It is important to establish the diagnosis as rapidly as possible and institute treatment early. In immunocompromised patients other than those with AIDS, therapy should be continued for at least 4-6 wk beyond complete resolution of all signs and symptoms of active disease and, if possible, resolution of cause for immune suppression. Careful follow-up of these patients is imperative because relapse may occur, requiring prompt reinstitution of therapy. Relapse was once common in AIDS patients without antiretroviral treatment, and suppressive therapy with pyrimethamine and sulfonamides, or TMP-SMX, was continued for life. Now it is possible to discontinue maintenance therapy when the CD4 count remains at >200 cells/µL for 4 mo and all lesions have resolved. Therapy usually induces a beneficial response clinically but does not eradicate cysts. Treatment of *T. gondii* –seropositive patients with AIDS should be continued as long as CD4 counts remain at <200/µL. Prophylactic TMP-SMX therapy for *Pneumocystis jirovecii* pneumonia significantly reduces the incidence of toxoplasmosis in AIDS patients.

Congenital Toxoplasmosis

All fetuses and newborns infected with *T. gondii* should be treated regardless of whether they have clinical manifestations of infection, because treatment may be effective in interrupting acute disease that damages vital organs (Fig. 316.5 ; see Table 316.2). The fetus is treated by treating the pregnant woman with pyrimethamine and sulfadiazine (with leucovorin). Infants should be treated for 1 yr with pyrimethamine (2 mg/kg/day PO bid for 2 days, then beginning on the 3rd day, 1 mg/kg/day for 2 or 6 mo, and then 1 mg/kg given on Monday, Wednesday, and Friday), sulfadiazine (100 mg/kg/day PO bid), and leucovorin (5-10 mg PO given on Monday, Wednesday, and Friday, or more often depending on neutrophil count). The relative efficacy in reducing sequelae of infection and the safety of treatment with 2 mo vs 6 mo of the higher dosage of pyrimethamine are being compared in the U.S. National Collaborative Study. (Updated information about this study and these regimens is available from Dr. Rima McLeod, 773-834-4131.) Pyrimethamine and sulfadiazine are available only in tablet form but can be prepared as suspensions. **Prednisone** (1 mg/kg/day PO bid) has been used in addition when active chorioretinitis involves the macula or otherwise threatens vision, or when the CSF protein is >1,000 mg/dL at birth, but the efficacy of this adjunctive therapy is not established. Prednisone is continued only for as long as the active inflammatory process in the posterior pole of the eye is vision threatening or CSF protein is >1,000 mg/dL, then tapered rapidly if the duration of treatment has been brief.



Dispensing caps
Medication syringe marked with number of mL to be given in each dose during that week

Oral Suspension Formulations	
Sulfadiazine 100mg/mL suspension 1. Crush ten 500mg sulfadiazine tablets in a mortar to a fine powder 2. Add enough sterile water to make a smooth paste 3. Slowly triturate syrup vehicle close to 50mL final volume 4. Transfer mixture to an amber bottle 5. Add enough syrup vehicle to q.s. to 50mL final volume 6. Shake very well. 7. Label and give a 7 day expiration 8. Store refrigerated	**Pyrimethamine** 2mg/mL suspension 1. Crush four 25mg pyrimethamine tablets in a mortar to a fine powder 2. Add 10cc of syrup vehicle 3. Transfer mixture to an amber bottle 4. Rinse motor with 10cc sterile water and transfer to bottle 5. Add enough syrup vehicle to q.s. to 50mL final volume 6. Shake very well. 7. Label and give 7 day expiration 8. Store refrigerated

Medication:	Sulfadiazine	Pyrimethamine	Folinic acid (calcium leukovorin)
Concentration:	100mg/mL	2mg/mL	5mg tablets
Dispense:	50mL*	25mL*	30 tablets
Dosage:	Half of infant's current weight in kg equals number of mL given in AM and PM†	Half of infant's current weight in kg equals number of mL given once daily‡§	10mg (two 5mg tablets) on Monday, Wednesday, and Friday. Crush and give with formula, water, milk, or juice in one dosage. May adjust based on neutrophil count.

* Suspended in 2% sugar solution. Suspension at usual concentration must be made each week. Store refrigerated.

† e.g. If infant weighs 5kg, give 2.5mL at 7AM and 7 PM.

‡ e.g. If infant weighs 5kg, give 2.5mL daily.

§ *For pyrimethamine*, first loading dose is 1mg/kg given BID for 2 days. Beginning third day, dose is 1mg/kg per day.

FIG. 316.5 Compounding and administration of medications to treat congenital toxoplasmosis in infants. (Adapted from Remington JS, McLeod R, et al: Toxoplasmosis. In Remington JS, Klein JO, editors: *Infectious diseases of the fetus and newborn infant,* ed 6, Philadelphia, 2006, Saunders; and McAuley J, Boyer K, Patel D, et al: Early and longitudinal evaluations of treated infants and children and untreated historical patients with congenital toxoplasmosis: the Chicago Collaborative Treatment Trial, *Clin Infect Dis* 18:38–72, 1994.)

Pregnant Women With *Toxoplasma gondii* Infection

The immunologically normal pregnant woman who acquired *T. gondii* >6 mo before conception does not need treatment to prevent congenital infection of her fetus. Although data are not available to allow for a definitive time interval, if infection occurs during or shortly before the pregnancy, it is reasonable to evaluate the fetus by PCR with amniotic fluid and ultrasonography and treat to prevent congenital infection in the fetus (see Table 316.2).

Treatment of a pregnant woman who acquires infection at any time during pregnancy reduces the chance of congenital infection in her infant. **Spiramycin** (1 g PO every 8 hr without food) is recommended for prevention of fetal infection if the mother develops acute toxoplasmosis during pregnancy. Spiramycin is available in the United States on an “emergency use” request by a physician through the FDA Division of Anti-Infective Drugs (301-796-1400) after the diagnosis of acute infection is confirmed in a reference laboratory (Palo Alto Medical Facility Toxoplasma Serology Lab, 650-853-4828). With this approval, the physician can then contact the spiramycin manufacturer, Sanofi Pasteur (1-800-822-2463), to obtain spiramycin for the patient. Adverse reactions are infrequent and include paresthesia, rash, nausea, vomiting, and diarrhea.

For treatment of the pregnant woman whose fetus has a confirmed or probable infection, in the second or third trimester, the combination of pyrimethamine, sulfadiazine, and leucovorin is recommended. Following a loading dose of pyrimethamine (50 mg bid) for 2 days, beginning on the 3rd day, pyrimethamine is administered at 50 mg once daily. Beginning on the 1st day of treatment with pyrimethamine, sulfadiazine (1.5-2.0 g PO bid), and leucovorin (10 mg PO once daily) are also given. In the first trimester, when there is definite infection, **sulfadiazine** alone is recommended because pyrimethamine is potentially teratogenic at that time. Spiramycin treatment is used for infection acquired early in gestation when fetal infection is uncertain. Treatment of the mother of an infected fetus with pyrimethamine and sulfadiazine reduces infection in the placenta and the severity of disease in the newborn. Delay in maternal treatment during gestation results in greater brain and eye disease in the infant. Diagnostic amniocentesis should be performed at >17-18 wk of gestation in pregnancies when there is high suspicion of fetal infection. Overall sensitivity of PCR for amniotic fluid is at 85% between 17 and 21 wk of gestation. The sensitivity of PCR using amniotic fluid for diagnosis of fetal infection is 92% in early and late gestation when amniotic fluid is tested for presence of the 529 bp, 300 copy gene. After 24 wk gestation, incidence of transmission is relatively high, and all pregnant women who are infected acutely after that time are treated with pyrimethamine and sulfadiazine to treat the fetus.

The approach in France to congenital toxoplasmosis includes systematic serologic screening of all women of childbearing age and for those who are sero-negative again intrapartum each month during gestation beginning at ≤11 wk gestational age, at birth, and 1 mo after birth. Mothers with acute infection early in gestation and without evidence of involvement of the fetus are treated with spiramycin, which decreases the transmission. Ultrasonography and amniocentesis for PCR at approximately 17-18 wk of gestation are used for fetal diagnosis and have 97% sensitivity and 100% specificity. Confidence intervals for sensitivity are larger early and late in gestation. Fetal infection is treated with pyrimethamine and sulfadiazine. Termination of pregnancy is very rare at present. Prompt initiation of treatment with pyrimethamine and sulfadiazine during pregnancy usually has an excellent outcome, with normal development of children. Only 19% have subtle findings of congenital infection, including intracranial calcifications (13%) and chorioretinal scars (6%), although 39% may have chorioretinal scars detected at follow-up later in childhood. Several studies have demonstrated improved outcomes with shorter times between diagnosis and initiation of treatment. In Germany, for seroconverting women who are between 15 and 17 weeks' gestation and before amniocentesis, administration of pyrimethamine, sulfadiazine, and leukovorin results in good outcomes for infants but sometimes sulfadiazine hypersensitivity for mothers.

Chronically infected pregnant women who are immunocompromised have transmitted *T. gondii* to their fetuses. Such women should be treated with spiramycin throughout gestation. The optimal management for prevention of congenital toxoplasmosis in the fetus of a pregnant woman with HIV infection, a CD4 count <200 cells/µL, and inactive *T. gondii* infection is unknown. Fortunately, this situation now is rarely encountered in the United States. If the pregnancy is not terminated, some investigators suggest that the mother should be treated with spiramycin or sulfadiazine alone during the 1st 14 wk of gestation and thereafter with pyrimethamine and sulfadiazine until term. There are no universally accepted guidelines at present. In a study of adult patients with AIDS and toxoplasmic encephalitis, pyrimethamine (75 mg PO once daily) combined with high dosages of intravenous clindamycin (1,200 mg every 6 hr) appeared equal in efficacy to sulfadiazine and pyrimethamine in the treatment of the toxoplasmic encephalitis. Other experimental agents include the macrolides clarithromycin and azithromycin.

Prognosis

Early institution of specific treatment for congenitally infected infants usually rapidly controls the active manifestations of toxoplasmosis, including active chorioretinitis, meningitis, encephalitis, hepatitis, splenomegaly, and thrombocytopenia. Rarely, hydrocephalus resulting from aqueductal obstruction may develop or become worse during therapy. Treatment appears to reduce the incidence of some sequelae, such as diminished cognitive and abnormal motor function. Without therapy and in some treated patients as well, chorioretinitis often recurs. Children with extensive involvement at birth may function normally later in life or have mild to severe impairment of vision, hearing, cognitive function, and other neurologic functions. Delays in diagnosis and therapy, perinatal hypoglycemia, hypoxia, hypotension, repeated shunt infections, and severe visual impairment are associated with a poorer prognosis. The prognosis is not necessarily poor for infected babies. Currently available treatments do not eradicate encysted parasites.

Studies in Lyon and Paris, France, demonstrated that outcome of treated fetal toxoplasmosis, even when infection is acquired early in gestation, is usually favorable if no hydrocephalus is detected on ultrasound, and treatment with pyrimethamine and sulfadiazine is initiated promptly. The **Systematic Review on Congenital Toxoplasmosis** (SYROCOT) study in Europe indicated that neurologic outcome is improved with shorter times between diagnosis and initiation of treatment of fetal toxoplasmosis. Work in Lyon has indicated a low incidence of recurrent eye disease in children with congenital toxoplasmosis who had been treated in utero and in their 1st yr of life. The NCCCTS (1981–2004) in the United States found that neurologic, developmental, audiologic, and ophthalmologic outcomes are considerably better for most, but not all, children who were treated in the 1st yr of life with pyrimethamine and sulfadiazine (with leucovorin) compared to children who had not been treated or were treated for only 1 mo in earlier decades described in the literature.

Prevention

Counseling pregnant women about the methods of preventing transmission of *T. gondii* (see Fig. 316.1) during pregnancy can reduce acquisition of infection during gestation. Women who do not have specific antibody to *T. gondii* before pregnancy should only eat well-cooked meat during pregnancy and avoid contact with oocysts excreted by cats. Cats that are kept indoors, maintained on prepared food, and not fed fresh, uncooked meat should not contact encysted *T. gondii* or shed oocysts. Serologic screening, ultrasound monitoring, and treatment of pregnant women during gestation can also reduce the incidence and manifestations of congenital toxoplasmosis. No protective vaccine is yet available for human use.

Point-of-care testing to facilitate gestational screening, recent developments in medicines for treatment of active and chronic infections, and progress toward vaccines to prevent infections in humans and oocyst shedding by cats are all recent advances with promise to prevent or improve outcomes for *Toxoplasma gondii* infections.

Acknowledgment

We gratefully acknowledge the participant families, physicians, and other personnel of the National Collaborative Congenital Toxoplasmosis Study (NCCTS), and colleagues, for helping to create the understanding and knowledge in this chapter; and Cornwell Mann family, Taking out Toxo (TOT), TRI, and NIH, NIAID/DMID ROI AI27530 and RO1 AI071319-01 for support.

Ascariasis *(Ascaris lumbricoides)*

Arlene E. Dent, James W. Kazura

Etiology

Ascariasis is caused by the nematode, or **roundworm** , *Ascaris lumbricoides*. Adult worms of *A. lumbricoides* inhabit the lumen of the small intestine. The reproductive potential of *Ascaris* is prodigious; a gravid female worm produces 200,000 eggs per day. The fertile ova are oval in shape with a thick, mammillated covering measuring 45-70 µm in length and 35-50 µm in breadth (Fig. 317.1). After passage in the feces, the eggs embryonate and become infective in 5-10 days under favorable environmental conditions. Adult worms can live for 12-18 mo (Fig. 317.2).

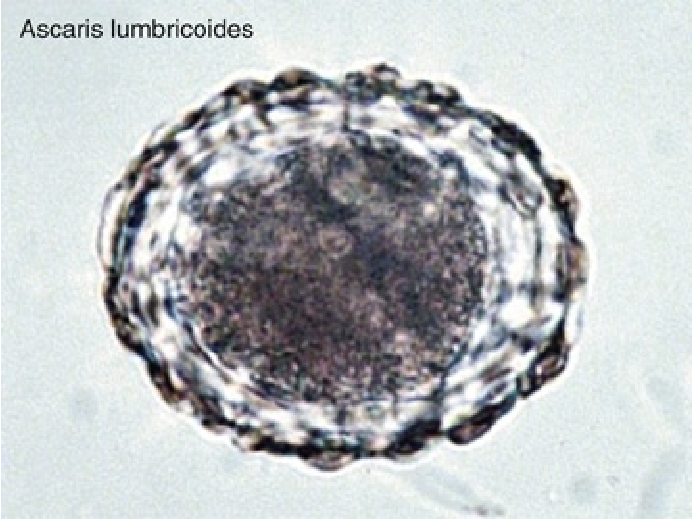

FIG. 317.1 Soil-transmitted helminth eggs *(A. lumbricoides)* . (From Bethony J, Brooker S, Albonico M, et al: Soil-transmitted helminth infections: ascariasis, trichuriasis, and hookworm, *Lancet* 367:1521–1532, 2006.)

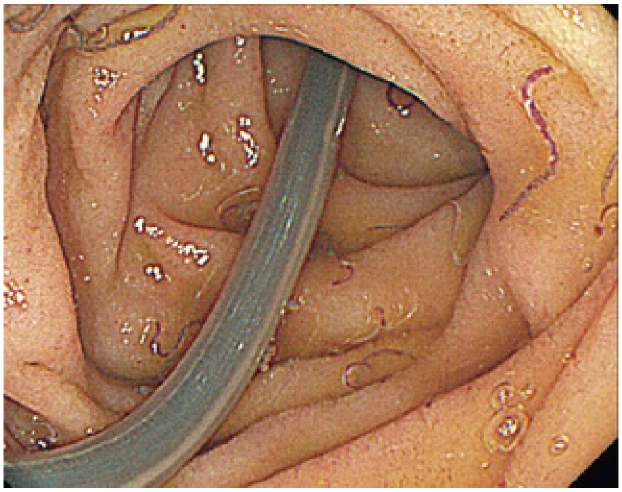

FIG. 317.2 Endoscopic image of intestinal *Ascaris lumbricoides* and hookworm co-infection. The ascaris worm is large in relation to the lumen and multiple blood-filled hookworms. (Courtesy of Dr. Kunimitsu Inoue, Almeida Hospital, Oita, Japan.)

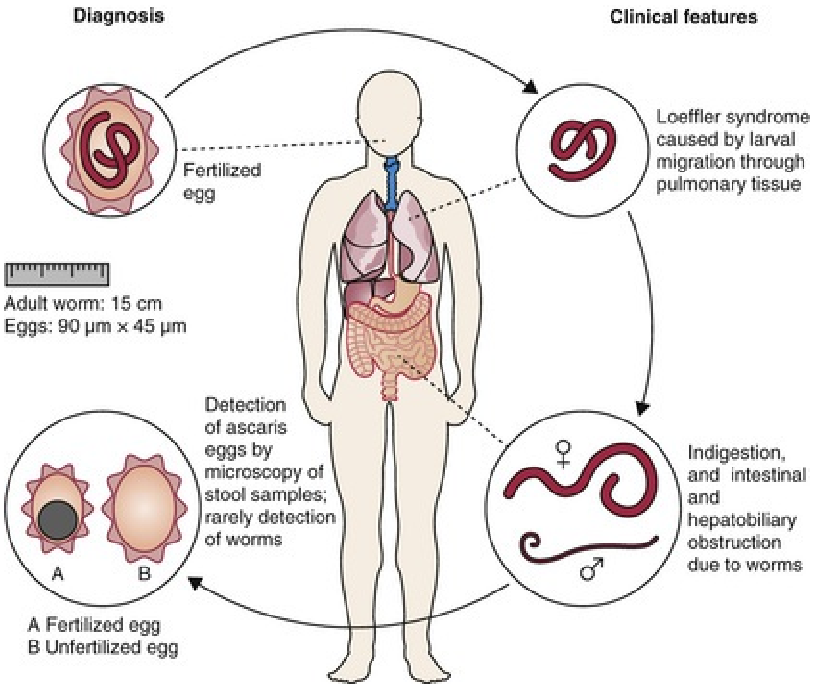
Epidemiology

Ascariasis occurs globally and is the most prevalent human **helminthiasis** in the world. It is most common in tropical areas (South America, Africa, Asia) where environmental conditions are optimal for maturation of ova in the soil. Approximately 1 billion persons are estimated to be infected. Although the number of cases in the United States is not known precisely, the highest prevalence is thought to be in high-poverty areas of the South and Appalachia. Pig farming in Maine is also associated with *Ascaris* species. Key factors linked with a higher prevalence of infection include poor socioeconomic conditions, use of human feces as fertilizer, and geophagia. Even though infection can occur at any age, the highest rate is in preschool or early school-age children. Transmission is primarily hand to mouth but may also involve ingestion of contaminated raw fruits and vegetables. Transmission is enhanced by the high output of eggs by fecund female worms and resistance of ova to the outside environment. *Ascaris* eggs can remain viable at 5-10°C (41-50°F) for as long as 2 yr.

Pathogenesis

Ascaris ova hatch in the small intestine after ingestion by the human host. Larvae are released, penetrate the intestinal wall, and migrate to the lungs by way of the venous circulation. The parasites then cause **pulmonary ascariasis** as they enter into the alveoli and migrate through the bronchi and trachea (Fig. 317.3). They are subsequently swallowed and return to the intestines, where they mature into adult worms. Female *Ascaris* begin depositing eggs in 8-10 wk.



Diagnosis
Clinical features
Fertilized egg
Loeffler syndrome caused by larval migration through pulmonary tissue
Adult worm: 15 cm
Eggs: 90 µm × 45 µm
Detection of ascaris eggs by microscopy of stool samples; rarely detection of worms
Indigestion, and intestinal and hepatobiliary obstruction due to worms

FIG. 317.3 **Transmission of *Ascaris lumbricoides* : diagnosis and clinical features. (From Jourdan PM, Lamberton PHL, Fenwick A, Addiss DG: Soil-transmitted helminth infections, *Lancet* 391:252–262, 2018, Fig 2A.)**

Clinical Manifestations

The clinical presentation depends on the intensity of infection and the organs involved. Most individuals have low to moderate worm burdens and have no symptoms or signs. The most common clinical problems are from **pulmonary disease** and **obstruction of the intestinal or biliary tract** . Larvae migrating through these tissues may cause allergic symptoms, fever, urticaria, and granulomatous disease. The pulmonary manifestations resemble Loeffler syndrome and include transient respiratory symptoms such as cough and dyspnea, pulmonary infiltrates, and blood eosinophilia. Larvae may be observed in the sputum. Vague abdominal complaints have been attributed to the presence of adult worms in the small intestine, although the precise contribution of the parasite to these symptoms is difficult to ascertain. A more serious complication occurs when a large mass of worms leads to acute bowel obstruction. Children with heavy infections may present with vomiting, abdominal distention, and cramps. In some cases, worms may be passed in the vomitus or stools. *Ascaris* worms occasionally migrate into the biliary and pancreatic ducts, where they cause cholecystitis or pancreatitis. Worm migration through the intestinal wall can lead to peritonitis. Dead worms can serve as a nidus for stone formation. Studies show that chronic infection with *A. lumbricoides* (often coincident with other helminth infections) impairs growth, physical fitness, and cognitive development.

Diagnosis

Microscopic examination of fecal smears can be used for diagnosis because of the high number of eggs excreted by adult female worms (see Fig. 317.1). A high index of suspicion in the appropriate clinical context is needed to diagnose pulmonary ascariasis or obstruction of the gastrointestinal tract. Ultrasound examination of the abdomen is capable of visualizing intraluminal adult worms.

Treatment

Although several chemotherapeutic agents are effective against ascariasis, none has documented utility during the pulmonary phase of infection. Treatment options for gastrointestinal ascariasis include **albendazole** (400 mg orally once, for all ages), **mebendazole** (100 mg orally twice daily for 3 days or 500 mg once, for all ages), or **ivermectin** (150-200 µg/kg orally once). **Piperazine citrate** (75 mg/kg/day for 2 days; maximum dose: 3.5 g/day), which causes neuromuscular paralysis of the parasite and rapid expulsion of the worms, is the treatment of choice for intestinal or biliary obstruction and is administered as syrup through a nasogastric tube. Surgery may be required for cases with severe obstruction. **Nitazoxanide** (100 mg orally twice per day for 3 days for children

1-3 yr old; 200 mg twice per day for 3 days for children 4-11 yr; 500 mg twice per day for 3 days for adolescents and adults) produces cure rates comparable to single-dose albendazole. Drug resistance has not been reported, but repeated treatment for ascariasis may be necessary because reinfection is common.

Prevention

Although ascariasis is the most prevalent worm infection in the world, little attention has been given to its control (Table 317.1). **Anthelmintic chemotherapy programs** can be implemented in 1 of 3 ways: (1) offering universal treatment to all individuals in an area of high endemicity; (2) offering treatment targeted to groups with high frequency of infection, such as children attending primary school; or (3) offering individual treatment based on intensity of current or past infection. Improving education about and practices of sanitary conditions and sewage facilities, discontinuing the practice of using human feces as fertilizer, and education are the most effective long-term preventive measures.

Table 317.1

Clinical and Public Health Control of Soil-Transmitted Helminthiasis

	CLINICAL DIAGNOSIS AND MANAGEMENT	PUBLIC HEALTH CONTROL
Diagnosis	Individual	Community level (e.g., in select schools)
Diagnostic criteria	Parasitological	Residence in an area with soil-transmitted helminthiasis prevalence >20%
Treatment approach	Single dose or multiple dose	Single-dose periodic mass treatment
Threshold for treatment	Travel history, symptoms and signs, positive laboratory test	Estimated prevalence of infection in target population
Treatment objective	Parasitological cure	Decreased worm burden; reduction in transmission
Ancillary treatment	Based on clinical signs and symptoms	Typically, only if included in mass treatment (e.g., vitamin A supplementation)
Follow-up	Parasitological test of cure; improvement in associated health conditions	Not usually done
Health education (sanitation/hygiene)	Recommended	Recommended

CHAPTER 318

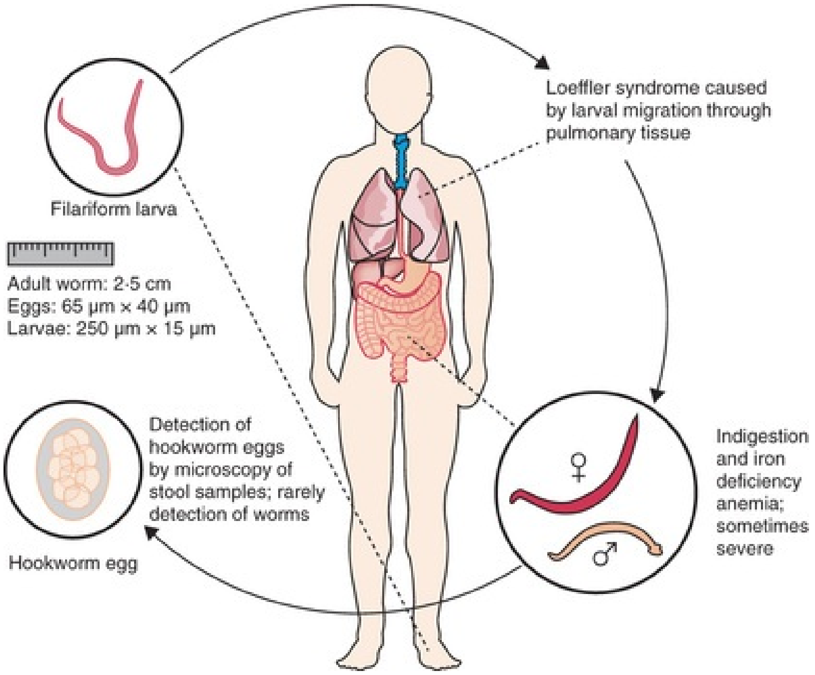
Hookworms (*Necator americanus* and *Ancylostoma* spp.)

Peter J. Hotez

Etiology

Two major genera of hookworms, which are nematodes, or roundworms, infect humans. *Necator americanus,* the only representative of its genus, is a major **anthropophilic** hookworm and is the most common cause of human hookworm infection. Hookworms of the genus *Ancylostoma* include the anthropophilic hookworm *Ancylostoma duodenale,* which also causes classic hookworm infection, and the less common **zoonotic** species *Ancylostoma ceylanicum* (restricted mostly to Southeast Asia). Human zoonotic infection with the dog hookworm *Ancylostoma caninum* is associated with an eosinophilic enteritis syndrome. The larval stage of *Ancylostoma braziliense,* whose definitive hosts include dogs and cats, is the principal cause of cutaneous larva migrans.

The infective larval stages of the anthropophilic hookworms live in a developmentally arrested state in warm, moist soil. Larvae infect humans either by penetrating through the skin (*N. americanus* and *A. duodenale*) or when they are ingested *(A. duodenale).* Larvae entering the human host by skin penetration undergo **extraintestinal migration** through the venous circulation and lungs before they are swallowed, whereas orally ingested larvae may undergo extraintestinal migration or remain in the gastrointestinal (GI) tract (Figs. 318.1 and 318.2). Larvae returning to the small intestine undergo 2 molts to become adult, sexually mature, male and female worms ranging in length from 5-13 mm. The buccal capsule of the adult hookworm is armed with cutting plates *(N. americanus)* or teeth *(A. duodenale)* to facilitate attachment to the mucosa and submucosa of the small intestine. Hookworms can remain in the intestine for 1-5 yr, where they mate and produce eggs. Although up to 2 mo is required for the larval stages of hookworms to undergo extraintestinal migration and develop into mature adults, *A. duodenale* larvae may remain developmentally arrested for many months before resuming development in the intestine. Mature *A. duodenale* female worms produce about 30,000 eggs per day; daily egg production by *N. americanus* is <10,000/day (Fig. 318.3). The eggs are thin shelled and ovoid, measuring approximately 40-60 µm. Eggs that are deposited on soil with adequate moisture and shade develop into first-stage larvae and hatch. Over the ensuing several days and under appropriate conditions, the larvae molt twice to the **infective** stage. Infective larvae are developmentally arrested and nonfeeding. They migrate vertically in the soil until they either infect a new host or exhaust their lipid metabolic reserves and die.



Loeffler syndrome caused by larval migration through pulmonary tissue
Filariform larva
Adult worm: 2-5 cm
Eggs: 65 µm × 40 µm
Larvae: 250 µm × 15 µm
Detection of hookworm eggs by microscopy of stool samples; rarely detection of worms
Hookworm egg
♀

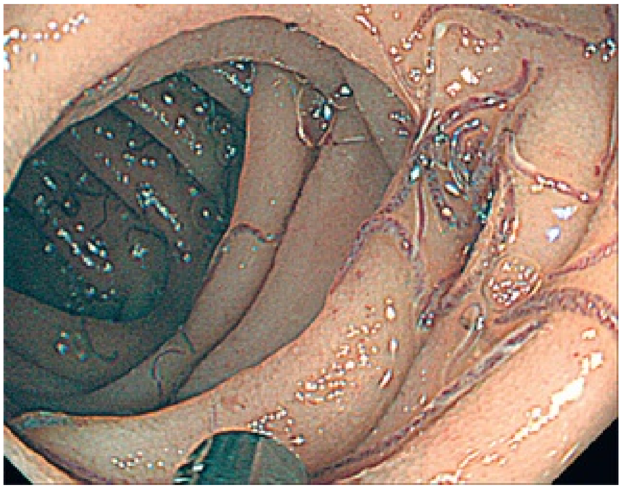

FIG. 318.2 Endoscopic images of intestinal hookworm infection. (Courtesy of Dr. Kunimitsu Inoue, Almeida Hospital, Oita, Japan.)

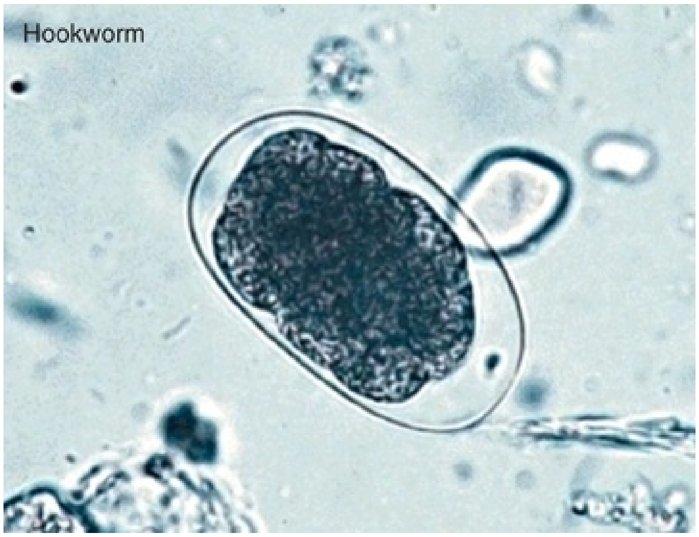

FIG. 318.3 Soil-transmitted hookworm helminth eggs. (From Bethony J, Brooker S, Albonico M, et al: Soil-transmitted helminth infections: ascariasis, trichuriasis, and hookworm, *Lancet* 367:1521–1532, 2006.)

Epidemiology

Hookworm infection is one of the most prevalent infectious diseases of humans. The Global Burden of Disease Study 2015 reported that approximately 428 million people are infected with hookworms, with further estimates indicating that hookworm infection globally results in 4.1 million disability-adjusted life-years, possibly leading all **neglected tropical diseases** in years lost through disability. In the case of hookworm infection, all the years lost through disability are attributed to anemia from intestinal blood loss. There is also a massive socioeconomic impact from hookworm infection, with estimates that hookworm can cause up to $139 billion in losses from diminished productivity.

Because of the requirement for adequate soil moisture, shade, and warmth, hookworm infection is usually confined to rural areas, especially where human feces are used for fertilizer or where sanitation is inadequate. Hookworm is an infection associated with *economic underdevelopment and poverty* throughout the tropics and subtropics. Sub-Saharan Africa, East Asia, and tropical regions of the Americas have the highest prevalence of hookworm infection. High rates of infection are often associated with cultivation of certain agricultural products, such as tea in India; sweet potato, corn, cotton, and mulberry trees in China; coffee in Central and South America; and rubber in Africa. It is not uncommon to find dual *N. americanus* and *A. duodenale* infections. *N. americanus* predominates in Central and South America as well as in southern China and Southeast Asia, whereas *A. duodenale* predominates in North Africa, in northern India, in China north of the Yangtze River, and among aboriginal people in Australia. The ability of *A. duodenale* to withstand somewhat harsher environmental and climatic conditions may reflect its ability to undergo arrested development in human tissues. *A. ceylanicum* infection occurs in India and Southeast Asia.

Eosinophilic enteritis caused by *A. caninum* was first described in Queensland, Australia, with 2 reported cases in the United States. Because of its global distribution in dogs, it was initially anticipated that human *A. caninum* infections would be identified in many locales, but this has not been found.

Pathogenesis

The major morbidity of human hookworm infection is a direct result of **intestinal blood loss** . Adult hookworms adhere tenaciously to the mucosa and submucosa of the proximal small intestine by using their cutting plates or teeth and a muscular esophagus that creates negative pressure in their buccal capsules. At the attachment site, host inflammation is downregulated by the release of antiinflammatory polypeptides by the hookworm. Rupture of capillaries in the lamina propria is followed by blood extravasation, with some of the blood ingested directly by the hookworm. After ingestion, the blood is anticoagulated, the red blood cells are lysed, and the hemoglobin released and digested. Each adult *A. duodenale* hookworm causes loss of an estimated 0.2 mL of blood/day; blood loss is less for *N. americanus*. Individuals with light infections have minimal blood loss and thus may have hookworm infection but not hookworm disease. There is a direct correlation between the number of adult hookworms in the gut and the volume of fecal blood loss. Hookworm disease results only when individuals with moderate and heavy infections experience sufficient blood loss to develop iron deficiency and anemia. Hypoalbuminemia and consequent edema and anasarca from the loss of intravascular oncotic pressure can also occur. These features depend heavily on the dietary reserves of the host.

Clinical Manifestations

Chronically infected children with moderate and heavy hookworm infections suffer from intestinal blood loss that results in **iron deficiency** and can lead to anemia as well as protein malnutrition. Prolonged iron deficiency associated with hookworms in childhood can lead to physical growth retardation and cognitive and intellectual deficits.

Anthropophilic hookworm larvae elicit dermatitis sometimes referred to as **ground itch** when they penetrate human skin. The vesiculation and edema of ground itch are exacerbated by repeated infection. Infection with a zoonotic hookworm, especially *A. braziliense*, can result in lateral migration of the larvae to cause the characteristic cutaneous tracts of **cutaneous larva migrans** (see Chapter 318.1). Cough subsequently occurs in *A. duodenale* and *N. americanus* hookworm infection when larvae migrate through the lungs to cause laryngotracheobronchitis, usually about 1 wk after exposure. Pharyngitis also can occur. The onset of eosinophilia coincides with the entry of hookworm larvae into the GI tract. Upper abdominal pain can occur during this period, but it eventually subsides.

Chronic intestinal hookworm infection is not typically associated with specific GI complaints, although pain, anorexia, and diarrhea have been attributed to the presence of hookworms. The major clinical manifestations are related to intestinal blood loss. Heavily infected children exhibit all the signs and symptoms of **iron-deficiency anemia** and **protein malnutrition** . In some cases, children with chronic hookworm disease acquire a yellow-green pallor known as **chlorosis.**

An infantile form of **ancylostomiasis** resulting from heavy *A. duodenale* infection has been described. Affected infants experience diarrhea, melena, failure to thrive, and profound anemia. Infantile ancylostomiasis has significant mortality.

Eosinophilic enteritis caused by *A. caninum* is associated with colicky abdominal pain that begins in the epigastrium and radiates outward and is usually exacerbated by food. Extreme cases may mimic acute appendicitis.

Diagnosis

Children with hookworm release eggs that can be detected by direct fecal examination (see Fig. 318.3). Quantitative methods are available to determine whether a child has a heavy **worm burden** that can cause hookworm disease. The eggs of *N. americanus* and *A. duodenale* are morphologically indistinguishable. Species identification typically requires egg hatching and differentiation of third-stage infective larvae; methods using polymerase chain reaction (PCR) methods have been developed but are not generally used in clinical practice.

In contrast, eggs are generally not present in the feces of patients with eosinophilic enteritis caused by *A. caninum.* Eosinophilic enteritis is often diagnosed by demonstrating ileal and colonic ulcerations by colonoscopy in the presence of significant blood eosinophilia. An adult canine hookworm may occasionally be recovered during colonoscopic biopsy. Patients with this syndrome develop IgG and IgE serologic responses.

Treatment

The goal of **deworming** is removal of the adult hookworms with an **anthelmintic** drug. The **benzimidazole** anthelmintics, mebendazole and albendazole, are effective at eliminating hookworms from the intestine, although multiple doses are sometimes required. **Albendazole** (400 mg orally [PO] once, for all ages) often results in cure, although *N. americanus* adult hookworms are sometimes more refractory and require additional doses. **Mebendazole** (100 mg PO twice daily [bid] for 3 days, for all ages) is also effective. In many developing countries, mebendazole is administered as a single dose of 500 mg; however, the cure rates with this regimen can be as low as 10% or less.

According to the World Health Organization (WHO), children should be encouraged to chew tablets of albendazole or mebendazole, because forcing very young children to swallow large tablets may cause choking or asphyxiation. Mebendazole is recommended for *A. caninum* –associated eosinophilic enteritis, although recurrences are common. Because the benzimidazoles have been reported to be embryotoxic and teratogenic in laboratory animals, their safety during pregnancy and in young children is a potential concern, and the risks vs benefits must be carefully considered. WHO currently supports the use of benzimidazoles in infected children ≥1 yr old but at a reduced dose (200 mg for albendazole) in the youngest age-group (1-2 yr old). In some countries, **pyrantel pamoate** (11 mg/kg PO once daily for 3 days; maximum dose: 1 g) is available in liquid form and is an effective alternative to the benzimidazoles. A newer drug known as **tribendimidine** is still under clinical development and may be available in the future. Replacement therapy with oral iron is not usually required to correct hookworm-associated iron deficiency in children.

Prevention

In 2001, the World Health Assembly urged its member states to implement programs of periodic deworming so as to control the morbidity of hookworm and other soil-transmitted helminth infections (see Table 317.1 in Chapter 317). Although anthelmintic drugs are effective at eliminating hookworms from the intestine, the high rates of drug failure from single-dose mebendazole or albendazole and posttreatment reinfection among children suggest that mass drug administration alone is not effective for controlling hookworm in highly endemic areas. Moreover, data suggest that the efficacy of mebendazole decreases with frequent, periodic use, leading to concerns about the possible emergence of **anthelmintic drug resistance** . To reduce the reliance exclusively on anthelmintic drugs, a recombinant human hookworm vaccine has been developed and is undergoing clinical testing. Economic development and associated improvements in sanitation, health education, and avoidance of human feces as fertilizer remain critical for reducing hookworm transmission and endemicity.

318.1

Cutaneous Larva Migrans

Peter J. Hotez

Keywords

A. braziliense
creeping eruption

Etiology

Cutaneous larva migrans (**creeping eruption**) is caused by the larvae of several nematodes, primarily hookworms, which are not usually parasitic for humans. *A. braziliense,* a hookworm of dogs and cats, is the most common cause, but other animal hookworms may also produce the disease.

Epidemiology

Cutaneous larva migrans is usually caused by *A. braziliense,* which is endemic to the southeastern United States and Puerto Rico. Travelers account for a significant percentage of the cases. Recently, autochthonous cases have been reported from Europe.

Clinical Manifestations

After penetrating the skin, larvae localize at the epidermal-dermal junction and migrate in this plane, moving at a rate of 1-2 cm/day. The response to the parasite is characterized by raised, erythematous, serpiginous tracks, which occasionally form bullae (Fig. 318.4). These lesions may be single or numerous and are usually localized to an extremity, although any area of the body may be affected. As the organism migrates, new areas of involvement may appear every few days. Intense localized pruritus, without any systemic symptoms, may be associated with the lesions. Bacterial superinfection can occur.

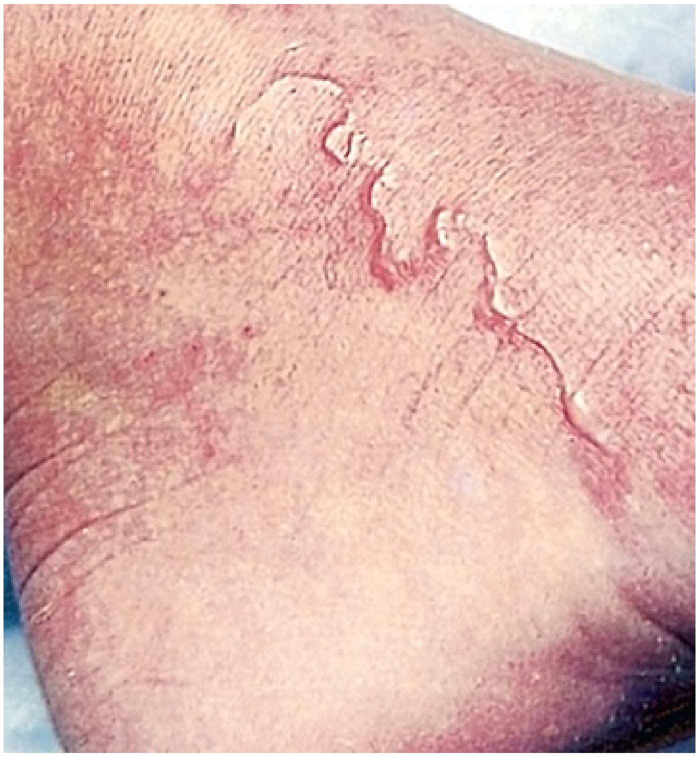

FIG. 318.4 **Creeping eruption of cutaneous larva migrans. (From Korting GW: *Hautkrankheitenbeikindern und jugendlichen* , Stuttgart, Germany, 1969, FK Schattauer Verlag.)**

Diagnosis

Cutaneous larva migrans is diagnosed by clinical examination of the skin. Patients are often able to recall the exact time and location of exposure, because the larvae produce intense itching at the site of penetration. Eosinophilia may occur but is uncommon.

Treatment

If left untreated, the larvae die, and the syndrome resolves within a few weeks to several months. Treatment with **ivermectin** (200 µg/kg PO daily for 1-2 days; considered drug of choice by some investigators), **albendazole** (400 mg PO daily for 3 days, for all ages), or topical **thiabendazole** hastens resolution, if symptoms warrant treatment. The U.S. Food and Drug Administration has not approved these drugs for cutaneous larva migrans. The safety of ivermectin in young children (weighing <15 kg) and pregnant women remains to be established. Albendazole should be taken with a fatty meal.

CHAPTER 319

Trichuriasis *(Trichuris trichiura)*

Arlene E. Dent, James W. Kazura

Etiology

Trichuriasis is caused by the **whipworm** , *Trichuris trichiura,* a nematode, or roundworm, that inhabits the cecum and ascending colon. The principal hosts of *T. trichiura* are humans, who acquire infection by ingesting embryonated, barrel-shaped eggs (Fig. 319.1). The larvae escape from the shell in the upper small intestine and penetrate the intestinal villi. The worms slowly move toward the cecum, where the anterior three-quarters whiplike portion remains within the superficial mucosa and the short posterior end is free in the lumen (Fig. 319.2). In 1-3 mo, the adult female worm begins producing 5,000-20,000 eggs per day. After excretion in the feces, embryonic development occurs in 2-4 wk with optimal temperature and soil conditions. The adult worm life span is approximately 2 yr.

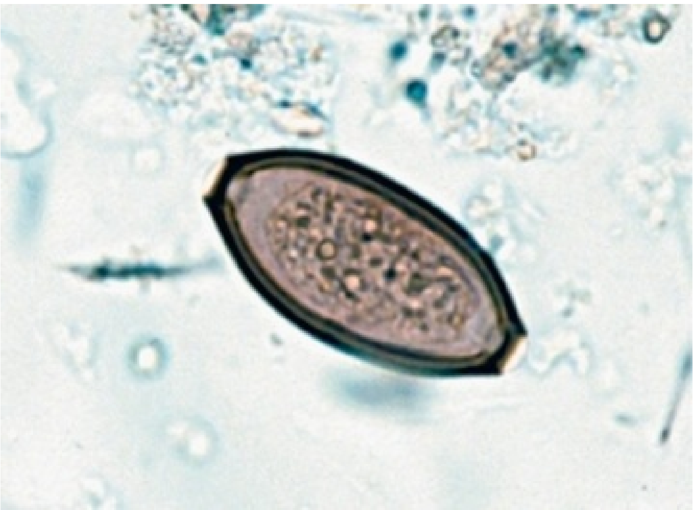

FIG. 319.1 **Trichuris trichiura. Soil-transmitted helminth eggs. (From Bethony J, Brooker S, Albonico M, et al: Soil-transmitted helminth infections: ascariasis, trichuriasis, and hookworm, *Lancet* 367:1521–1532, 2006.)**

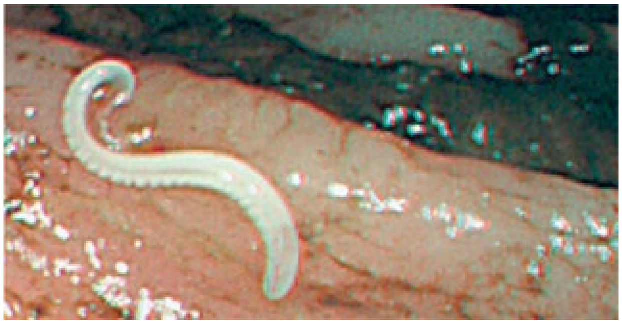

FIG. 319.2 ***Trichuris trichiura* infection. (Courtesy of Dr. Kunimitsu Inoue, Almeida Hospital, Oita, Japan).**

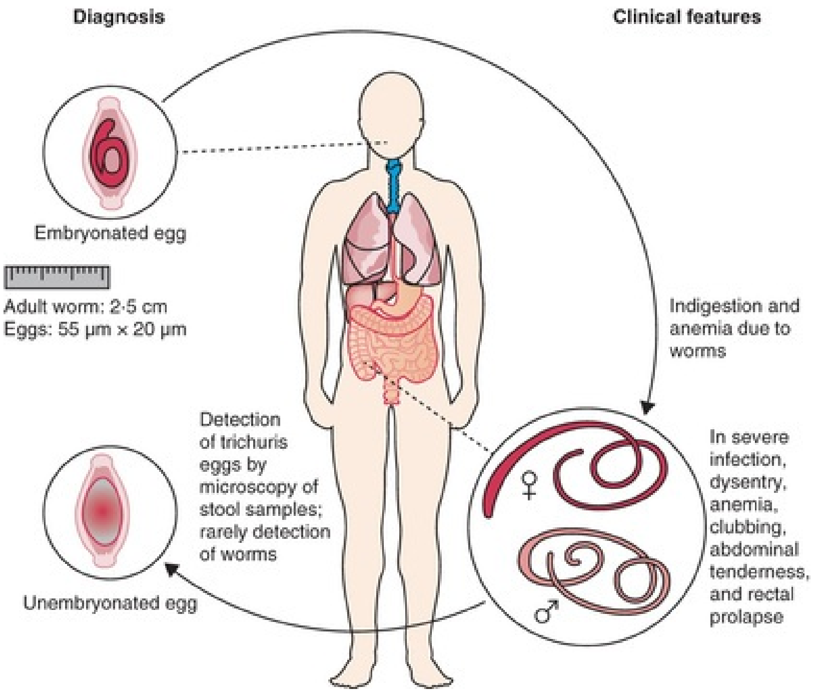
Epidemiology

Trichuriasis occurs throughout the world and is especially common in poor rural communities with inadequate sanitary facilities and soil contaminated with human or animal feces. Trichuriasis is one of the most prevalent human helminthiases, with an estimated 1 billion infected individuals worldwide. In many parts of the world, where protein-energy malnutrition and anemia are common, the prevalence of *T. trichiura* infection can be as high as 95%. Although trichuriasis occurs in the rural southeastern United States, its prevalence has not been reported. The highest rate of infection occurs among children 5-15 yr old. Infection develops after ingesting embryonated ova by direct contamination of hands, food (raw fruits and vegetables fertilized with human feces), or drink (Fig. 319.3). Transmission can also occur indirectly through flies or other insects.



Diagnosis
Clinical features
Embryonated egg
Adult worm: 2·5 cm
Eggs: 55 μm × 20 μm
Indigestion and anemia due to worms
Detection of trichuris eggs by microscopy of stool samples; rarely detection of worms
In severe infection, dysentry, anemia, clubbing, abdominal tenderness, and rectal prolapse
♀
♂
Unembryonated egg

FIG. 319.3 **Transmission of *Trichuris trichiura* : diagnosis and clinical features. (From Jourdan PM, Lamberton PHL, Fenwick A, Addiss DG: Soil-transmitted helminth infections, *Lancet* 391:252–262, 2018, Fig 2B.)**

Clinical Manifestations

Most persons harbor low worm burdens and do not have symptoms. Some individuals may have a history of right lower quadrant or vague periumbilical pain. Adult *Trichuris* ingest approximately 0.005 mL of blood per worm per day. Children, who are most likely to be heavily infected, frequently suffer from disease. Clinical manifestations include chronic dysentery, rectal prolapse, anemia, poor growth, as well as developmental and cognitive deficits. There is no significant eosinophilia, even though a portion of the worm is embedded in the mucosa of the large bowel.

Diagnosis

Because egg output is so high, fecal smears frequently reveal the characteristic barrel-shaped ova of *T. trichiura.*

Treatment

Albendazole (400 mg orally for 3 days, for all ages) is the drug of choice and is safe and effective, in part because it is poorly absorbed from the gastrointestinal tract. It reduces egg output by 90–99% and has cure rates of 70–90%, although reinfection and resumption of egg production by live worms that presumably survive after treatment may occur. Alternatives include **mebendazole** (100 mg orally twice daily for 3 days) and **ivermectin** (200 µg/kg orally for 3 days). Single-day treatment with albendazole, nitazoxanide, or albendazole plus nitazoxanide lead to cure rates that are low and short-lived. Combination treatment with **oxantel pamoate** (20 mg/kg) plus 400 mg albendazole on consecutive days may have the highest cure rate.

Prevention

Disease can be prevented by personal hygiene, improved sanitary conditions, and eliminating the use of human feces as fertilizer (see Table 317.1 in Chapter 317).

CHAPTER 320

Enterobiasis *(Enterobius vermicularis)*

Arlene E. Dent, James W. Kazura

Etiology

The cause of enterobiasis, or **pinworm** infection, is *Enterobius vermicularis,* which is a small (1 cm in length), white, threadlike nematode, or roundworm, that typically inhabits the cecum, appendix, and adjacent areas of the ileum and ascending colon. Gravid females migrate at night to the perianal and perineal regions, where they deposit up to 15,000 eggs. Ova are convex on one side and flattened on the other and have diameters of approximately 30 × 60 µm. Eggs embryonate within 6 hr and remain viable for 20 days. Human infection occurs by the fecal-oral route typically by ingestion of embryonated eggs that are carried on fingernails, clothing, bedding, or house dust. After ingestion, the larvae mature to form adult worms in 36-53 days.

Epidemiology

Enterobiasis infection occurs in individuals of all ages and socioeconomic levels. It is prevalent in regions with temperate climates and is the most common helminth infection in the United States. It infects 30% of children worldwide, and humans are the only known host. Infection occurs primarily in institutional or family settings that include children. The prevalence of pinworm infection is highest in children 5-14 yr of age. It is common in areas where children live, play, and sleep close together, thus facilitating egg transmission. Because the life span of the adult worm is short, chronic parasitism is likely caused by repeated cycles of reinfection. **Autoinoculation** can occur in individuals who habitually put their fingers in their mouth.

Pathogenesis

Enterobius infection may cause symptoms by mechanical stimulation and irritation, allergic reactions, and migration of the worms to anatomic sites where they become pathogenic. *Enterobius* infection has been associated with concomitant *Dientamoeba fragilis* infection, which causes diarrhea.

Clinical Manifestations

Pinworm infection is innocuous and rarely causes serious medical problems. The most common complaints include itching and restless sleep secondary to nocturnal perianal or **perineal pruritus** . The precise cause and incidence of pruritus are unknown but may be related to the intensity of infection, psychologic profile of the infected individual and the family, or allergic reactions to the parasite. Eosinophilia is not observed in most cases, because tissue invasion does not occur. Aberrant migration to ectopic sites occasionally may lead to appendicitis, chronic salpingitis, pelvic inflammatory disease, peritonitis, hepatitis, and ulcerative lesions in the large or small bowel.

Diagnosis

A history of nocturnal **perianal pruritus** in children strongly suggests enterobiasis. Definitive diagnosis is established by identification of parasite eggs or worms. Microscopic examination of adhesive cellophane tape pressed against the perianal region early in the morning frequently demonstrates eggs (Fig. 320.1). Repeated examinations increase the chance of detecting ova; 1 examination detects 50% of infections, 3 examinations 90%, and 5 examinations 99%. Worms seen in the perianal region should be removed and preserved in 75% ethyl alcohol until microscopic examination can be performed. Digital rectal examination may also be used to obtain samples for a wet mount. Routine stool samples rarely demonstrate *Enterobius* ova.

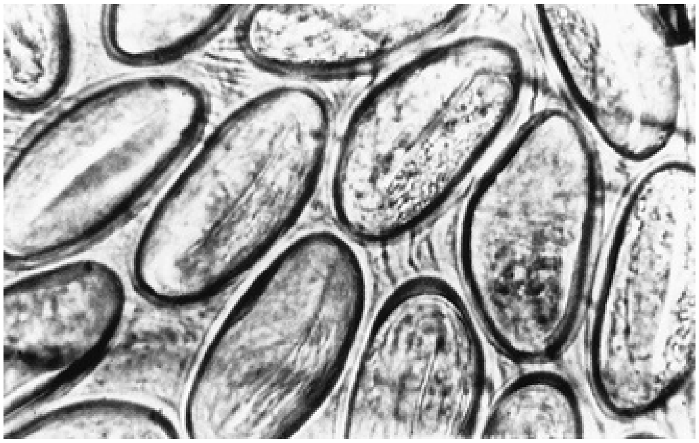

FIG. 320.1 Eggs of *Enterobius vermicularis* . (From Guerrant RL, Walker DH, Weller PF, et al: *Tropical infectious diseases* , Philadelphia, 2006, Churchill Livingstone, p 1248.)

Treatment

Anthelmintic drugs should be administered to infected individuals and their family members. **Albendazole** (400 mg orally with a repeat dose 2 wk later for all age-groups) is the treatment of choice and results in cure rates exceeding 90%. Alternatives include **mebendazole** (100 mg orally with a repeat dose 2 wk later) and **pyrantel pamoate** (11 mg/kg base orally 3 times for 1 day up to a maximum of 1 g; repeat at 2 wk). Morning bathing removes a large portion of eggs. Frequent changing of underclothes, bedclothes, and bedsheets decreases environmental egg contamination and may decrease the risk for autoinfection.

Prevention

Household contacts can be treated at the same time as the infected individual. Repeated treatments every 3-4 mo may be required in circumstances with repeated exposure, such as with institutionalized children. Good hand hygiene is the most effective method of prevention.

CHAPTER 321

Strongyloidiasis *(Strongyloides stercoralis)*

Arlene E. Dent, James W. Kazura

Etiology

Strongyloidiasis is caused by the nematode, or roundworm, *Strongyloides stercoralis*. Only adult female worms inhabit the small intestine. The nematode reproduces in the human host by parthenogenesis and releases eggs containing mature larvae into the intestinal lumen. **Rhabditiform** larvae immediately emerge from the ova and are passed in feces, where they can be visualized by stool examination. Rhabditiform larvae either differentiate into free-living adult male and female worms or metamorphose into the infectious **filariform** larvae. Sexual reproduction occurs only in the free-living stage. Humans are usually infected through skin contact with soil contaminated with infectious larvae (Fig. 321.1). Larvae penetrate the skin, enter the venous circulation and then pass to the lungs, break into alveolar spaces, and migrate up the bronchial tree. They are then swallowed and pass through the stomach, and adult female worms develop in the small intestine. Egg deposition begins approximately 28 days after initial infection.

FIG. 321.1 Transmission of *Strongyloides stercoralis* : diagnosis and clinical features. (From Jourdan PM, Lamberton PHL, Fenwick A, Addiss DG: Soil-transmitted helminth infections, *Lancet* 391:252–262, 2018, Fig 2D.)

The **hyperinfection syndrome** occurs when large numbers of larvae transform into infective organisms during their passage in feces and then reinfect (**autoinfect**) the host by way of the lower gastrointestinal (GI) tract or perianal region. This cycle may be accelerated in immunocompromised persons, particularly those with depressed T-cell function.

Epidemiology

S. stercoralis infection is prevalent in tropical and subtropical regions of the world and is endemic in several areas of Europe, the southern United States, and Puerto Rico. Transmission requires appropriate environmental conditions, particularly warm, moist soil. Poor sanitation and crowded living conditions are conducive to high levels of transmission. Dogs and cats can act as reservoirs. The highest prevalence of infection in the United States (4% of the general population) is in impoverished rural areas of Kentucky and Tennessee. Infection may be especially common among residents of mental institutions, veterans who were prisoners of war in areas of high endemicity, and refugees and immigrants. Because of internal autoinfection, individuals may remain infected for decades. Infection may be transmitted by organ transplantation. Individuals with hematologic malignancies, autoimmune diseases, malnutrition, and drug-induced immunosuppression (especially corticosteroids) are at high risk for the hyperinfection syndrome. Patients with AIDS may experience a rapid course of disseminated strongyloidiasis with a fatal outcome.

Pathogenesis

The initial host immune response to infection is production of immunoglobulin E and eosinophilia in blood and tissues, which presumably prevents dissemination and hyperinfection in the immunocompetent host. Adult female worms in otherwise healthy and asymptomatic individuals may persist in the GI tract for years. If infected persons become immunocompromised, the reduction in cellular and humoral immunity may lead to an abrupt and dramatic increase in parasite load with systemic dissemination.

Clinical Manifestations

Approximately 30% of infected individuals are asymptomatic. The remaining patients have symptoms that correlate with the 3 stages of infection: invasion of the skin, migration of larvae through the lungs, and parasitism of the small intestine by adult worms. **Larva currens** is the manifestation of an allergic reaction to filariform larvae that migrate through the skin, where they leave pruritic, tortuous, urticarial tracks. The lesions may recur and are typically found over the lower abdominal wall, buttocks, or thighs, resulting from larval migration from defecated stool. Pulmonary disease secondary to larval migration through the lung rarely occurs and may resemble **Loeffler syndrome** (cough, wheezing, shortness of breath, transient pulmonary infiltrates accompanied by eosinophilia). GI strongyloidiasis is characterized by indigestion, crampy abdominal pain, vomiting, diarrhea, steatorrhea, protein-losing enteropathy, protein-caloric malnutrition, and weight loss. Edema of the duodenum with irregular mucosal folds, ulcerations, and strictures can be seen radiographically. Infection may be chronic in nature and is associated with **eosinophilia** .

Strongyloidiasis is potentially lethal because of the ability of the parasite to replicate within the host and cause overwhelming hyperinfection in immunocompromised persons. The **hyperinfection syndrome** is characterized by an exaggeration of the clinical features that develop in symptomatic immunocompetent individuals. The onset is usually sudden, with generalized abdominal pain, distention, and fever. Multiple organs can be affected as massive numbers of larvae disseminate throughout the body and introduce bowel flora. The latter may result in bacteremia and septicemia. Cutaneous manifestations may include petechiae and purpura. Cough, wheezing, and hemoptysis are indicative of pulmonary involvement. Whereas eosinophilia is a prominent feature of strongyloidiasis in immunocompetent persons, this sign may be absent in immunocompromised persons. Because of the low incidence of strongyloidiasis in industrialized countries, it is often misdiagnosed, resulting in a significant delay in treatment.

Diagnosis

Intestinal strongyloidiasis is diagnosed by examining feces or duodenal fluid for the characteristic larvae (Fig. 321.2). Several stool samples should be examined by direct smear, the Koga agar plate method, or the Baermann test. Alternatively, duodenal fluid can be sampled by the **enteric string test** (Entero-Test) or aspiration via endoscopy. In children with the hyperinfection syndrome, larvae may be found in sputum, gastric aspirates, and rarely in small intestinal biopsy specimens. An enzyme-linked immunosorbent assay for IgG antibody to *Strongyloides* may be more sensitive than parasitological methods for diagnosing intestinal infection in the immunocompetent host. The utility of the assay in diagnosing infection in immunocompromised patients with the hyperinfection syndrome has not been determined. Eosinophilia is common.

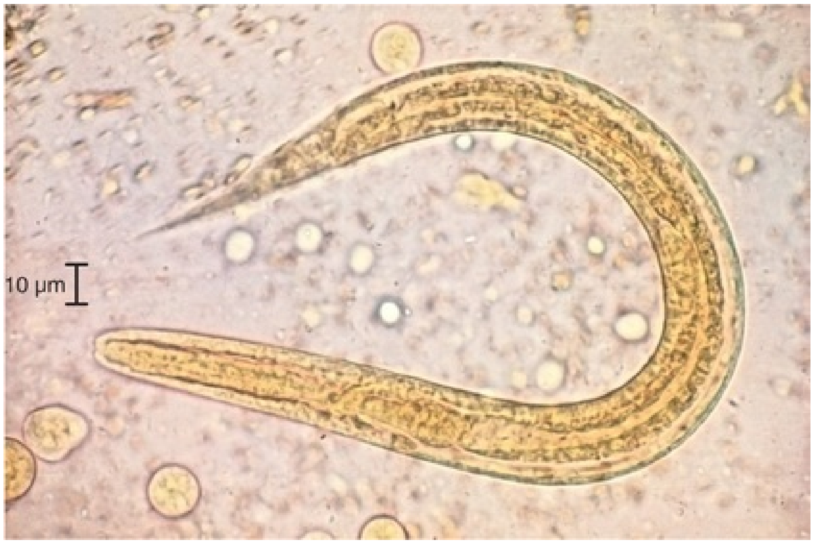

FIG. 321.2 **Larvae of intestinal strongyloidiasis.**

Treatment

Treatment is directed at eradication of infection. **Ivermectin** (200 µg/kg/day once daily orally for 2 days) is the drug of choice for uncomplicated strongyloidiasis. Alternatively, **albendazole** (400 mg orally twice daily for 7 days) may be used. Patients with the hyperinfection syndrome should be treated with ivermectin for 7-10 days and may require repeated courses. Reducing the dose of immunosuppressive therapy and treatment of concomitant bacterial infections are essential in the management of the **hyperinfection syndrome** . Close follow-up with repeated stool examination is necessary to ensure complete elimination of the parasite. *Strongyloides* antibodies decrease within 6 mo after successful treatment.

Prevention

Sanitary practices designed to prevent soil and person-to-person transmission are the most effective control measures (see Table 317.1). Wearing **shoes** is a main preventive strategy. Reducing transmission in institutional settings can be achieved by decreasing fecal contamination of the environment, such as by the use of clean bedding. Because infection is uncommon in most settings, case detection and treatment are advisable. Individuals who will be given prolonged high-dose corticosteroids, immunosuppressive drugs before organ transplantation, or cancer chemotherapy should have a screening examination for *S. stercoralis*. If infected, they should be treated before immunosuppression is initiated.

CHAPTER 322

Lymphatic Filariasis (*Brugia malayi, Brugia timori*, and *Wuchereria bancrofti*)

Arlene E. Dent, James W. Kazura

Etiology

The filarial worms *Brugia malayi* (**Malayan filariasis**), *Brugia timori*, and *Wuchereria bancrofti* (**bancroftian filariasis**) are threadlike nematodes that cause similar infections. Infective larvae are introduced into humans during blood feeding by the **mosquito** vector. Over 4-6 mo, the larval forms develop into sexually mature adult worms. Once an adequate number of male and female worms accumulate in the afferent lymphatic vessels, adult female worms release large numbers of microfilariae that circulate in the bloodstream. The life cycle of the parasite is completed when mosquitoes ingest microfilariae in a blood meal, which molt to form infective larvae over 10-14 days. Adult worms have a 5-7 yr life span.

Epidemiology

More than 120 million people living in tropical Africa, Asia, and Latin America are infected; approximately 10–20% of these individuals have clinically significant morbidity attributable to filariasis. *W. bancrofti* is transmitted in Africa, Asia, and Latin America and accounts for 90% of lymphatic filariasis. *B. malayi* is restricted to the South Pacific and Southeast Asia, and *B. timori* is restricted to several islands of Indonesia. Travelers from nonendemic areas of the world who spend brief periods in endemic areas are rarely infected. Global elimination has been targeted for 2020.

Clinical Manifestations

The clinical manifestations of *B. malayi, B. timori,* and *W. bancrofti* infection are similar; manifestations of acute infection include transient, recurrent lymphadenitis and lymphangitis. The early signs and symptoms include episodic fever, lymphangitis of an extremity, lymphadenitis (especially the inguinal and axillary areas), headaches, and myalgias that last a few days to several weeks. These symptoms are caused by an acute inflammatory response triggered by death of adult worms. Initial damage to lymphatic vessels may remain subclinical for years. The syndrome is most frequently observed in persons 10-20 yr old. Manifestations of chronic lymphatic filariasis occur mostly in adults ≥30 yr old and result from anatomic and functional obstruction to lymph flow. This obstruction results in lymphedema of the legs, arms, breasts, and/or genitalia. Male genital involvement, such as hydrocele, is very common in *W. bancrofti* infection, but uncommon in *Brugia* spp. infection. Chronic lymphedema predisposes affected extremities to bacterial superinfections, sclerosis, and verrucous skin changes, resulting in **elephantiasis** , which may involve 1 or more limbs, the breasts, or genitalia. It is uncommon for children to have overt signs of chronic filariasis.

Tropical Pulmonary Eosinophilia

The presence of microfilariae in the body has no apparent pathologic consequences except in persons with tropical pulmonary eosinophilia, a syndrome of filarial etiology in which microfilariae are found in the lungs and lymph nodes but not the bloodstream. It occurs only in individuals who have lived for years in endemic areas. Men 20-30 yr old are most likely to be affected, although the syndrome occasionally occurs in children. The presentation includes paroxysmal nocturnal cough with dyspnea, fever, weight loss, and fatigue. Rales and rhonchi are found on auscultation of the chest. The x-ray findings may occasionally be normal, but increased bronchovascular markings, discrete opacities in the middle and basal regions of the lung, or diffuse miliary lesions are usually present (Fig. 322.1). Recurrent episodes may result in interstitial fibrosis and chronic respiratory insufficiency in untreated individuals. Hepatosplenomegaly and generalized lymphadenopathy are often seen in children. The **diagnosis** is suggested by residence in a filarial endemic area, eosinophilia (>2,000/µL), compatible clinical symptoms, increased serum IgE (>1,000 IU/mL), and high titers of antimicrofilarial antibodies in the absence of microfilaremia. Although microfilariae may be found in sections of lung or lymph node, biopsy of these tissues is unwarranted in most situations. The clinical response to **diethylcarbamazine** (2 mg/kg/dose orally 3 times daily for 12-21 days) is the final criterion for diagnosis; the majority of patients improve with this therapy. If symptoms recur, a 2nd anthelmintic course should be administered. Patients with chronic symptoms are less likely to show improvement than those who have been ill for a short time.

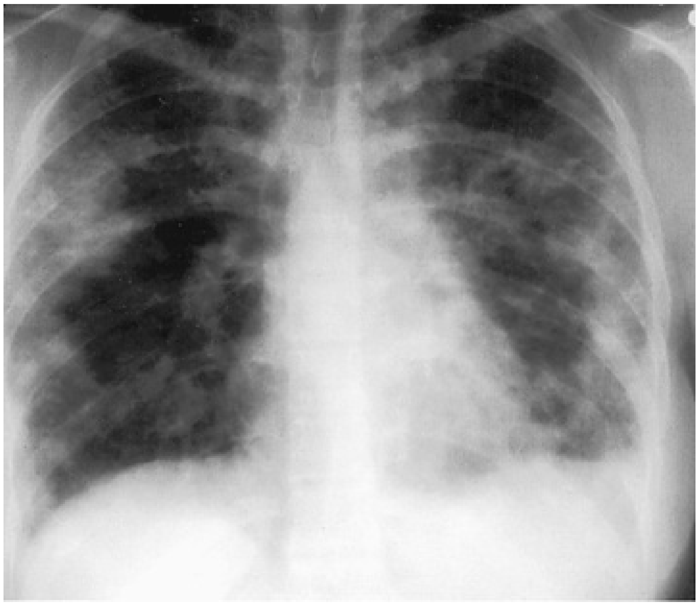

FIG. 322.1 **Chest radiograph of a woman with tropical pulmonary eosinophilia. Reticulonodular opacities are scattered throughout both lungs. (From Mandell GL, Bennett JE, Dolin R, editors: *Principles and practice of infectious diseases* , ed 6, Philadelphia, 2006, Elsevier, p 3274.)**

Diagnosis

Demonstration of microfilariae in the blood is the primary means for confirming the diagnosis of lymphatic filariasis. Because microfilaremia is **nocturnal** in most cases, blood samples should be obtained between 10 PM and 2 AM . Anticoagulated blood is passed through a Nuclepore filter that is stained and examined microscopically for microfilariae. Adult worms or microfilariae can be identified in tissue specimens obtained at biopsy. Infection with *W. bancrofti* in the absence of bloodborne microfilariae may be diagnosed by detection of parasite antigen in the serum. Adult worms in lymphatic vessels can be visualized by ultrasonography.

Treatment

The use of antifilarial drugs in the management of acute lymphadenitis and lymphangitis is controversial. No controlled studies demonstrate that administration of drugs such as diethylcarbamazine modifies the course of acute lymphangitis. Diethylcarbamazine may be given to asymptomatic microfilaremic persons to lower the intensity of parasitemia. The drug also kills a proportion of the adult worms. Because treatment-associated complications such as pruritus, fever, generalized body pain, hypotension, and even death may occur, especially with high microfilarial levels, the dose of **diethylcarbamazine** should be increased gradually (*children* : 1 mg/kg orally as a single dose on day 1, 1 mg/kg 3 times daily on day 2, 1-2 mg/kg 3 times daily on day 3, and 2 mg/kg 3 times daily on days 4-14; *adults* : 50 mg orally on day 1, 50 mg 3 times daily on day 2, 100 mg 3 times daily on day 3, and 2 mg/kg 3 times daily on days 4-14). For patients with no microfilaria in the blood, the full dose (2 mg/kg/day orally divided 3 times daily) can be given beginning on day 1. Repeat doses may be necessary to further reduce the microfilaremia and kill lymph-dwelling adult parasites. *W. bancrofti* is more sensitive than *B. malayi* to diethylcarbamazine.

Global programs to control and ultimately eradicate lymphatic filariasis from endemic populations currently recommend a single annual dose of diethylcarbamazine (6 mg/kg orally once) in combination with **albendazole** (400 mg orally once) for 5 yr (mass drug administration). In coendemic areas of filariasis and **onchocerciasis** , mass drug applications with single-dose **ivermectin** (150 µg/kg orally once) and albendazole are used because of severe adverse reactions with diethylcarbamazine in onchocerciasis-infected individuals. Five years of annual mass treatment is thought to be necessary to stop transmission. Adjuvant medicines (e.g., doxycycline) that target endosymbiont bacteria *(Wolbachia)* in filarial parasites may accelerate eradication.

CHAPTER 323

Other Tissue Nematodes

Arlene E. Dent, James W. Kazura

Onchocerciasis *(Onchocerca Volvulus)*

Infection with *Onchocerca volvulus* leads to onchocerciasis or **river blindness** . Onchocerciasis occurs primarily in West Africa but also in Central and East Africa and is the world's 2nd leading infectious cause of blindness. There have been scattered foci in Central and South America, but the infection is now thought to be eliminated in the Americas. *O. volvulus* larvae are transmitted to humans by the bite of *Simulium* black flies that breed in fast-flowing streams. The larvae penetrate the skin and migrate through the connective tissue and eventually develop into adult worms that can be found tangled in fibrous tissue. Adult worms can live in the human body for up to 14 yr. Female worms produce large numbers of microfilariae that migrate through the skin, connective tissue, and eye. Most infected individuals are asymptomatic. In heavily infected individuals, clinical manifestations are a result of localized host inflammatory reactions to dead or dying microfilariae and subcutaneous adult worms surrounded by a palpable fibrous capsule. Cutaneous and ocular reactions to microfilariae produce pruritic dermatitis, punctate keratitis, corneal pannus formation, and chorioretinitis. Adult worms in subcutaneous nodules are not painful and tend to occur over bony prominences of the hip. The **diagnosis** can be established by obtaining snips of skin covering the scapulae, iliac crests, buttocks, or calves. The snips are immersed in saline for several hours and examined microscopically for microfilariae that have emerged into the fluid. The diagnosis can also be established by demonstrating microfilariae in the cornea or anterior chamber on slit-lamp examination or finding adult worms on a nodule biopsy specimen. Ophthalmology consultation should be obtained before treatment of eye lesions.

A single dose of **ivermectin** (150 µg/kg orally) is the drug of choice and clears *O. volvulus* microfilariae from the skin for several months but has no effect on the adult worm. Treatment with ivermectin should be repeated every 6-12 mo until the patient is asymptomatic or has no evidence of eye infection. Adverse effects of ivermectin therapy include fever, urticaria, and pruritus, which are more frequent in individuals not born in endemic areas who acquired the infection following periods of intense exposure, such as Peace Corps volunteers. Patients with concurrent high-density microfilaremia from loiasis may develop potentially fatal encephalopathy with ivermectin therapy. Treatment with ivermectin should be withheld until *Loa loa* microfilaremia can be reduced. **Moxidectin** is a promising new agent. Personal protection includes avoiding areas where biting flies are numerous, wearing protective clothing, and using insect repellent. Programs of mass treatment with ivermectin have been implemented in Africa in an effort to reduce the prevalence of onchocerciasis.

The World Health Organization (WHO) set goals for onchocerciasis elimination by 2020 using mass drug administration with ivermectin. Elimination can be declared only after 3 yr of posttreatment surveillance without microfilaria detection in skin biopsies.

Nodding syndrome , a form of epilepsy in African children living in focal areas of Uganda and South Sudan, was epidemiologically associated with onchocerciasis, but an etiologic link was not established. Recently, researchers identified neurotoxic autoantibodies that cross-react with *O. volvulus* proteins, which were found more frequently in people with nodding syndrome than in those in the same village without the syndrome. Nodding syndrome may be an autoimmune epileptic disorder triggered by *O. volvulus* infection.

Loiasis *(Loa Loa)*

Loiasis is caused by infection with the tissue nematode *Loa loa*. The parasite is transmitted to humans by diurnally biting flies *(Chrysops)* that live in the rain forests of West and Central Africa. Migration of adult worms through skin, subcutaneous tissue, and subconjunctival area can lead to transient episodes of pruritus, erythema, and localized edema known as **Calabar swellings** , which are nonerythematous areas of subcutaneous edema 10-20 cm in diameter typically found around joints such as the wrist or the knee (Fig. 323.1). They resolve over several days to weeks and may recur at the same or different sites. Lifelong residents of *L. loa* –endemic regions may have microfilaremia and eosinophilia but are often asymptomatic. In contrast, travelers to endemic regions may have a hyperreactive response to *L. loa* infection characterized by frequent recurrences of swelling, high level eosinophilia, debilitation, and serious complications such as glomerulonephritis and encephalitis. **Diagnosis** is usually established on clinical grounds, often assisted by the infected individual reporting a worm being seen crossing the conjunctivae. Microfilariae may be detected in blood smears collected between 10 AM and 2 PM . Adult worms should be surgically excised when possible.

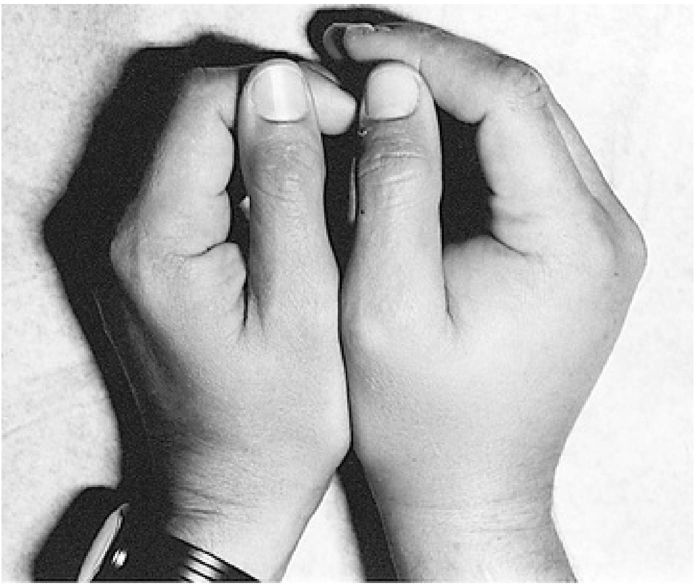

FIG. 323.1 **Calabar swelling of the right hand. (From Guerrant RL, Walker DH, Weller PF, et al: *Tropical infectious diseases* , Philadelphia, 2006, Churchill Livingstone, p 1165.)**

Diethylcarbamazine is the agent of choice for eradication of microfilaremia, but the drug does not kill adult worms. Because treatment-associated complications such as pruritus, fever, generalized body pain, hypertension, and even death may occur, especially with high microfilaria levels, the dose of diethylcarbamazine should be increased gradually in such cases (*children* : 1 mg/kg orally on day 1, 1 mg/kg 3 times daily on day 2, 1-2 mg/kg three times daily on day 3, 2 mg/kg three times daily on days 4-21; *adults* : 50 mg orally on day 1, 50 mg three times daily on day 2, 100 mg three times daily on day 3, 2 mg/kg three times daily on days 4-21). Full doses can be instituted on day 1 in persons without microfilaremia (3 mg/kg orally three times daily for 12 days). A 3 wk course of **albendazole** can also be used to slowly reduce *L. loa* microfilarial levels as a result of embryotoxic effects on the adult worms. Antihistamines or corticosteroids may be used to limit allergic reactions secondary to killing of microfilariae. Personal protective measures include avoiding areas where biting flies are present, wearing protective clothing, and using insect repellents. Diethylcarbamazine (300 mg orally once weekly) prevents infection in travelers who spend prolonged periods in endemic areas. *L. loa* do not harbor *Wolbachia* endosymbionts, and therefore doxycycline has no effect on infection.

Infection With Animal Filariae

The most commonly recognized zoonotic filarial infections are caused by members of the genus *Dirofilaria.* The worms are introduced into humans by the bites of mosquitoes containing third-stage larvae. The most common filarial zoonosis in the United States is *Dirofilaria tenuis,* a parasite of raccoons. In Europe, Africa, and Southeast Asia, infections are usually caused by the dog parasite *Dirofilaria repens.* The **dog heartworm** , *Dirofilaria immitis,* is the second most frequently encountered filarial zoonosis worldwide. Other genera, including *Dipetalonema* -like worms, *Onchocerca,* and *Brugia,* are rare causes of zoonotic filarial infections.

Animal filariae do not undergo normal development in the human host. The clinical manifestations and pathologic findings correspond to the anatomic site of infection and can be categorized into 4 major groups: subcutaneous, lung, eye, and lymphatic. Pathologic examination of affected tissue reveals a localized foreign body reaction around a dead or dying parasite. The lesion consists of granulomas with eosinophils, neutrophils, and tissue necrosis. *D. tenuis* does not leave the subcutaneous tissues, whereas *Brugia beaveri* eventually localizes to superficial lymph nodes. Infections may be present for up to several months. *D. immitis* larvae migrate for several months in subcutaneous tissues and most frequently result in a well-circumscribed, coinlike lesion in a single lobe of the lung. The chest radiograph typically reveals a solitary pulmonary nodule 1-3 cm in diameter. Definitive **diagnosis** and cure depend on surgical excision and identification of the nematode within the surrounding granulomatous response. *D. tenuis* and *B. beaveri* infections present as painful, rubbery, 1-5 cm nodules in the skin of the trunk, of the extremities, and around the orbit. Patients often report having been engaged in activities predisposing to exposure to infected mosquitoes, such as working or hunting in swampy areas. Management is by

surgical excision .

Angiostrongylus Cantonensis

Angiostrongylus cantonensis, the **rat lungworm,** is the most common cause of **eosinophilic meningitis** worldwide. Rats are the definitive host. Human infection follows ingestion of third-stage larvae in raw or undercooked intermediate hosts such as snails and slugs, or transport hosts such as freshwater prawns, frogs, and fish. Most cases are sporadic, but clusters have been reported, including clusters related to consumption of lettuce contaminated with intermediate or transport hosts. Even though most infections have been described in Southeast Asia, the South Pacific, and Taiwan, shipboard travel of infected rats has spread the parasite to Madagascar, Africa, the Caribbean, and most recently Australia and North America. Larvae penetrate the vasculature of the intestinal tract and migrate to the meninges, where they usually die but induce eosinophilic aseptic meningitis. Patients present 2-35 days after ingestion of larvae with severe headache, neck pain or nuchal rigidity, hyperesthesias and paresthesias (often migrating), fatigue, fever, rash, pruritus, nausea, and vomiting. Neurologic involvement varies from asymptomatic to paresthesias, severe pain, weakness, and focal neurologic findings such as cranial nerve palsies. Symptoms can last for several weeks to months, especially headache. Coma and death from hydrocephalus occur rarely in heavy infections. Peripheral blood eosinophilia is not always present on initial examination but peaks about 5 wk after exposure, often when symptoms are improving. Cerebrospinal fluid (CSF) analysis reveals pleocytosis with >10% eosinophils in more than half of patients, with mildly elevated protein, a normal glucose level, and an elevated opening pressure. Head CT or MRI is usually unremarkable. The **diagnosis** is established clinically with supporting travel and diet history. A sensitive and specific enzyme-linked immunosorbent assay (ELISA) is available on a limited basis from the Centers for Disease Control and Prevention (CDC) for testing CSF or serum.

Treatment is primarily supportive because the majority of infections are mild, and most patients recover within 2 mo without neurologic sequelae. Analgesics should be given for headache. Careful, repeated lumbar punctures should be performed to relieve hydrocephalus. Anthelmintic drugs have not been shown to influence the outcome and may exacerbate neurologic symptoms. The use of corticosteroids may shorten the duration of persistent and severe headaches.

There is a higher incidence of permanent neurologic sequelae and mortality among children than among adults. Infection can be avoided by not eating raw or undercooked crabs, prawns, or snails.

Angiostrongylus Costaricensis

Angiostrongylus costaricensis is a nematode that infects several species of rodents and causes abdominal **angiostrongyliasis** , which has been described predominantly in Latin America and the Caribbean. The mode of transmission to humans, who are accidental hosts, is unknown. It is speculated that infectious larvae from a molluscan intermediate host, such as the slug *Vaginulus plebeius*, contaminate water or vegetation that is inadvertently consumed (chopped up in salads or on vegetation contaminated with the slug's mucus secretions). Although this slug is not indigenous to the continental United States, it has been found on imported flowers and produce. The incubation period for abdominal angiostrongyliasis is unknown, but limited data suggest that it ranges from 2 wk to several months after ingestion of larvae. Third-stage larvae migrate from the gastrointestinal tract to the mesenteric arteries, where they mature into adults. These eggs degenerate and elicit an eosinophilic granulomatous reaction. The clinical findings of abdominal angiostrongyliasis mimic **appendicitis,** although the former are typically more indolent. Children can have fever, right lower quadrant pain, a tumor-like mass, abdominal rigidity, and a painful rectal examination. Most patients have leukocytosis with eosinophilia. Radiologic examination may show bowel wall edema, spasticity, or filling defects in the ileocecal region and the ascending colon. Examination of stool for ova and parasites is not useful for *A. costaricensis* but is useful for evaluating the presence of other intestinal parasites. An ELISA is available for **diagnosis** on a limited basis from the CDC, but the test has a low specificity and is known to cross react with *Toxocara, Strongyloides,* and *Paragonimus.*

Many patients undergo laparotomy for suspected appendicitis and are found to have a mass in the terminal ileum to the ascending colon. *No specific treatment is known for abdominal angiostrongyliasis.* Even though the use of anthelmintic therapy has not been studied systematically, thiabendazole or diethylcarbamazine has been suggested. The prognosis is generally good. Most cases are self-limited, although surgery may be required in some patients. Cornerstones of **prevention** include avoidance of slugs and not ingesting raw food and water that may be contaminated with imperceptible slugs or slime from slugs. Rat control is also important in preventing the spread of infection.

Dracunculiasis *(Dracunculus Medinensis)*

Dracunculiasis is caused by the guinea worm, *Dracunculus medinensis.* WHO has targeted dracunculiasis for eradication. As of 2016, the transmission of the infection was confined to Chad, Ethiopia, Mali, and South Sudan. Humans become infected by drinking contaminated stagnant water that contains immature forms of the parasite in the gut of tiny crustaceans (copepods or water fleas). Larvae are released in the stomach, penetrate the mucosa, mature, and mate. Approximately 1 yr later, the adult female worm (1-2 mm in diameter and up to 1 m long) migrates and partially emerges through the human host skin, usually of the legs. Thousands of immature larvae are released when the affected body part is immersed in the water. The cycle is completed when larval forms are ingested by the crustaceans. Infected humans have no symptoms until the worm reaches the subcutaneous tissue, causing a **stinging papule** that may be accompanied by urticaria, nausea, vomiting, diarrhea, and dyspnea. The lesion vesiculates, ruptures, and forms a painful ulcer in which a portion of the worm is visible. **Diagnosis** is established clinically. Larvae can be identified by microscopic examination of the discharge fluid.

Metronidazole (25 mg/kg/day orally divided into 3 doses for 10 days; maximum dose: 750 mg) decreases local inflammation. Although the drug does not kill the worm, it facilitates its removal. The worm must be physically removed by rolling the slowly emerging 1 m–long parasite onto a thin stick over a week. Topical corticosteroids shorten the time to complete healing while topical antibiotics decrease the risk of secondary bacterial infection. Dracunculiasis can be prevented by boiling or chlorinating drinking water or passing the water through a cloth sieve before consumption. Eradication is dependent on behavior modification and education.

Gnathostoma Spinigerum

Gnathostoma spinigerum is a dog and cat nematode endemic to Southeast Asia, Japan, China, Bangladesh, and India, but has been identified in Mexico and parts of South America. Infection is acquired by ingesting intermediate hosts containing larvae of the parasite, such as raw or undercooked freshwater fish, chickens, pigs, snails, or frogs. Penetration of the skin by larval forms and prenatal transmission has also been described. Nonspecific signs and symptoms such as generalized malaise, fever, urticaria, anorexia, nausea, vomiting, diarrhea, and epigastric pain develop 24-48 hr after ingestion of *G. spinigerum*. Ingested larvae penetrate the gastric wall and migrate through soft tissue for up to 10 yr. Moderate to severe eosinophilia can develop. Cutaneous **gnathostomiasis** manifests as intermittent episodes of localized, migratory nonpitting edema associated with pain, pruritus, or erythema. Central nervous system involvement in gnathostomiasis is suggested by focal neurologic findings, initially neuralgia followed within a few days by paralysis or changes in mental status. Multiple cranial nerves may be involved, and CSF may be xanthochromic but typically shows an eosinophilic pleocytosis. **Diagnosis** of gnathostomiasis is based on clinical presentation and epidemiologic background. Brain and spinal cord lesions may be seen on CT or MRI. Serologic testing varies in sensitivity and specificity and is available through the CDC.

There is no well-documented effective chemotherapy, although **albendazole** (400 mg orally twice daily for 21 days) as first-line therapy or **ivermectin** (200 µg/kg for 2 days) as an alternative is recommended without or with surgical removal. Multiple courses may be needed. Corticosteroids have been used to relieve focal neurologic deficits. **Surgical resection** of the *Gnathostoma* is the major mode of therapy and the treatment of choice. Blind surgical resection of subcutaneous areas of diffuse swelling is not recommended because the worm can rarely be located. **Prevention** through the avoidance of ingestion of poorly cooked or raw fish, poultry, or pork should be emphasized for individuals living in or visiting endemic areas.

CHAPTER 324

Toxocariasis (Visceral and Ocular Larva Migrans)

Arlene E. Dent, James W. Kazura

Etiology

Most cases of human toxocariasis are caused by the **dog roundworm** , *Toxocara canis.* Adult female *T. canis* worms live in the intestinal tracts of young puppies and their lactating mothers. Large numbers of eggs are passed in the feces of dogs and embryonate under optimal soil conditions. *Toxocara* eggs can survive relatively harsh environmental conditions and are resistant to freezing and extremes of moisture and pH. Humans ingest embryonated eggs contaminating soil, hands, or fomites. The larvae hatch and penetrate the intestinal wall and travel via the circulation to the liver, lung, and other tissues. Humans do not excrete *T. canis* eggs because the larvae are unable to complete their maturation to adult worms in the intestine. The **cat roundworm** , *Toxocara cati,* is responsible for far fewer cases of **visceral larva migrans (VLM)** than *T. canis.* Ingestion of infective larvae of the raccoon ascarid *Baylisascaris procyonis* rarely leads to VLM but can cause **neural larva migrans** , resulting in fatal eosinophilic meningitis. Ingestion of larvae from the opossum ascarid *Lagochilascaris minor* leads to VLM rarely.

Epidemiology

Human *T. canis* infections have been reported in almost all parts of the world, primarily in temperate and tropical areas where dogs are popular household pets. Young children are at highest risk because of their unsanitary play habits and tendency to place fingers in the mouth. Other behavioral risk factors include

pica , contact with puppy litters, and institutionalization. In North America, the highest prevalences of infection are in the southeastern United States and Puerto Rico, particularly among socially disadvantaged African American and Hispanic children. In the United States, serosurveys show that 4.6–7.3% of children are infected. Assuming an unrestrained and untreated dog population, toxocariasis is prevalent in settings where other **geohelminth infections** , such as ascariasis, trichuriasis, and hookworm infections, are common.

Pathogenesis

T. canis larvae secrete large amounts of immunogenic glycosylated proteins. These antigens induce immune responses that lead to eosinophilia and polyclonal and antigen-specific immunoglobulin E production. The characteristic histopathologic lesions are granulomas containing eosinophils, multinucleated giant cells (histiocytes), and collagen. Granulomas are typically found in the liver but may also occur in the lungs, central nervous system (CNS), and ocular tissues. Clinical manifestations reflect the intensity and chronicity of infection, anatomic localization of larvae, and host granulomatous responses.

Clinical Manifestations

Three major clinical syndromes are associated with human toxocariasis: VLM, **ocular larva migrans (OLM)** , and **covert toxocariasis** (Table 324.1). The classic presentation of VLM includes eosinophilia, fever, and hepatomegaly and occurs most often in toddlers with a history of pica and exposure to puppies. The findings include fever, cough, wheezing, bronchopneumonia, anemia, hepatomegaly, leukocytosis, eosinophilia, and positive *Toxocara* serology. Cutaneous manifestations such as pruritus, eczema, and urticaria can be present. OLM tends to occur in older children without signs or symptoms of VLM. Presenting symptoms include unilateral visual loss, eye pain, white pupil, or strabismus that develops over weeks. Granulomas occur on the posterior pole of the retina and may be mistaken for retinoblastoma. Serologic testing for *Toxocara* has allowed the identification of individuals with less obvious or covert symptoms of infection. These children may have nonspecific complaints that do not constitute a recognizable syndrome. Common findings include hepatomegaly, abdominal pain, cough, sleep disturbance, failure to thrive, and headache with elevated *Toxocara* antibody titers. Eosinophilia may be present in 50–75% of cases. The prevalence of positive *Toxocara* serology in the general population supports that most children with *T. canis* infection are asymptomatic and will not develop overt clinical sequelae over time. A correlation between positive *Toxocara* serology and allergic asthma has also been described.

Table 324.1

Clinical Syndromes of Human Toxocariasis

SYNDROME	CLINICAL FINDINGS	AVERAGE AGE	INFECTIOUS DOSE	INCUBATION PERIOD	LABORATORY FINDINGS	ELISA
Visceral larva migrans	Fevers, hepatomegaly, asthma	5 yr	Moderate to high	Weeks to months	Eosinophilia, leukocytosis, elevated IgE	High (≥1 : 16)
Ocular larva migrans	Visual disturbances, retinal granulomas, endophthalmitis, peripheral granulomas	12 yr	Low	Months to years	Usually none	Low
Covert toxocariasis	Abdominal pain, gastrointestinal symptoms, weakness, hepatomegaly, pruritus, rash	School-age to adult	Low to moderate	Weeks to years	± Eosinophilia ± Elevated IgE	Low to moderate

ELISA, Enzyme-linked immunosorbent assay; IgE, immunoglobulin E; ±, with or without.

Adapted from Liu LX: Toxocariasis and larva migrans syndrome. In Guerrant RL, Walker DH, Weller PF, editors: *Tropical infectious diseases: principles, pathogens & practice,* Philadelphia, 206, Churchill-Livingstone, p 1209.

Diagnosis

A presumptive diagnosis of toxocariasis can be established in a young child with **eosinophilia** (>20%), leukocytosis, hepatomegaly, fevers, wheezing, and a history of geophagia and exposure to puppies or unrestrained dogs. Supportive laboratory findings include hypergammaglobulinemia and elevated isohemagglutinin titers to A and B blood group antigens. Most patients with VLM have an absolute eosinophil count >500/µL. Eosinophilia is less common in patients with OLM. Biopsy confirms the diagnosis. When biopsies cannot be obtained, an enzyme-linked immunosorbent assay using excretory-secretory proteins harvested from *T. canis* larvae maintained in vitro is the standard serologic test used to confirm toxocariasis. A titer of 1 : 32 is associated with a sensitivity of approximately 78% and a specificity of approximately 92%. The sensitivity for OLM is significantly less. The diagnosis of OLM can be established in patients with typical clinical findings of a retinal or peripheral pole granuloma or endophthalmitis with elevated antibody titers. Vitreous and aqueous humor fluid anti-*Toxocara* titers are usually greater than serum titers. The diagnosis of covert toxocariasis should be considered in individuals with chronic weakness, abdominal pain, or allergic signs with eosinophilia and increased IgE. In temperate regions of the world, nonparasitic causes of eosinophilia that should be considered in the differential diagnosis include allergies, drug hypersensitivity, lymphoma, vasculitis, and **idiopathic hypereosinophilic syndrome** (see Chapter 155).

Treatment

Most patients do not require treatment because signs and symptoms are mild and subside over weeks to months. Several anthelmintic drugs have been used for symptomatic cases, often with adjunctive corticosteroids to limit inflammatory responses that presumably result from release of *Toxocara* antigens by dying parasites. **Albendazole** (400 mg orally twice daily for 5 days for all ages) has demonstrated efficacy in both children and adults. **Mebendazole** (100-200 mg PO twice daily for 5 days for all ages) is also useful. Anthelmintic treatment of CNS and ocular disease should be extended (3-4 wk). Even with no clinical trials on OLM therapy, a course of oral corticosteroids such as **prednisone** (1 mg/kg/day PO for 2-4 wk) has been recommended to suppress local inflammation while treatment with anthelmintic agents is initiated.

Prevention

Transmission can be minimized by public health measures that prevent dog feces from contaminating the environment. These include keeping dogs on leashes and excluding pets from playgrounds and sandboxes that toddlers use. Children should be discouraged from putting dirty fingers in their mouth and eating dirt. Vinyl covering of sandboxes reduces the viability of *T. canis* eggs. Widespread veterinary use of broad-spectrum anthelmintics effective against *Toxocara* may lead to a decline in parasite transmission to humans.

CHAPTER 325

Trichinellosis *(Trichinella spiralis)*

Arlene E. Dent, James W. Kazura

Etiology

Human trichinellosis (also called **trichinosis**) is caused by consumption of meat containing encysted larvae of *Trichinella spiralis,* a tissue-dwelling nematode with a worldwide distribution. After ingestion of raw or inadequately cooked meat from pigs (or other commercial meat sources such as horses) containing viable *Trichinella* larvae, the organisms are released from the cyst by acid-pepsin digestion of the cyst walls in the stomach and then pass into the small intestine. The larvae invade the small intestine columnar epithelium at the villi base and develop into adult worms. The adult female worm produces about 500 larvae over 2 wk and is then expelled in the feces. The larvae enter the bloodstream and seed striated muscle by burrowing into individual muscle fibers. Over a period of 3 wk, they coil as they increase about 10 times in length and become capable of infecting a new host if ingested. The larvae eventually become encysted and can remain viable for years. **Sylvatic** *Trichinella* spp. (*T. brivoti, T. nativa, T. pseudospiralis,* and *T. murrelli*) present in traditional native foods such as walrus meat, and **game meat** may also cause disease similar to that caused by *T. spiralis* .

Epidemiology

Despite public health efforts to control trichinellosis by eliminating the practice of feeding garbage to domestic swine, epidemics and isolated cases of *Trichinella* spp. infection continue to be a health problem in many areas of the world. It is most common in Asia, Latin America, and Central Europe. Swine fed with garbage may become infected when given uncooked trichinous scraps, usually pig meat, or when the carcasses of infected wild animals such as rats are eaten. Prevalence rates of *T. spiralis* in domestic swine range from 0.001% in the United States to ≥25% in China. The resurgence of this disease can be attributed to translocations of animal populations, human travel, and export of food as well as ingestion of sylvatic *Trichinella* through game meat. In the United States from 1997 to 2001, wild game meat (especially bear or walrus meat) was the most common source of infection. Most outbreaks occur from the consumption of *T. spiralis* –infected pork (or horse meat in areas of the world where horse is eaten) obtained from a single source.

Pathogenesis

During the 1st 2-3 wk after infection, pathologic reactions to infection are limited to the gastrointestinal (GI) tract and include a mild, partial villous atrophy with an inflammatory infiltrate of neutrophils, eosinophils, lymphocytes, and macrophages in the mucosa and submucosa. Larvae are released by female worms and disseminate over the next several weeks. Skeletal muscle fibers show the most striking changes with edema and basophilic degeneration. The muscle fiber may contain the typical coiled worm, the cyst wall derived from the host cell, and the surrounding lymphocytic and eosinophilic infiltrate.

Clinical Manifestations

The development of symptoms depends on the number of viable larvae ingested. Most infections are asymptomatic or mild, and children often show milder symptoms than adults who consumed the same amount of infected meat. Watery diarrhea is the most common symptom corresponding to maturation of the adult worms in the GI tract, which occurs during the 1st 1-2 wk after ingestion. Patients may also complain of abdominal discomfort and vomiting. Fulminant **enteritis** may develop in individuals with extremely high worm burdens. The classic symptoms of facial and periorbital edema, fever, weakness, malaise, and myalgia peak approximately 2-3 wk after the infected meat is ingested, as the larvae migrate and then encyst in the muscle. Headache, cough, dyspnea, dysphagia, subconjunctival and splinter hemorrhages, and a macular or petechial rash may occur. Patients with high-intensity infection may die from myocarditis, encephalitis, or pneumonia. In symptomatic patients, **eosinophilia** is common and may be dramatic.

Diagnosis

The Centers for Disease Control and Prevention (CDC) diagnostic criteria for trichinellosis require positive serology or muscle biopsy for *Trichinella* with 1 or more compatible clinical symptoms (eosinophilia, fever, myalgia, facial or periorbital edema). To declare a discrete outbreak, at least 1 person must have positive serology or muscle biopsy. Antibodies to *Trichinella* are detectable approximately 3 wk after infection. Severe muscle involvement results in elevated serum creatine phosphokinase and lactic dehydrogenase levels. Muscle biopsy is not usually necessary, but if needed, a sample should be obtained from a tender swollen muscle. A history of eating undercooked meat supports the diagnosis. The cysts may calcify and may be visible on radiograph.

Treatment

Recommended treatment of trichinellosis diagnosed at the GI phase is **albendazole** (400 mg orally twice daily for 8-10 days for all ages) to eradicate the adult worms if a patient has ingested contaminated meat within the previous 1 wk. An alternative regimen is mebendazole (200-400 mg PO 3 times daily for 3 days followed by 400-500 mg three times daily for 10 days). There is no consensus for treatment of muscle-stage trichinellosis. Corticosteroids may be used, although evidence for efficacy is anecdotal.

Prevention

Trichinella larvae can be killed by cooking meat (≥55°C [131°F]) until there is no trace of pink fluid or flesh, or by storage in a freezer (−15°C [5°F]) for ≥3 wk. Freezing to kill larvae should only be applied to pork meat, because larvae in horse, wild boar, or game meat can remain viable even after 4 wk of freezing. Smoking, salting, and drying meat are unreliable methods of killing *Trichinella*. Strict adherence to public health measures, including garbage feeding regulations, stringent rodent control, prevention of exposure of pigs and other livestock to animal carcasses, constructing barriers between livestock, wild animals, and domestic pets, and proper handling of wild animal carcasses by hunters, can reduce infection with *Trichinella*. Current meat inspection for trichinellosis is by direct digestion and visualization of encysted larvae in meat samples. Serologic testing does not have a role in meat inspection.

CHAPTER 326

Schistosomiasis *(Schistosoma)*

Charles H. King, Amaya L. Bustinduy

The term **schistosomiasis (bilharzia)** encompasses the acute and chronic inflammatory disorders caused by human infection with *Schistosoma* spp. parasites. Disease is related to both the systemic and the focal effects of schistosome infection and its consequent host immune responses triggered by parasite eggs deposited in the tissues. For the affected individuals, this frequently manifests as disabling chronic morbidity.

Etiology

Schistosoma organisms are the trematodes, or **flukes** , that parasitize the bloodstream. Five schistosome species infect humans: *Schistosoma haematobium, S. mansoni, S. japonicum, S. intercalatum,* and *S. mekongi* . Humans are infected through contact with water contaminated with *cercariae* , the free-living infective stage of the parasite. These motile, forked-tail organisms emerge from infected snails and are capable of penetrating intact human skin. As they reach maturity, adult worms migrate to specific anatomic sites characteristic of each schistosome species: *S. haematobium* adults are found in the perivesical and periureteral venous plexus, *S. mansoni* in the inferior mesenteric veins, and *S. japonicum* in the superior mesenteric veins. *S. intercalatum* and *S. mekongi* are usually found in the mesenteric vessels. Adult schistosome worms (1-2 cm long) are clearly adapted for an intravascular existence. The female accompanies the male in a groove formed by the lateral edges of its body. On fertilization, female worms begin oviposition in the small venous tributaries. The eggs of the 3 main schistosome species have characteristic morphologic features: *S. haematobium* has a terminal spine, *S. mansoni* has a lateral spine, and *S.*

japonicum has a smaller size with a short, curved spine (Fig. 326.1). Parasite eggs provoke a significant granulomatous inflammatory response that allows them to ulcerate through host tissues to reach the lumen of the urinary tract or the intestines. They are carried to the outside environment in urine or feces (depending on the species), where they will hatch if deposited in freshwater. Motile miracidia emerge, infect specific freshwater snail intermediate hosts, and divide asexually. After 4-12 wk, the infective cercariae are released by the snails into the contaminated water.

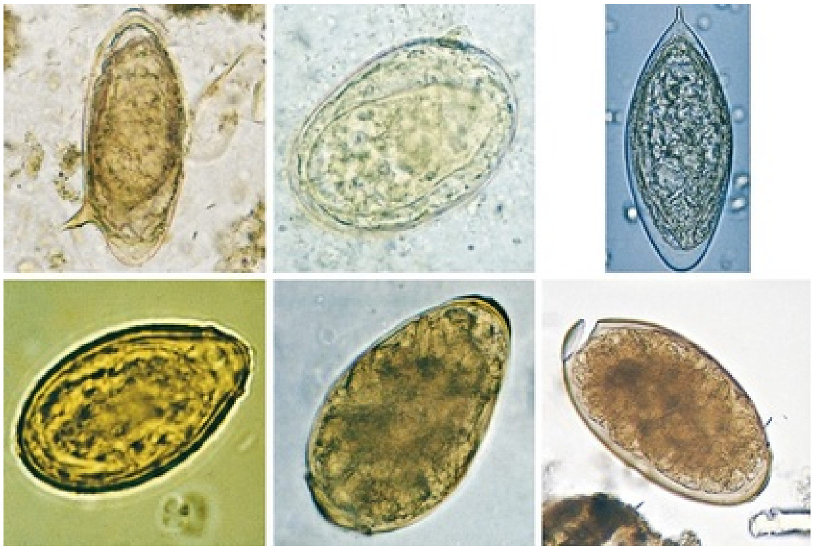

FIG. 326.1 Eggs of common human trematodes. Clockwise from upper left: *Schistosoma mansoni, S. japonicum, S. haematobium, Clonorchis sinensis, Paragonimus westermani* , and *Fasciola hepatica* (note the partially open operculum). (From Centers for Disease Control and Prevention: DPDx: laboratory identification of parasites of public health concern. http://www.cdc.gov/dpdx/az.html .)

Epidemiology

Schistosomiasis infects more than 300 million people worldwide and puts more than 700 million people at risk, primarily children and young adults. There are 3.3 million disability-adjusted life-years (DALYs) attributed to schistosomiasis, making it the 2nd most disabling parasitic disease after malaria. Prevalence is increasing in many areas as population density increases and new irrigation projects provide broader habitats for vector **snails** . Humans are the main definitive hosts for the 5 clinically important species of schistosomes, although

S. japonicum is also a zoonosis, infecting animals such as dogs, rats, pigs, and cattle. *S. haematobium* is prevalent in Africa and the Middle East; *S. mansoni* is prevalent in Africa, the Middle East, the Caribbean, and South America; and *S. japonicum* is prevalent in China, the Philippines, and Indonesia, with some sporadic foci in parts of Southeast Asia. The other 2 species are less prevalent. *S. intercalatum* is found in West and Central Africa, and *S. mekongi* is found only along the upper Mekong River in the Far East.

Transmission depends on water contamination by human excreta, the presence of specific intermediate snail hosts, and the patterns of water contact and social habits of the population (Fig. 326.2). The distribution of infection in endemic areas shows that prevalence increases with age, to a peak at 10-20 yr old. Exposure to infected water starts early in life for children living in endemic areas. Passive water contact by infants (accompanying mothers in their daily household activities) evolves to more active water contact as preschool and school-age children pursue recreational activities such as swimming and wading.

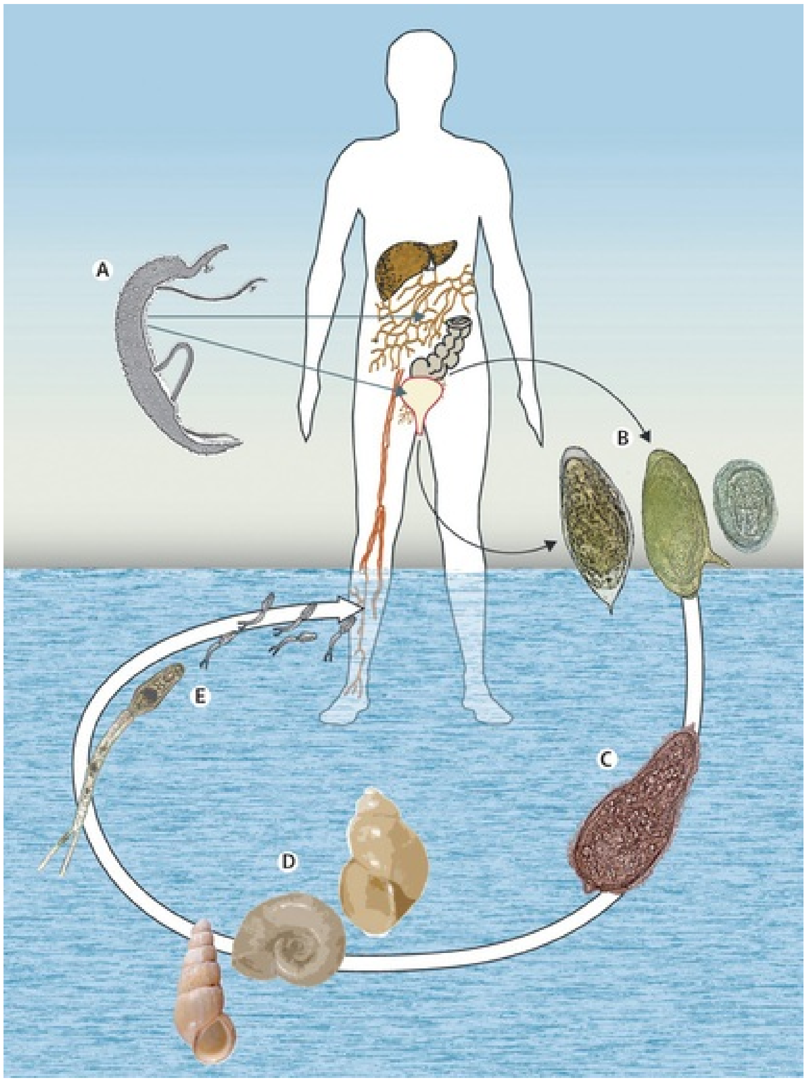

FIG. 326.2 Life cycle of *Schistosoma mansoni, S. haematobium,* and *S. japonicum* . *A,* Paired adult worms (larger male enfolding slender female). *B,* Eggs (left to right, *S. haematobium, S. mansoni, S. japonicum)* . *C,* Ciliated miracidium. *D,* Intermediate host snails (left to right, *Oncomelania, Biomphalaria, Bulinus)* . *E,* Cercariae. (From Colley DG, Bustinduy AL, Secor WE, King CH: Human schistosomiasis, *Lancet* 383:2253–2264, 2014, Fig 1.)

Measuring intensity of infection (by quantitative egg count in urine or feces) demonstrates that the heaviest worm loads are found in school-age and adolescent children. Even though schistosomiasis is most prevalent and most severe in older children and young adults, who are at maximal risk for suffering from its acute and chronic sequelae, preschool children can also exhibit significant disease manifestations.

Pathogenesis

Both early and late manifestations of schistosomiasis are immunologically mediated. *Acute* schistosomiasis, known as **snail fever** or **Katayama syndrome**, is a febrile illness that represents an immune complex disease associated with early infection and oviposition. The major pathology of infection occurs later, with *chronic* schistosomiasis, in which retention of eggs in the host tissues is associated with chronic granulomatous injury. Eggs may be trapped at sites of deposition (urinary bladder, ureters, intestine) or may be carried by the bloodstream to other organs, most frequently the liver and less often the lungs and central nervous system (CNS). The host response to these eggs involves local as well as systemic manifestations. The cell-mediated immune response leads to granulomas composed of lymphocytes, macrophages, and eosinophils that surround the trapped eggs and add significantly to the degree of tissue destruction. Granuloma formation in the bladder wall and at the ureterovesical junction results in the major disease manifestations of schistosomiasis haematobia: hematuria, dysuria, and obstructive uropathy. Intestinal as well as hepatic granulomas underlie the pathologic sequelae of the other schistosome infections: ulcerations and fibrosis of intestinal wall, hepatosplenomegaly, and portal hypertension caused by presinusoidal obstruction of blood flow. In terms of systemic disease, antischistosome inflammation increases circulating levels of proinflammatory cytokines such as tumor necrosis factor-α and interleukin-6, associated with elevated levels of C-reactive protein. These responses are associated with hepcidin-mediated inhibition of iron uptake and use, leading to anemia of chronic inflammation. Schistosomiasis-related undernutrition may be the result of similar pathways of chronic inflammation. Acquired partial protective immunity against schistosomiasis has been demonstrated in some animal species and may occur in humans.

Clinical Manifestations

Two main chronic clinical syndromes arise from *Schistosoma* spp. infection: **urogenital schistosomiasis** caused by *S. haematobium* and **intestinal schistosomiasis** caused by *S. mansoni* or *S. japonicum.* Most chronically infected individuals experience mild symptoms and may not seek medical attention; the more severe symptoms of schistosomiasis occur mainly in those who are heavily infected or who have been infected over longer periods. In addition to organ-specific morbidities, infected patients frequently demonstrate anemia, chronic pain, diarrhea, exercise intolerance, and chronic undernutrition manifesting as growth stunting. Cercarial penetration of human skin may result in a papular pruritic rash known as **schistosomal dermatitis** or **swimmer's itch** . It is more pronounced in previously exposed individuals and is characterized by edema and intense cellular infiltrates in the dermis and epidermis. Acute schistosomiasis (Katayama syndrome) may occur, particularly in heavily infected individuals, 4-8 wk after exposure; this is a serum sickness–like syndrome manifested by the acute onset of fever, cough, chills, sweating, abdominal pain, lymphadenopathy, hepatosplenomegaly, and eosinophilia. Acute schistosomiasis typically presents in first-time visitors to endemic areas who experience primary infection at an older age.

Symptomatic children with chronic urogenital schistosomiasis usually complain of frequency, dysuria, and hematuria. Urine examination shows erythrocytes, parasite eggs, and occasional eosinophiluria. In endemic areas, moderate to severe pathologic lesions have been demonstrated in the urinary tract of >20% of infected children. The extent of disease correlates with the intensity of infection, but significant morbidity can occur even in lightly infected children. The advanced stages of urogenital schistosomiasis are associated with chronic renal failure, secondary infections, and squamous carcinoma of the bladder.

An important complication of *S. haematobium* infection is **female genital schistosomiasis** . Eggs migrate from the vesical plexus to lodge in the female genital tract where they induce a granulomatous inflammatory response that can manifest as contact bleeding, pain, and eventual infertility. Symptoms start as early as 10 yr of age, with an apparent 3-4–fold greater risk of HIV transmission. Pathognomonic lesions can be visualized in the cervix by photocolposcopy. **Male genital schistosomiasis** can also present with hematospermia, pain, and lumpy semen.

Children with chronic schistosomiasis mansoni, japonica, intercalatum, or mekongi may have intestinal symptoms; colicky abdominal pain and bloody diarrhea are the most common. However, the intestinal phase may remain subclinical, and the late syndrome of hepatosplenomegaly, portal hypertension, ascites, and hematemesis may then be the first clinical presentation. Liver disease is caused by granuloma formation and subsequent **periportal fibrosis** ; no appreciable liver cell injury occurs, and hepatic function may be preserved for a long time. Schistosome eggs may escape into the lungs, causing **pulmonary hypertension** and cor pulmonale. *S. japonicum* worms may migrate to the brain vasculature and produce localized lesions that cause seizures.

Transverse myelitis , spinal compression, and other CNS involvement (meningoencephalitis) are rare but well-known complications in children or young adults with either acute or chronic *S. haematobium* or *S. mansoni* infection.

Although end-organ scarring is pathognomonic, affected children may also have persistent long-term systemic effects of infection, including poor growth, anemia, decreased aerobic capacity, and cognitive impairment.

Diagnosis

Schistosome eggs are found in the excreta of infected individuals; quantitative methods should be used to provide an indication of the burden of infection. For diagnosis of *S. haematobium* infection, a volume of 10 mL of urine should be collected around midday, the time of maximal egg excretion, and filtered for microscopic examination. Stool examination by the Kato-Katz thick smear procedure and detection of parasite antigen in patient serum or urine are the methods of choice for diagnosis and quantification of other schistosome infections (*S. mansoni* and *S. japonicum*). The unique schistosome antigens *circulating anodic antigen* (CAA) and *circulating cathodic antigen* (CCA) may also be detected in the urine or plasma.

Treatment

Treatment of children with schistosomiasis should be based on an appreciation of the intensity of infection and the extent of disease. The recommended treatment for schistosomiasis is **praziquantel** (40 mg/kg/day orally [PO] divided twice daily [bid] for 1 day for schistosomiasis haematobia, mansoni, and intercalatum; 60 mg/kg/day PO divided 3 times daily [tid] for 1 day for schistosomiasis japonica and mekongi). Children <5 yr old with *S. mansoni* may need up to 60 mg/kg/day PO tid for 1 day to achieve clearance. A 2nd treatment 4-6 wk after the 1st course may help in eliminating residual infection.

Prevention

Transmission in endemic areas may be decreased by reducing the parasite load in the human population. The availability of oral, single-dose, effective chemotherapeutic agents may help achieve this goal. When added to national drug-based control programs, other measures such as improved sanitation, antiparasitic treatment given at well-child visits, focal application of molluscicidals, and animal vaccination may prove useful in breaking the cycle of transmission. Ultimately, control of schistosomiasis is closely linked to economic and social development.

CHAPTER 327

Flukes (Liver, Lung, and Intestinal)

Charles H. King, Amaya L. Bustinduy

Several different **trematodes** , or flukes, can parasitize humans and cause disease. Flukes are endemic worldwide but are more prevalent in the less developed parts of the world. They include *Schistosoma*, or the blood flukes (see Chapter 326), as well as fluke species that cause infection in the human biliary tree, lung tissue, and intestinal tract. These latter trematodes are characterized by complex life cycles (Fig. 327.1). Sexual reproduction of adult worms in the definitive host produces eggs that are passed in the stool. Larvae, called **miracidia** , develop in freshwater. These in turn infect certain species of mollusks (aquatic snails or clams), in which asexual multiplication by parasite larvae produces cercariae. Cercariae then seek a 2nd intermediate host, such as an insect, crustacean, or fish, or attach to vegetation to produce infectious **metacercariae** . Humans acquire liver, lung, and intestinal fluke infections by eating uncooked, lightly cooked, pickled, or smoked foods containing these infectious parasite cysts. The “alternation of generations” requires that flukes parasitize more than 1 host (often 3) to complete their life cycle. Because parasitic flukes are dependent on these nonhuman species for transmission, the distribution of human fluke infection closely matches the ecologic range of the flukes’ intermediate hosts. As a group, these parasites are commonly referred to as **food-borne trematodes** .

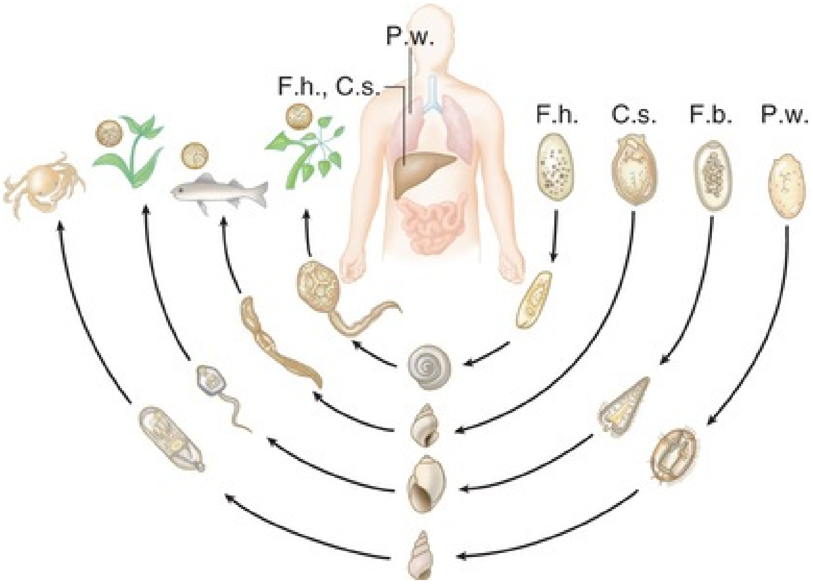

FIG. 327.1 **Life cycle of parasitic liver, lung, and intestinal flukes. C.s., *Clonorchis sinensis* ; F.b., *Fasciolopsis buski* ; F.h., *Fasciola hepatica* ; P.w., *Paragonimus westermani.* (Adapted from Mandell GL, Bennett JE, Dolin R, editors: *Principles and practice of infectious diseases* , ed 7, Philadelphia, 2010, Elsevier, Fig 289-2.)**

Liver Flukes

Fascioliasis *(Fasciola hepatica)*

Fasciola hepatica, the sheep liver fluke, infects cattle, other ungulates, and occasionally humans. This infection affects approximately 17 million people worldwide and has been reported in many different parts of the world, particularly South America, Europe, Africa, China, Australia, and Cuba. Although *F. hepatica* is enzootic in North America, reported cases are extremely rare. Humans are infected by ingestion of metacercariae attached to vegetation, especially wild watercress, lettuce, and alfalfa. In the duodenum, the parasites excyst and penetrate the intestinal wall, liver capsule, and parenchyma. They wander for a few weeks before entering the bile ducts, where they mature. Adult *F. hepatica* (1-2.5 cm) commence oviposition approximately 12 wk after infection; the eggs are large (75-140 µm) and operculated. They pass to the intestines with bile and exit the body in the feces (see Fig. 327.1). On reaching freshwater, the eggs mature and hatch into miracidia, which infect specific snail intermediate hosts to multiply into many cercariae. These then emerge from infected snails and encyst on aquatic grasses and plants.

Clinical manifestations usually occur either during the liver migratory phase of the parasites or after their arrival at their final habitat in upper bile ducts. Fever, right upper quadrant pain, and hepatosplenomegaly characterize the 1st phase of illness. Peripheral blood eosinophilia is usually marked. As the worms enter bile ducts, most of the acute symptoms subside. On rare occasions, patients may have obstructive jaundice or biliary cirrhosis, with signs of cholestasis, ascending cholangitis, cholelithiasis and jaundice and increased liver enzymes, direct bilirubin, and γ-glutamyl transpeptidase. *F. hepatica* infection is diagnosed by identifying the characteristic eggs in fecal smears or duodenal aspirates. **Diagnosis** can be suggested by positive serology and imaging that reveals acute, hypodense liver lesions that change over time. Presentation can be dramatic in children, with features including generalized edema, hepatic cirrhosis with esophageal varices, and in severe cases, death from generalized organ failure.

The recommended **treatment** of fascioliasis is triclabendazole (10 mg/kg orally [PO] once or twice) or bithionol (30-50 mg/kg PO once daily on alternate days for a total of 10-15 doses). In the United States, bithionol is not generally available, but may be available from compounding pharmacies.

Clonorchiasis *(Clonorchis sinensis)*

Infection of bile passages with *Clonorchis sinensis*, the Chinese or oriental liver fluke, is endemic in China, South Korea, northern Vietnam, and parts of Russia and Japan, affecting more than 15 million people. Humans acquire infection by ingestion of raw or inadequately cooked freshwater fish carrying the encysted metacercariae of the parasite under their scales or skin. Metacercariae excyst in the duodenum and pass through the ampulla of Vater to the common bile duct and bile capillaries, where they mature into hermaphroditic adult worms (3-15 mm). *C. sinensis* worms deposit small operculated eggs (14-30 µm), which are discharged through the bile duct to the intestine and feces (see Fig. 327.1). The eggs mature and hatch outside the body, releasing motile miracidia into local freshwater streams, rivers, or ponds. If these are taken up by the appropriate snails, they develop into cercariae, which are in turn released from the snail to encyst under the skin or scales of freshwater fish.

Most individuals with *C. sinensis* infection, particularly those with few organisms, are minimally symptomatic. Among heavily infected individuals, who tend to be older (>30 yr), localized obstruction of a bile duct results from repeated local trauma and inflammation. In these patients, cholangitis and cholangiohepatitis may lead to liver enlargement and jaundice. In Hong Kong, Korea, and other parts of Asia, cholangiocarcinoma is associated with chronic *C. sinensis* infection.

Clonorchiasis is diagnosed by examination of feces or duodenal aspirates for the parasite eggs. The recommended **treatment** of clonorchiasis is praziquantel (75 mg/kg/day PO divided 3 times daily [tid] for 2 days). An alternative, used in adults, is albendazole (10 mg/kg once daily PO for 7 days). Tribendimidine (400 mg PO for 3 days) has been recently used in China with good cure rates.

Opisthorchiasis (*Opisthorchis* spp.)

Infections with species of *Opisthorchis* are clinically similar to those caused by *C. sinensis. Opisthorchis felineus* and *Opisthorchis viverrini* are liver flukes of cats and dogs that infect humans through ingestion of metacercariae in freshwater fish. Infection with *O. felineus* is endemic in Eastern Europe and Southeast Asia, and *O. viverrini* is found mainly in Thailand, affecting an estimated 10 million people. Most individuals are minimally symptomatic; liver enlargement, relapsing cholangitis, and jaundice may occur in heavily infected individuals. Diagnosis is based on recovering eggs from stools or duodenal aspirates. The recommended **treatment** of opisthorchiasis is praziquantel (75 mg/kg/day PO tid for 2 days).

Lung Flukes

Paragonimiasis (*Paragonimus* spp.)

Human infection by the lung fluke *Paragonimus westermani,* and less frequently other species of *Paragonimus,* occurs throughout the Far East, in localized areas of West Africa, and in several parts of Central and South America, affecting approximately 20 million people. The highest incidence of paragonimiasis occurs in older children and adolescents 11-15 yr of age. Although *P. westermani* is found in many carnivores, human cases are relatively rare and seem to be associated with specific dietary habits, such as eating raw freshwater crayfish or crabs. These crustaceans contain the infective metacercariae in their tissues. After ingestion, the metacercariae excyst in the duodenum, penetrate the intestinal wall, and migrate to their final habitat in the lungs. Adult worms (5-10 mm) encapsulate within the lung parenchyma and deposit brown operculated eggs (60-100 µm) that pass into the bronchioles and are expectorated by coughing (see Fig. 327.1). Ova can be detected in the sputum of infected individuals or in their feces. If eggs reach freshwater, they hatch and undergo asexual multiplication in specific snails. The cercariae encyst in the muscles and viscera of crayfish and freshwater crabs.

Most individuals infected with *P. westermani* harbor low or moderate worm loads and are minimally symptomatic. The clinical manifestations include cough, production of rust-colored sputum, and hemoptysis (mimicking tuberculosis), which is the principal manifestation and occurs in 98% of symptomatic children. There are no characteristic physical findings, but laboratory examination usually demonstrates marked eosinophilia. Chest radiographs often reveal small, patchy infiltrates or radiolucencies in the middle lung fields; however, radiographs may appear normal in one fifth of infected individuals. In rare circumstances, lung abscess, pleural or pericardial effusion, or bronchiectasis may develop. Extrapulmonary localization of *P. westermani* in the brain, peritoneum, intestines, or pericardium may rarely occur. Cerebral paragonimiasis occurs primarily in heavily infected individuals living in highly endemic areas of the Far East. The clinical presentation resembles jacksonian epilepsy or the symptoms of cerebral tumors.

Definitive diagnosis of paragonimiasis is established by identification of eggs in fecal or sputum smears. The recommended **treatment** of paragonimiasis is praziquantel (75 mg/kg/day PO tid for 2 days). Triclabendazole can also be used (10 mg/kg PO daily for 1-2 days).

Intestinal Flukes

Several wild and domestic animal intestinal flukes, including *Fasciolopsis buski*, *Nanophyetus salmincola*, and *Heterophyes heterophyes*, may accidentally infect humans who eat uncooked or undercooked fish or water plants. For example, *F. buski* is endemic in the Far East, where humans who ingest metacercariae encysted on aquatic plants become infected. These develop into large flukes (1-5 cm) that inhabit the duodenum and jejunum. Mature worms produce operculated eggs that pass with feces; the organism completes its life cycle through specific snail intermediate hosts. Individuals with *F. buski* infection are usually asymptomatic; heavily infected patients complain of abdominal pain and diarrhea and show signs of malabsorption. Diagnosis of fasciolopsiasis and other intestinal fluke infections is established by fecal examination and identification of the eggs (see Fig. 327.1). As for other fluke infections, praziquantel (75 mg/kg/day PO tid for 2 days) is the drug of choice.

CHAPTER 328

Adult Tapeworm Infections

Philip R. Fischer, A. Clinton White Jr

Tapeworms are adult forms of **cestodes** , multicellular helminth parasites, that live in human intestines and cause non–life-threatening illness. Invasive larval forms of cestodes are associated with cysts that lead to severe human disease such as neurocysticercosis (*Taenia solium* ; see Chapter 329) and echinococcosis (mostly *Echinococcus granulosa* and *E. multilocularis* ; Chapter 330). The adult worms themselves are flat and multisegmented, varying in length from 8 mm to 10 meters (m). Table 328.1 summarizes the key features of tapeworms that affect children.

Table 328.1

Key Features of Common Tapeworms in Children

PARASITE SPECIES	GEOGRAPHY	SOURCE	SYMPTOMS	TREATMENT
Taenia saginata	Asia, Africa, Latin America	Cysts in beef	Abdominal discomfort, motile proglottid migration, passing segments	Praziquantel *or* niclosamide, possibly nitazoxanide
Taenia solium	Asia, Africa, Latin America	Cysticerci in pork	Minimal, proglottids in stool	Praziquantel *or* niclosamide, possibly nitazoxanide
Taenia asiatica	Asia	Pigs	Minimal	Praziquantel *or* niclosamide, possibly nitazoxanide
Diphyllobothrium spp.	Worldwide, often northern areas	Plerocercoid cysts in freshwater fish	Usually minimal; with prolonged or heavy infection with *D. latum* , vitamin B_{12} deficiency	Praziquantel *or* niclosamide
Hymenolepis	Worldwide, often northern	Infected humans,	Mild abdominal discomfort	Praziquantel, niclosamide, *or*

	areas	rodents		nitazoxanide
Dipylidium caninum	Worldwide	Domestic dogs and cats	Proglottids in stool, anal pruritus confused with pinworm	Praziquantel *or* niclosamide

Etiology

The **beef tapeworm** *(Taenia saginata)* , the **pork tapeworm** *(T. solium)*, and the Asian tapeworm *(Taenia asiatica)* are long worms (4-10 m) named for their intermediate hosts (*T. saginata* , *T. solium*) or geographic distribution (*T. asiatica* ; larval host is the pig). The adult worms are found only in the human intestine. As with the adult stage of all tapeworms, their body is a series of 100s or 1000s of flattened segments (**proglottids**) with an anterior attachment organ **(scolex)** that anchors the parasite to the bowel wall. New segments arise from the distal aspect of the scolex with progressively more mature segments attached distally. The gravid terminal segments contain 50,000-100,000 eggs, and the eggs or even detached intact proglottids pass out of the child through the anus (with or separate from defecation). These tapeworms differ most significantly in that the intermediate stage of the pork tapeworm (**cysticercus**) can also infect humans and cause significant morbidity (see Chapter 329), whereas the larval stage of *T. saginata* does not cause human disease. *T. asiatica* is similar to and often confused with the beef tapeworm.

Epidemiology

The pork and beef tapeworms are distributed worldwide, with the highest risk for infection in Latin America, Africa, India, Southeast Asia, and China, where the relevant intermediate host is raised domestically. The prevalence in adults may not reflect the prevalence in young children, because cultural practices may dictate how well meat is cooked and how much is served to children.

Pathogenesis

When children ingest raw or undercooked meat containing larval cysts, gastric acid and bile facilitate release of immature scolices that attach to the lumen of the small intestine. The parasite grows, adding new segments at the base of the scolex. The terminal segments mature and after 2-3 mo produce eggs that are released in stool. The surface of proglottids serves as an absorptive organ to “steal” nutritional elements from the child's small bowel for use by the parasite. There is sometimes a transient eosinophilia before the parasite matures enough to release eggs.

Clinical Manifestations

Nonspecific abdominal symptoms have been reported with beef and pork tapeworm infections, but the most bothersome symptom is the psychologic distress caused by seeing proglottids in the stool or undergarments. The released segments of the worms are motile (especially those of *T. saginata*) and sometimes lead to anal pruritus. The adult beef and pork tapeworms are only rarely associated with other symptoms.

Diagnosis

Identification of the infecting tapeworm species facilitates understanding of risk for invasive disease. Carriers of adult pork tapeworms are at increased risk for transmitting eggs with the pathogenic intermediate stage (cysticercus) to themselves or others, whereas children infected with the beef tapeworm or *T. asiatica* are a risk only to livestock. Because proglottids are generally passed intact, visual examination for gravid proglottids in the stool is a sensitive test; these segments may be used to identify species. Eggs, by contrast, are often absent from stool and cannot distinguish between *T. saginata* and *T. solium* (Fig. 328.1). If the parasite is completely expelled, the scolex of each species is diagnostic. The scolex of *T. saginata* has only a set of 4 anteriorly oriented suckers, whereas *T. solium* is armed with a double row of hooks in addition to suckers. The proglottids of *T. saginata* have >20 branches from a central uterine structure, and the proglottids of *T. solium* have ≤10 branches. Expelled proglottid segments are usually approximately 0.5 × 1-2 × 0.1 cm in size. Molecular methods can distinguish *T. saginata* from *T. asiatica* . Antigen detection tests are increasingly available.

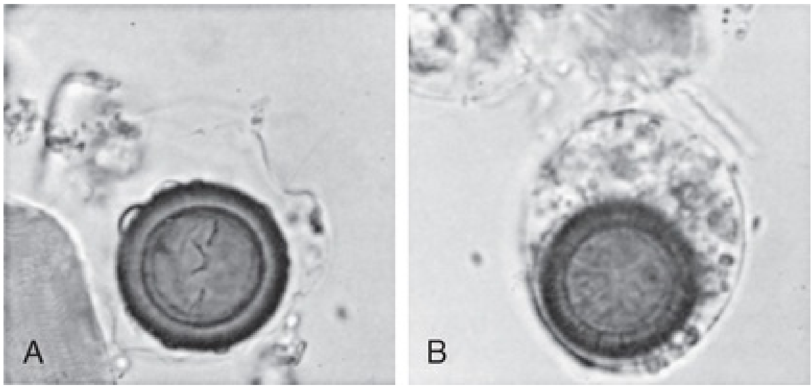

FIG. 328.1 Eggs of *Taenia saginata* recovered from feces (original magnification ×400). A and B, The eggs are generally bile-stained, dark, and prismatic. There is occasionally some surrounding cellular material from the proglottid in which the egg develops, which is more evident in B than in A. The larva within the egg shows 3 pairs of hooklets (A), which may occasionally be observed in motion.

Differential Diagnosis

Anal pruritus may mimic symptoms of pinworm *(Enterobius vermicularis)* infection. *Diphyllobothrium latum* and *Ascaris lumbricoides* (a long round worm) may be mistaken for *T. saginata* or *T. solium* in stools.

Treatment

Infections with all adult tapeworms respond to praziquantel (25 mg/kg orally [PO] once). When available, an alternative treatment for **taeniasis** is niclosamide (50 mg/kg PO once for children; 2 g PO once for adults). Nitazoxanide is sometimes effective as well. The parasite is usually expelled on the day of administration. Treatment with electrolyte–polyethylene glycol bowel preparations can increase the yield of passage of scolices.

Prevention

Prolonged freezing or thorough cooking of beef and pork kills the larval cystic forms of the parasite. Appropriate human sanitation can interrupt transmission by preventing infection in livestock.

Diphyllobothriasis (*Diphyllobothrium*

Spp.)

Etiology

The **fish tapeworms** of the genus *Diphyllobothrium* are the longest human tapeworms, reaching >10 m in length, and have an anatomic organization similar to that of other adult cestodes. An elongated scolex, equipped with slits (**bothria**) along each side but no suckers or hooks, is followed by 1000s of segments looped in the small bowel. Gravid terminal proglottids detach periodically but tend to disintegrate before expulsion, thus releasing eggs rather than intact worm segments in the feces. In contrast to taeniids, the life cycle of *Diphyllobothrium* spp. requires 2 intermediate hosts. Small, freshwater crustaceans (copepods) take up the larvae that hatch from parasite eggs. The parasite passes up the food chain as small fish eat the copepods and are in turn eaten by larger fish. In this way, the juvenile parasite becomes concentrated in pike, walleye, perch, burbot, and perhaps salmon associated with aquaculture. Consumption of raw or undercooked fish leads to human infection with adult fish tapeworms.

Epidemiology

The fish tapeworm is most prevalent in the temperate climates of Europe, North America, and Asia but may be found along the Pacific coast of South America and in Africa. In North America the prevalence is highest in Alaska, Canada, and northern areas of continental United States. The tapeworm is found in fish from those areas that are then taken to market. Persons who prepare raw fish for home or commercial use or who sample fish before cooking are particularly at risk for infection.

Pathogenesis

The adult worm of *Diphyllobothrium latum* (found in northern Europe) has high-affinity receptors and efficiently scavenges vitamin B_{12} for its own use in the constant production of large numbers of segments and as many as 1 million eggs per day. As a result, diphyllobothriasis causes **megaloblastic anemia** in 2–9% of infections. Interestingly, other *Diphyllobothrium* spp. do not out-compete the host for vitamin B_{12} . Children with other causes of vitamin B_{12} or folate deficiency, such as chronic infectious diarrhea, celiac disease, or congenital malabsorption, are more likely to develop symptomatic infection.

Clinical Manifestations

Infection is largely asymptomatic. Segments may be noted in stool. Those who develop vitamin B_{12} or folate deficiency present with megaloblastic anemia with leukopenia, thrombocytopenia, glossitis, and/or signs of spinal cord posterior column dysfunction (loss of vibratory sense, proprioception, and coordination).

Diagnosis

Parasitological examination of the stool is useful because eggs are abundant in the feces and have morphology distinct from that of all other tapeworms. The eggs are ovoid and have an **operculum** , which is a cap structure at one end that opens to release the embryo (Fig. 328.2). The worm itself has a distinct scolex and proglottid morphology; however, these are not likely to be passed spontaneously.

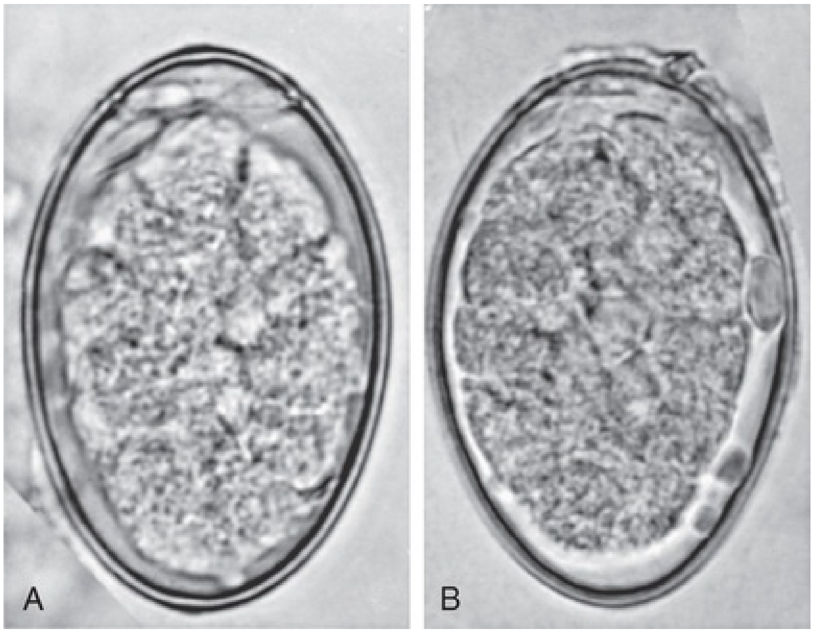

FIG. 328.2 **Eggs of *Diphyllobothrium latum* as seen in feces (original magnification ×400). A and B, The caplike operculum is at the upper end of the eggs here.**

Differential Diagnosis

A segment or a whole section of the worm might be confused with *Taenia* or *Ascaris* after it is passed. Pernicious anemia, bone marrow toxins, and dietary restriction may contribute to or mimic the nutritional deficiencies associated with diphyllobothriasis.

Treatment

As with all adult tapeworms, *D. latum* infections respond to praziquantel (5-10 mg/kg PO once). Niclosamide (50 mg/kg PO in a single dose) is also effective.

Prevention

The intermediate stage is easily killed by brief cooking or prolonged freezing of fish before ingestion. Because humans are the major reservoir for adult worms, health education is one of the most important tools for preventing transmission, together with improved human sanitation.

Hymenolepiasis *(Hymenolepis)*

Infection with *Hymenolepis nana,* the **dwarf tapeworm,** is very common in developing countries. Most cases are asymptomatic. However, heavy infection has been associated with diarrhea, weight loss, fever, and eosinophilia. The intermediate stage of *Hymenolepis diminuta* develops in various hosts (e.g., rodents, ticks, fleas), but the entire life cycle of *H. nana* is completed in humans. Therefore, hyperinfection with 1000s of small adult worms in a single child may occur. A similar infection may occur less often with *H. diminuta*. Eggs but not segments may be found in the stool. *H. nana* infection responds to praziquantel (25 mg/kg PO once). Nitazoxanide is effective in about three fourths of children (100 mg PO twice daily [bid] for 3 days for children 1-3 yr old, 200 mg bid for 3 days for children 4-11 yr old, and 500 mg bid for 3 days for older children).

Dipylidiasis *(Dipylidium Caninum)*

Dipylidium caninum is a common tapeworm of domestic dogs and cats. Human infection is relatively rare. Direct transmission between pets and humans does not occur; human infection requires ingestion of the parasite's intermediate host, the dog or cat flea. Infants and small children are particularly susceptible because of their level of hygiene, generally more intimate contact with pets, and activities in areas where fleas can be encountered. Thus, children are most at risk of inadvertent ingestion of fleas infected with the larvae. The most common symptom is passage of proglottids in stool. The proglottids are similar in size and shape to white rice grains. Anal pruritus, vague abdominal pain, and diarrhea have at times been associated with dipylidiasis, which is thus sometimes confused with pinworm *(E. vermicularis).* Dipylidiasis responds to treatment with praziquantel (5-10 mg/kg PO once) and niclosamide (50 mg/kg PO as a single dose). **Deworming** of pets and **flea control** are the best preventive measures.

CHAPTER 329

Cysticercosis

A. Clinton White Jr., Philip R. Fischer

Etiology

Taenia solium, also known as the **pork tapeworm** , causes 2 different infections in children. In its normal life cycle, children can acquire the tapeworm form by ingestion of undercooked pork containing the larval cysts (see Chapter 328). In the intestines, the cyst converts into the tapeworm form. Children are also susceptible to infection by the eggs shed by tapeworm carriers. After the eggs are ingested, the larvae are released from the eggs, invade through the intestines, and migrate through the bloodstream to the muscles (and other organs), where they form tissue cysts (0.2-2.0 cm fluid-filled bladders containing a single invaginated **scolex**). Infection with the cystic form is termed **cysticercosis** , and involvement of the central nervous system (CNS) is termed **neurocysticercosis.** The tapeworm form only develops after ingestion of undercooked pork. Ingestion of pork is not necessary to develop cysticercosis, but individuals harboring an adult worm may infect themselves with the eggs by the fecal-oral route.

Epidemiology

The pork tapeworm is widely distributed wherever pigs are raised and have contact with human fecal material. Intense transmission occurs in Central and South America, southern and Southeast Asia, and much of sub-Saharan Africa. In these areas, approximately 30% of cases of seizures may be a result of cysticercosis. Most cases of cysticercosis in the United States are imported; however, local transmission has been documented.

Pathogenesis

Living, intact cystic stages usually suppress the host immune and inflammatory responses. Intact cysts can be associated with disease when they obstruct the flow of cerebrospinal fluid. Most cysts remain asymptomatic for a few years. Symptoms typically develop as the cysticerci begin to degenerate, associated with a host inflammatory response. The natural history of cysts is eventually to resolve by complete resorption or calcification, but this process may take years. Cysticerci can also present as subcutaneous nodules, ocular infection, or spinal lesions with myelopathy or radiculopathy.

Clinical Manifestations

Seizures are the presenting finding in the vast majority of children with neurocysticercosis. Less common manifestations include hydrocephalus, diffuse cerebral edema, or focal neurologic findings. It is important to classify neurocysticercosis as parenchymal, intraventricular, subarachnoid, spinal, or ocular on the basis of anatomic location, clinical presentation, and radiologic appearance, since the prognosis and management vary with location.

Parenchymal neurocysticercosis typically presents with seizures. The seizures are usually focal, but often generalize. Children may present with a single seizure or recurrent epilepsy. Mild neurocognitive defects have been documented from cysticerci alone but are more commonly associated with poorly controlled seizures. A fulminant encephalitis-like presentation may rarely occur after a massive initial infection associated with cerebral edema. **Intraventricular** neurocysticercosis (up to 20% of cases) is associated with obstructive hydrocephalus and acute, subacute, or intermittent signs of increased intracranial pressure, usually without localizing signs. **Subarachnoid** neurocysticercosis is rare in children. It can be associated with basilar arachnoiditis that can present with signs of meningeal irritation, communicating hydrocephalus, cerebral infarction, or **spinal** disease with radiculitis or transverse myelitis. Cysticerci in the tissues may present with focal findings from mass effect. **Ocular** neurocysticercosis causes decreased visual acuity because of cysticerci in the retina or vitreous, retinal detachment, or iridocyclitis.

Diagnosis

Neurocysticercosis should be suspected in a child with onset of seizures or hydrocephalus and who also has a history of residence in an endemic area and/or a care provider from an endemic area. The most useful diagnostic study for parenchymal disease is MRI of the head. MRI provides the most information about cyst location, cyst viability, and associated inflammation. The **protoscolex** is sometimes visible within the cyst, which provides a pathognomonic sign for cysticercosis (Fig. 329.1*A*). The MRI also better detects basilar arachnoiditis (Fig. 329.1*B*), intraventricular cysts (Fig. 329.1*C*), and cysts in the spinal cord. CT is best for identifying calcifications. A solitary parenchymal cyst, with or without contrast enhancement, or CNS calcifications are the most common findings in children (Fig. 329.2). Plain films may reveal calcifications in muscle or brain consistent with cysticercosis. In children from endemic regions, the presentation with a single enhancing lesion that is round and <2 cm in diameter, absence of symptoms or signs of other diseases (e.g., no fever or lymph nodes), no focal findings, and no evidence of increased intracranial pressure is highly specific for neurocysticercosis.

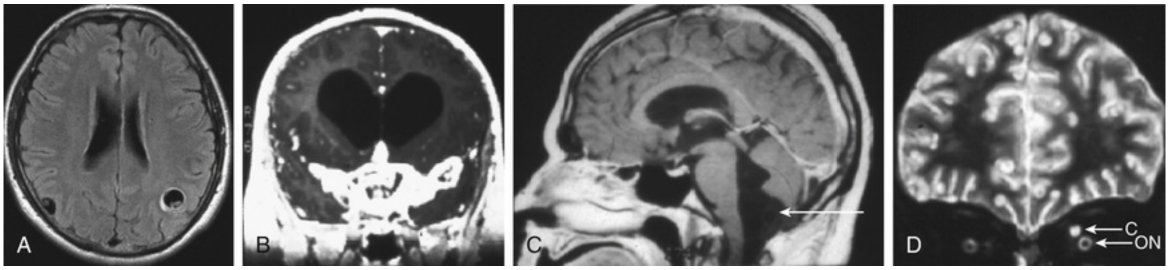

FIG. 329.1 Neurocysticercosis. A, MRI (T1 weighted) demonstrating 2 parenchymal cysts with protoscoleces. B, MRI (T1 weighted) of cysticercal basilar arachnoiditis. C, MRI (T1 weighted) showing a cyst below the fourth ventricle *(arrow).* D, MRI (T2 weighted) showing a cysticercus (C) above the optic nerve (ON).

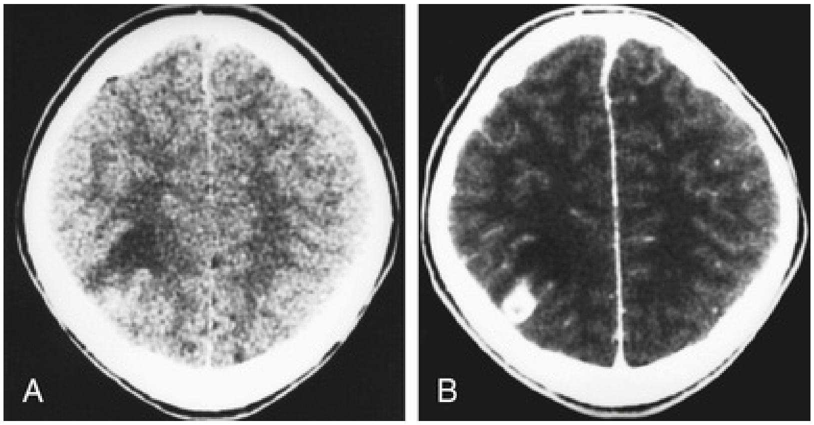

FIG. 329.2 Neurocysticercosis. CT image of a solitary lesion with (A) and without (B) contrast, showing contrast enhancement. (Courtesy of Dr. Wendy G. Mitchell and Dr. Marvin D. Nelson, Children's Hospital, Los Angeles.)

Serologic diagnosis using the enzyme-linked immunotransfer blot is available commercially in the United States and through the Centers for Disease Control and Prevention (CDC). Serum antibody testing is highly specific but is frequently negative in children with single lesions or just calcifications. Antigen-detection assays and polymerase chain reaction assays show promise as diagnostic procedures but currently are not commercially available in the United States.

Differential Diagnosis

Neurocysticercosis is often confused clinically with other seizure disorders. Clinical suspicion is based on travel history, a history of contact with an individual who might carry an adult tapeworm, or suggestive imaging studies. The imaging appearance can be confused with brain abscess, granulomas (including tuberculomas, fungal infections, Langerhans histiocytosis, and toxoplasmosis), and tumors.

Treatment

The initial management of cysticercosis should focus on symptomatic therapy for seizures and/or hydrocephalus. Seizures can usually be controlled using standard antiepileptic drugs. If the lesions resolve, antiepileptic drugs can often be tapered and stopped. Frequent seizures or the development of calcified lesions are risk factors for recurrent seizures and indications for prolonged or lifelong antiepileptic therapy.

The natural history of **parenchymal** lesions is to resolve spontaneously, with or without antiparasitic drugs, but this process is often prolonged (months to years). Solitary parenchymal cysts resolve slightly more rapidly with antiparasitic therapy. Antiparasitic drugs also decrease the frequency of recurrent seizures. Other forms of the disease are less common in children. In adults with cystic lesions, randomized controlled trials suggested an overall 2-fold decrease in recurrence of generalized seizures with albendazole treatment. The benefit to children was significantly less, perhaps because most of these infections were with only 1-2 cysts. Corticosteroids likely also decrease seizure frequency.

The most commonly used antiparasitic is **albendazole** (15 mg/kg/day orally [PO] divided twice daily [bid]). It can be taken with a fatty meal to improve absorption. The most common duration of therapy is 7 days for single parenchymal lesions. However, longer duration (months), higher doses (up to 30 mg/kg/day), or combination therapy with praziquantel is often required for multiple lesions or subarachnoid disease. For example, in adults with more than 2 cysticerci, recent trials note improved resolution with combination therapy with albendazole, praziquantel, and corticosteroids. **Praziquantel** (50-100 mg/kg/day PO divided 3 times daily [tid] for 28 days) can be used with albendazole or as an alternative to it. First-pass metabolism is common with corticosteroids or antiepileptic drugs. **Cimetidine** can be used in conjunction with praziquantel to blunt the first-pass metabolism. A worsening of symptoms can follow the use of either drug based on the host's inflammatory response to the dying parasite. Patients should be medicated with prednisone (1-2 mg/kg/day) or oral dexamethasone (0.15 mg/kg/day) beginning before the 1st dose of antiparasitic drugs and continuing for at least 2 wk. **Methotrexate** can be used as a steroid-sparing agent in patients requiring prolonged antiinflammatory therapy.

Most patients with hydrocephalus require neurosurgical interventions. Some cases require emergent placement of a ventriculostomy, but most can be managed by cystectomy alone. For obstructive hydrocephalus caused by ventricular cysticercosis, many patients can be cured by minimally invasive surgery. **Neuroendoscopy** is the preferred approach to cysticerci in the lateral or 3rd ventricle. Cysticerci in the 4th ventricle can be removed by a suboccipital craniotomy. There are also reports of endoscopic removal of 4th ventricular cysticerci using flexible neuroendoscopy. Adherent cysticerci that cannot be removed can be treated by placement of a ventriculoperitoneal shunt (VPS).

However, there is a high rate of shunt failure, which can be minimized somewhat by treatment with antiparasitic drugs plus corticosteroids.

Subarachnoid disease has a poor prognosis. The prognosis is much improved by aggressive therapy, including antiparasitic drugs, antiinflammatory treatment, and neurosurgical procedures for hydrocephalus (e.g., VPS placement). However, the duration of antiparasitic and antiinflammatory therapy often needs to be prolonged. **Ocular** cysticercosis is usually treated surgically, although there are reports of cure using medical therapy alone.

Prevention

In areas with evolved public health systems, cysticercosis can largely be eliminated by meat inspection, condemnation of infected meat, and thorough cooking of pork. This approach has not worked in countries where most meat is butchered informally. Mass chemotherapy for tapeworm carriers, mass treatment of pigs, and improved personal hygiene have decreased or eliminated transmission in some areas. Screening family members and those preparing food for index cases for cysticercosis has a very low yield, in part because of the poor sensitivity of current tests. Those who have noted passing material consistent with taeniasis should be treated with praziquantel regardless of the results of stool studies. Veterinary vaccines for several cestode infections have a high degree of efficacy and have a potential role in decreasing parasite transmission.

CHAPTER 330

Echinococcosis (*Echinococcus granulosus* and *Echinococcus multilocularis*)

Miguel M. Cabada, Philip R. Fischer, A. Clinton White Jr.

Etiology

Echinococcosis (**hydatid disease** or **hydatidosis**) is a widespread, serious human cestode infection (Fig. 330.1). Two major *Echinococcus* groups of species are responsible for distinct clinical presentations. *Echinococcus granulosus* and related species cause **cystic hydatid disease, and** *Echinococcus multilocularis* causes **alveolar hydatid disease** . The adult parasites are small (2-7 mm) tapeworms with only 2-6 segments that inhabit the intestines of canines such as dogs, wolves, dingoes, jackals, coyotes, and foxes. Canines are infected by ingesting contaminated viscera from ungulates (*E. granulosus*) or mice (*E. multilocularis*). These carnivores pass the eggs in their stool, which contaminates the soil, pasture, and water, as well as their own fur. Domestic animals, such as sheep, goats, cattle, and camels, ingest *E. granulosus* complex eggs while grazing. Some species of *E. granulosus* complex have a **sylvatic** cycle involving wild cervids such as moose, elk, and deer. For *E. multilocularis* , the main intermediate hosts are small rodents. Humans are infected by consuming eggs by direct contact with infected canines or from ova in the environment. In Europe, contamination of gardens by fox excrement is a major risk factor for transmission. The larvae hatch, penetrate the gut, and are carried by the vascular or lymphatic systems to the liver, lungs, and less frequently, bones, kidney, brain, or heart in *E. granulosus* infection. *E. multilocularis* larvae infect the liver almost exclusively.

FIG. 330.1 **Worldwide distribution of *Echinococcus granulosus* and cystic echinococcosis (hydatidosis), 2009. (From Control of Neglected Tropical Diseases. © World Health Organization, 2011. http://gamapserver.who.int/mapLibrary/Files/Maps/Global_echinococcosis_2009.png.)**

Echinococcus granulosus complex comprises several recognized species previously arranged in genotype groups. These are *E. granulosussensustricto* (G1-G3), *E. equinus* (G4), *E. ortleppi* (G5), and *E. canadensis* (G6-G10). The species within the *E. granulosus* complex show significant variation not only in genetics but also in ecology. While *E. granulosussensustricto* is mainly found in domesticated ovines and dogs around the world, *E. canadensis* is found in a sylvatic wolf/moose cycle in North America and Siberia and has been identified in bovines and swine in South America.

Epidemiology

There is potential for transmission of *E. granulosus* to humans wherever dogs are allowed to ingest the entrails of herd animals. Cysts have been detected in up to 10% of the human population in northern Kenya and western China. Disease is highly endemic in the Middle East and Central Asia. In South America, the disease is prevalent in sheepherding areas of the Andes, the beef-herding areas of the Brazilian/Argentine Pampas, and Uruguay. Among developed countries, the disease is recognized in Italy, Greece, Portugal, Spain, and Australia, and is reemergent in dogs in Great Britain. In North America, transmission rarely occurs through a sylvatic cycle in the Arctic, as well as in foci of the domestic cycle in sheep-raising areas of western United States.

Transmission of *E. multilocularis* occurs primarily in Western China, Central Europe, Siberia, and Turkey. Transmission is now rare in the Arctic regions of North America. Ingestion of infected rodents by dogs or foxes facilitates transmissions to children. Separate species, *E. vogeli* and *E. oligarthrus* , have mainly a sylvatic cycle involving canines and felines that causes polycystic disease in northern South America.

Pathogenesis

E. granulosus complex parasites are often acquired in childhood, but cysts require many years to become large enough to be detected or cause symptoms. In children the lung is a common site, whereas in adults up to 70% of cysts develop in the liver. Cysts can also develop in bone, the genitourinary system, spleen, subcutaneous tissues, and brain. The host surrounds the primary cyst with a tough, fibrous capsule. Inside this capsule, the parasite produces a thick lamellar layer with the consistency of a soft-boiled egg white. Inside the lamellar layer is the thin germinal layer of cells responsible for production of 1000s of protoscoleces that remain attached to the wall or float free in the cyst fluid (Video 330.1 ▶). Smaller internal daughter cysts may develop within the primary cyst capsule. The fluid in a healthy cyst is clear, colorless, and watery. Rupture of the cyst, which can occur spontaneously, with trauma, or during surgery, can be associated with immediate hypersensitivity reactions, including anaphylaxis. Protoscoleces released into the tissues can also develop into new cysts.

E. multilocularis almost always involves the liver. The lesions grow very slowly and rarely present in children. The secondary reproductive units bud externally and are not confined within a single, well-defined structure. Thus the lesions are invasive and often confused with a malignancy. Furthermore, the cyst tissues are poorly demarcated from those of the host, making surgical removal difficult. The secondary cysts are also capable of distant metastatic spread. The growing cyst mass eventually replaces a significant portion of the liver and compromises adjacent tissues and structures.

Clinical Manifestations

In the liver, cysts may remain asymptomatic, may regress spontaneously, or may produce nonspecific symptoms. Symptomatic cysts can cause increased abdominal girth, hepatomegaly, a palpable mass, vomiting, or abdominal pain. In the lung, cysts produce chest pain, chronic cough, or hemoptysis. Expectorated fluid from ruptured lung cysts is often described as "salty." Mass effects can be noted in the brain and bone. Serious complications result from compression of adjacent structures or spillage of cyst contents. **Anaphylaxis** can occur with cyst rupture or spontaneous spillage, from trauma or intraoperatively. Cyst fluid may cause hypersensitivity pneumonitis after rupture. Spillage can also be catastrophic long-term, because each protoscolex can form a new cyst and fill up the abdominal cavity or rarely the pleural space. Jaundice from cystic hydatid disease is rare.

Alveolar hydatid disease may be diagnosed incidentally, but often the proliferating mass may compromise the biliary system and/or hepatic tissue, causing progressive obstructive jaundice and hepatic failure. Symptoms also occur from expansion of extrahepatic foci.

Diagnosis

Ultrasonography is the most valuable tool for both the diagnosis and treatment of cystic hydatid disease of the liver. The World Health Organization (WHO) standardized ultrasound criteria for classification of liver cystic echinococcosis have been shown to be reliable with excellent inter/intraobserver reliability. Ultrasonography staging has a direct use in defining optimal therapy (Fig. 330.2). Chest radiographs frequently reveal characteristic rounded masses in lung hydatid disease (Fig. 330.3). Alveolar disease resembles a diffuse solid tumor. CT findings are similar to those of ultrasonography and may at times be useful in distinguishing alveolar from cystic hydatid disease in geographic regions where both occur (Fig. 330.4). CT or MRI is also important in planning a surgical intervention.

FIG. 330.2 Ultrasound classification of cystic echinococcosis (CE) cysts. The WHO informal working group on echinococcosis classification differs from that of Gharbi and colleagues by the addition of a "cystic lesion" (CL) stage (undifferentiated) *(not shown),* and by reversing the order of CE types 2 and 3. CE3 transitional cysts may be differentiated into CE3a (with detached endocyst) and CE3b (predominantly solid with daughter vesicles). CE1 and CE3a are early-stage cysts and CE4 and CE5 late-stage cysts. (From McManus DP, Gray DJ, Zhang W, Yang Y: Diagnosis, treatment, and management of echinococcosis, *BMJ* 344:e3866, 2012, Fig 4.)

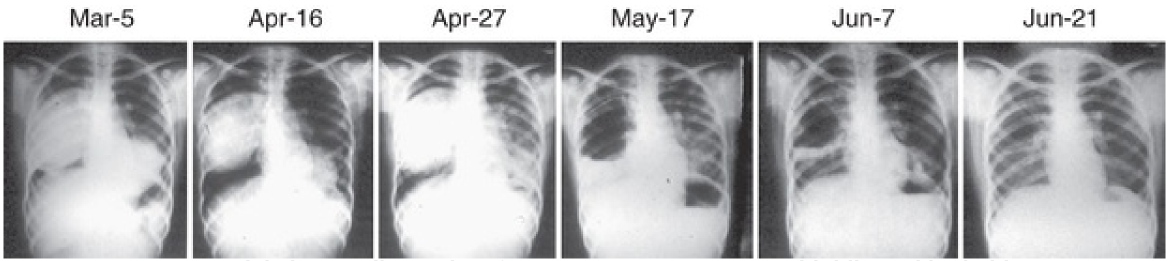

FIG. 330.3 Serial chest radiographs of a young Kenyan woman with bilateral hydatid cysts. After 2 mo of albendazole therapy, sudden rupture of the right cyst was associated with massive aspiration and acute respiratory distress.

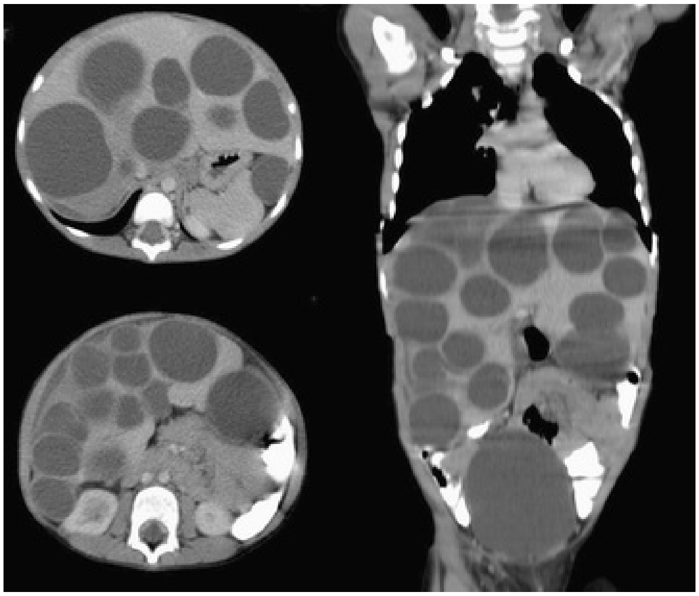

FIG. 330.4 Liver cystic echinococcosis (hydatid disease). Abdominal CT revealed hepatomegaly and multiple (>20) liver cysts. (From Ben-Shimol S, Zelcer I: Liver hydatid cysts, *J Pediatr* 163:1792, 2013.)

Serologic studies are used to confirm the diagnosis of cystic echinococcosis.

However, most of the antibody detection tests available use crude hydatid fluid antigens, which include epitopes that cross-react with other helminths. Cross-reaction has been reported with other noninfectious illness as well. In addition, some children with active cystic echinococcosis may not have circulating levels of specific antibody. Thus the sensitivity and specificity of the enzyme-linked immunosorbent assay to diagnose cystic echinococcosis may vary from 50–100% and 40–100%, respectively, depending on the antigen used and cyst stage, location, number, and viability. The sensitivity is higher for hepatic or bone disease, but the false-negative rate may be >50% with pulmonary or central nervous system (CNS) infection.

Differential Diagnosis

Benign hepatic cysts are common but can be distinguished from cystic hydatid disease by the absence of a distinct 3-layer wall, internal membranes, and hydatid sand. The density of bacterial hepatic abscesses is distinct from the watery cystic fluid characteristic of *E. granulosus* infection, but hydatid cysts may also be complicated by secondary bacterial infection. Alveolar echinococcosis is often confused with hepatoma or metastatic tumor.

Treatment

Management of cystic hydatid disease should be individualized and guided by disease stage and location. Approaches range from surgical resection for disease that tends to respond poorly to drugs and complicated cysts to watchful waiting for cysts that have already degenerated. For cystic echinococcosis (**CE**) types 1 or 3a (see Fig. 330.2) that are <5 cm in diameter, **albendazole** chemotherapy alone (15 mg/kg/day orally divided twice daily for 1-6 mo; maximum 800 mg/day) may result in a high rate of cure. Adverse effects include occasional alopecia, mild gastrointestinal disturbance, and elevated transaminases on prolonged use. Because of leukopenia, the U.S. Food and Drug Administration (FDA) recommends that blood counts be monitored at the beginning and every 2 wk during therapy. Medical treatment with albendazole may also be used for cysts that are not suitable for interventions such as **PAIR** (percutaneous, aspiration, instillation, and reaspiration) or surgery, but response rates are low.

For larger CE1 and CE3a lesions, ultrasound- or CT-guided PAIR is the preferred therapy. Compared with surgical treatment alone, PAIR plus albendazole results in similar cyst disappearance with fewer adverse events and fewer days in the hospital. Spillage with PAIR is uncommon, but prophylactic albendazole therapy is routinely administered at least 1 wk before PAIR and 1 mo afterward. PAIR is contraindicated in pregnancy and for bile-stained cysts, which may indicate the presence of a biliary fistula. The scolicidal agents instilled during PAIR may increase risk for biliary complications in these patients. Surgery with albendazole treatment is the recommended approach for CE2 and CE3b cysts of the liver. In experienced centers, cysts with thick internal septation (CE2) can be managed using a trocar to break up the membranes and external drainage. CE4 and CE5 cysts do not require immediate interventions and are followed ultrasonographically for signs of reactivation.

Surgery is the treatment of choice for complicated **cysts** , including ruptured cysts, cysts communicating with the biliary tract, large pulmonary cysts, or cysts of the CNS or bones. Small thoracic cysts may resolve with chemotherapy, but most cysts require operative removal.

For conventional surgery, the inner cyst wall (only laminate and germinal layers are of parasite origin) can be easily peeled from the fibrous layer, although some studies suggest that removal of the whole capsule has a better outcome in terms of recurrent disease. Considerable care must be taken to avoid spillage of cyst contents, and surgical drapes should be soaked in hypertonic saline because cyst fluid contains viable protoscoleces, each capable of producing secondary cysts. An additional risk is anaphylaxis because of spilled cyst fluid, making it useful to employ a surgeon experienced in this surgery. For hepatic cysts, patients should begin therapy with albendazole (ideally in combination with praziquantel) for several days to weeks preoperatively. Antiparasitic drugs should be continued for 4-12 wk postoperatively.

Alveolar hydatidosis frequently requires radical surgery, including partial hepatectomy, lobectomy, or liver transplantation. Medical therapy with albendazole should be continued for 2 yr after presumably curative surgery. In patients who are not operative candidates or whose lesions are not amenable to surgical cure, albendazole long-term suppressive therapy should be used to slow the progression, but the infection generally recurs if albendazole is stopped.

Prognosis

Factors predictive of success with chemotherapy are age of the cyst (<2 yr), low internal complexity of the cyst, and small size. The site of the cyst is not important, although cysts in bone respond poorly. For alveolar hydatidosis, if surgical removal is unsuccessful, the average mortality is 92% by 10 yr after diagnosis.

Prevention

Important measures to interrupt transmission include, above all, thorough **handwashing** , avoiding contact with dogs in endemic areas, boiling or filtering water when camping, and proper disposal of animal carcasses. Strict procedures for proper disposal of refuse from slaughterhouses must be instituted and followed so that dogs and wild carnivores do not have access to entrails. Other useful measures are control or treatment of the feral dog population and regular praziquantel treatment of pets and working dogs in endemic areas. Vaccines have been developed to prevent infection in grazing animals but are not widely used.

CHAPTER 331

Normal Digestive Tract Phenomena

Asim Maqbool, Chris A. Liacouras

Gastrointestinal function varies with maturity; what is a physiologic event in a newborn or infant might be a pathologic symptom at an older age. A fetus can swallow amniotic fluid as early as 12 wk of gestation, but nutritive sucking in neonates first develops at about 34 wk of gestation. The coordinated oral and pharyngeal movements necessary for swallowing solids develop within the first few mo of life. Before this time, the tongue thrust is upward and outward to express milk from the nipple, instead of a backward motion, which propels solids toward the esophageal inlet. By 1 mo of age, infants appear to show preferences for sweet and salty foods. Infants' interest in solids increases at approximately 4 mo of age. The recommendation to begin solids at 6 mo of age is based on nutritional and cultural concepts rather than maturation of the swallowing process (see Chapter 56). Infants swallow air during feeding, and burping is encouraged to prevent gaseous distention of the stomach.

A number of normal anatomic variations may be noted in the mouth. A **short lingual frenulum** ("tongue-tie") may be worrisome to parents but only rarely interferes with nursing, bottle feeding, eating, or speech, generally requiring no treatment. **Surface furrowing** of the tongue (a geographic or scrotal tongue) is usually a normal finding. A **bifid uvula** may be isolated or associated with a submucous cleft of the soft palate (Fig. 331.1).

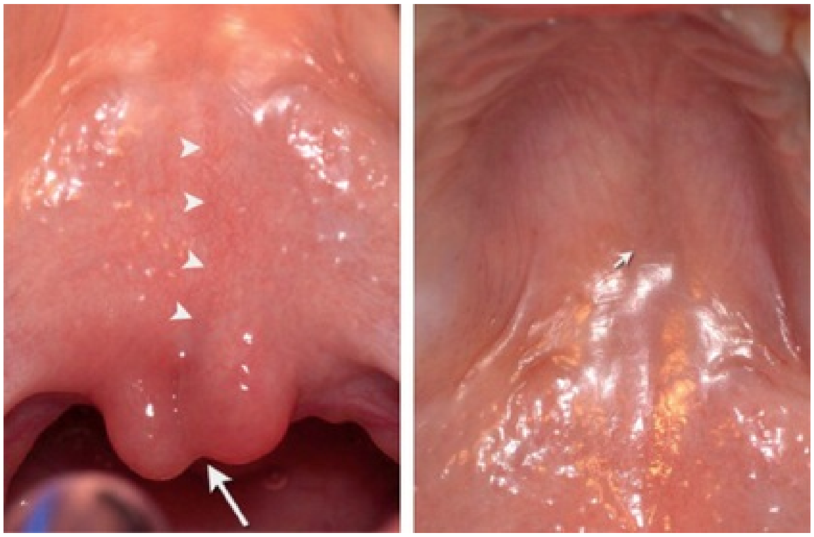

FIG. 331.1 Classic submucous cleft palate with triad of bifid uvula *(large arrow)* , furrow along the midline of the soft palate *(arrowheads)* , and a notch in the posterior margin of the hard palate *(small arrow)* . The midline furrow is sometimes referred to as the zona pellucida, reflecting the translucent nature of this area in some patients. (From Hasan A, Gardner A, Devlin M, Russell C: Submucous cleft palate with bifid uvula. *J Pediatr* 165:872, 2014.)

Regurgitation, the result of gastroesophageal reflux, occurs commonly in the 1st yr of life. Effortless regurgitation can dribble out of an infant's mouth but also may be forceful. In an otherwise healthy infant with regurgitation, volumes of emesis are commonly approximately 15-30 mL but occasionally are larger. Most often, the infant remains happy, although possibly hungry, after an episode of regurgitation. Episodes can occur from one to several times per day. Regurgitation gradually resolves in 80% of infants by 6 mo of age and in 90% by 12 mo. If complications develop or regurgitation persists, gastroesophageal reflux is considered pathologic rather than merely developmental and deserves further evaluation and treatment. Complications of gastroesophageal reflux include failure to thrive, pulmonary disease (apnea or aspiration pneumonitis), and esophagitis with its sequelae (see Chapters 349 and 350).

Infants and young children may be erratic eaters; this may be a worry to parents. A toddler might eat insatiably or refuse to consume food during a meal. Toddlers and young children also tend to eat only a limited variety of foods. Parents should be encouraged to view nutritional intake over several days and not be overly concerned about individual meals. Infancy and adolescence are periods of rapid growth; high nutrient requirements for growth may be associated with voracious appetites. The reduced appetite of toddlers and preschool children is often a worry to parents who are used to the relatively greater dietary intake during infancy. Demonstration of age-appropriate growth on a growth curve is reassuring.

The number, color, and consistency of stools can vary greatly in the same infant and between infants of similar age, without apparent explanation. The earliest stools after birth consist of meconium, a dark, viscous material that is normally passed within the 1st 48 hr of life. With the onset of feeding, meconium is replaced by green-brown transition stools, often containing curds, and, after 4-5 days, by yellow-brown milk stools. **Stool frequency** is extremely variable in normal infants and can vary from none to 7 per day. Breastfed infants can have frequent small, loose stools early (transition stools), and then after 2-3 wk can have very infrequent soft stools. Some nursing infants might not pass any stool for 1-2 wk and then have a normal soft bowel movement. The color of stool has little significance except for the presence of blood or absence of bilirubin products (white-gray rather than yellow-brown). The presence of vegetable matter, such as peas or corn, in the stool of an older infant or toddler ingesting solids is normal and suggests poor chewing and not malabsorption. A pattern of intermittent loose stools, known as **toddler's diarrhea,** occurs commonly between 1 and 3 yr of age. These otherwise healthy growing children often drink excessive carbohydrate-containing beverages. The stools typically occur during the day and not overnight. The volume of fluid intake is often excessive; limiting sugar and unabsorbable carbohydrate-containing beverages and increasing fat in the diet often lead to resolution of the pattern of loose stools.

A protuberant abdomen is often noted in infants and toddlers, especially after large feedings. This can result from the combination of weak abdominal musculature, relatively large abdominal organs, and lordotic stance. In the first yr of life, it is common to palpate the liver 1-2 cm below the right costal margin. The normal liver is soft in consistency and percusses to normal size for age. A Riedel lobe is a thin projection of the right lobe of the liver that may be palpated low in the right lateral abdomen. A soft spleen tip might also be palpable as a normal finding. In thin young children, the vertebral column is easily palpable, and an overlying structure may be mistaken for a mass. Pulsation of the aorta can be appreciated. Normal stool can often be palpated in the left lower quadrant in the descending or sigmoid colon.

Blood loss from the gastrointestinal tract is never normal, but swallowed blood may be misinterpreted as gastrointestinal bleeding. Maternal blood may be ingested at the time of birth or later by a nursing infant if there is bleeding near the mother's nipple. Nasal or oropharyngeal bleeding is occasionally mistaken for gastrointestinal bleeding (see Chapter 124.4). Red dyes in foods or drinks can turn the stool red but do not produce a positive test result for occult blood.

Jaundice is common in neonates, especially among premature infants, and usually results from the inability of an immature liver to conjugate bilirubin, leading to an elevated indirect component (see Chapter 123.3). Persistent elevation of indirect bilirubin levels in nursing infants may be a result of breast milk jaundice, which is usually a benign entity in full-term infants. An elevated direct bilirubin is not normal and suggests liver disease, although in infants it may be a result of extrahepatic infection (urinary tract infection). The direct bilirubin fraction should account for no more than 15–20% of the total serum bilirubin. Elevations in direct bilirubin levels can follow indirect hyperbilirubinemia as the liver converts excessive indirect to direct bilirubin and the rate-limiting step in bilirubin excretion shifts from the glucuronidation of bilirubin to excretion of direct bilirubin into the bile canaliculus. Indirect hyperbilirubinemia, which occurs commonly in normal newborns, tends to tint the sclerae and skin golden yellow, whereas direct hyperbilirubinemia produces a greenish yellow hue. The degree of jaundice does not always directly correlate with serum bilirubin levels. An elevated total serum bilirubin warrants closer examination, fractionation of bilirubin (direct and indirect), and ongoing surveillance. The American Academy of Pediatrics has issued guidelines on the evaluation and management of jaundice in the newborn and on how to follow elevated bilirubin levels, to identify causes of atypical bilirubin elevations, and how to prevent complications. Atypical elevations of unconjugated bilirubin are associated with risk for encephalopathy and kernicterus. Elevations in conjugated bilirubin are reviewed in the chapter on cholestasis (see Chapter 383.1).

CHAPTER 332

Major Symptoms and Signs of Digestive Tract Disorders

Asim Maqbool, Chris A. Liacouras

Disorders of organs outside the gastrointestinal (GI) tract can produce symptoms and signs that mimic digestive tract disorders and should be considered in the differential diagnosis (Table 332.1). In children with normal growth and development, treatment may be initiated without a formal evaluation based on a presumptive diagnosis after taking a history and performing a physical examination. Poor weight gain or weight loss is often associated with a significant pathologic process and usually necessitates a more formal evaluation.

Table 332.1

Some Nondigestive Tract Causes of Gastrointestinal Symptoms in Children

ANOREXIA
Systemic disease: inflammatory, neoplastic
Cardiorespiratory compromise
Iatrogenic: drug therapy, unpalatable therapeutic diets
Depression
Anorexia nervosa
VOMITING
Inborn errors of metabolism
Medications: erythromycin, chemotherapy, nonsteroidal antiinflammatory drugs, marijuana
Increased intracranial pressure
Brain tumor
Infection of the urinary tract
Labyrinthitis
Adrenal insufficiency
Pregnancy
Psychogenic
Abdominal migraine
Poisoning/toxins

Renal disease
DIARRHEA
Infection: otitis media, urinary tract infection Uremia Medications: antibiotics, cisapride Tumors: neuroblastoma Pericarditis Adrenal insufficiency
CONSTIPATION
Hypothyroidism Spina bifida Developmental delay Dehydration: diabetes insipidus, renal tubular lesions Medications: narcotics Lead poisoning Infant botulism
ABDOMINAL PAIN
Pyelonephritis, hydronephrosis, renal colic Pneumonia (lower lobe) Pelvic inflammatory disease Porphyria Fabry disease Angioedema Endocarditis Abdominal migraine Familial Mediterranean fever Sexual or physical abuse Systemic lupus erythematosus School phobia Sickle cell crisis Vertebral disk inflammation Psoas abscess Pelvic osteomyelitis or myositis Medications
ABDOMINAL DISTENTION OR MASS
Ascites: nephrotic syndrome, neoplasm, heart failure Discrete mass: Wilms tumor, hydronephrosis, neuroblastoma, mesenteric cyst, hepatoblastoma, lymphoma Pregnancy
JAUNDICE
Hemolytic disease Urinary tract infection Sepsis Hypothyroidism Panhypopituitarism

Dysphagia

Difficulty in swallowing is termed *dysphagia*. Painful swallowing is termed **odynophagia** . **Globus** is the sensation of something stuck in the throat without a clear etiology. Swallowing is a complex process that starts in the mouth with mastication and lubrication of food that is formed into a bolus. The bolus is pushed into the pharynx by the tongue. The pharyngeal phase of swallowing is rapid and involves protective mechanisms to prevent food from entering the airway. The epiglottis is lowered over the larynx while the soft palate is elevated against the nasopharyngeal wall; respiration is temporarily arrested while the upper esophageal sphincter opens to allow the bolus to enter the esophagus. In the esophagus, peristaltic coordinated muscular contractions push the food bolus toward the stomach. The lower esophageal sphincter relaxes shortly after the upper esophageal sphincter, so liquids that rapidly clear the esophagus enter the stomach without resistance.

Dysphagia is classified as oropharyngeal dysphagia and esophageal dysphagia. **Oropharyngeal dysphagia** occurs when the transfer of the food bolus from the mouth to the esophagus is impaired (also termed *transfer dysphagia*). The striated muscles of the mouth, pharynx, and upper esophageal sphincter are affected in oropharyngeal dysphagia. Neurologic and muscular disorders can give rise to oropharyngeal dysphagia (Table 332.2). Chiari malformations, Russell-Silver syndrome, and cri du chat may present with upper esophageal sphincter dysfunction, manifest by dysphagia with solids. The most serious complication of oropharyngeal dysphagia is life-threatening aspiration.

Table 332.2

Causes of Oropharyngeal Dysphagia

NEUROMUSCULAR DISORDERS
Cerebral palsy Brain tumors Cerebrovascular disease/stroke Chiari malformation Polio and postpolio syndromes Multiple sclerosis Myositis Dermatomyositis Myasthenia gravis Muscular dystrophies Acquired or inherited dystonia syndrome Dysautonomia
METABOLIC AND AUTOIMMUNE DISORDERS
Hyperthyroidism Systemic lupus erythematosus Sarcoidosis Amyloidosis
INFECTIOUS DISEASE
Meningitis

Botulism Diphtheria Lyme disease Neurosyphilis Viral infection: polio, coxsackievirus, herpes, cytomegalovirus
STRUCTURAL LESIONS
Inflammatory: abscess, pharyngitis Congenital web Cricopharyngeal bar Dental problems Bullous skin lesions Plummer-Vinson syndrome Zenker diverticulum Extrinsic compression: osteophytes, lymph nodes, thyroid swelling, aberrant right subclavian artery (dysphagia lusoria)
OTHER
Corrosive injury Side effects of medications After surgery After radiation therapy

Adapted from Gasiorowska A, Faas R: Current approach to dysphagia. *Gastroenterol Hepatol* 5(4):269–279, 2009.

A complex sequence of neuromuscular events is involved in the transfer of foods to the upper esophagus. Abnormalities of the muscles involved in the ingestion process and their innervation, strength, or coordination are associated with transfer dysphagia in infants and children. In such cases, an oropharyngeal problem is usually part of a more generalized neurologic or muscular problem (botulism, diphtheria, neuromuscular disease). Painful oral lesions, such as acute viral stomatitis or trauma, occasionally interfere with ingestion. If the nasal air passage is seriously obstructed, the need for respiration causes severe distress when suckling. Although severe structural, dental, and salivary abnormalities would be expected to create difficulties, ingestion proceeds relatively well in most affected children if they are hungry.

Esophageal dysphagia occurs when there is difficulty in transporting the food bolus down the esophagus. Esophageal dysphagia can result from neuromuscular disorders or mechanical obstruction (Table 332.3). Primary motility disorders causing impaired peristaltic function and dysphagia are rare in children. Eosinophilic esophagitis can present with esophageal dysphagia. Achalasia is an esophageal motility disorder with associated inability of relaxation of the lower esophageal sphincter, and it rarely occurs in children. Motility of the distal esophagus is disordered after surgical repair of tracheoesophageal fistula or achalasia. Abnormal motility can accompany collagen vascular disorders. Mechanical obstruction can be intrinsic or extrinsic.

Intrinsic structural defects cause a fixed impediment to the passage of food bolus because of a narrowing within the esophagus, as in a stricture, web, or tumor. Extrinsic obstruction is caused by compression from vascular rings, mediastinal lesions, or vertebral abnormalities. Structural defects typically cause more problems in swallowing solids than liquids. In infants, esophageal web, tracheobronchial remnant, or vascular ring can cause dysphagia. An esophageal stricture secondary to esophagitis (chronic gastroesophageal reflux, eosinophilic esophagitis, chronic infections) occasionally has dysphagia as the first manifestation. An esophageal foreign body or a stricture secondary to a caustic ingestion also causes dysphagia. A Schatzki ring, a thin ring of mucosal tissue near the lower esophageal sphincter, is another mechanical cause of recurrent dysphagia, and again is rare in children.

Table 332.3

Causes of Esophageal Dysphagia

NEUROMUSCULAR
Eosinophilic esophagitis Achalasia cardia Diffuse esophageal spasm Scleroderma
GERD
INTRINSIC LESIONS
Foreign bodies including pills Esophagitis: GERD, eosinophilic esophagitis, infections Stricture: corrosive injury, pill induced, peptic Esophageal webs Esophageal rings Esophageal diverticula Neoplasm Chagas disease
EXTRINSIC LESIONS
Vascular compression Mediastinal lesion Cervical osteochondritis Vertebral abnormalities

GERD , Gastroesophageal reflux disease.

Adapted from Gasiorowska A, Faas R: Current approach to dysphagia. *Gastroenterol Hepatol* 5(4):269–279, 2009.

When dysphagia is associated with a delay in passage through the esophagus, the patient may be able to point to the level of the chest where the delay occurs, but esophageal symptoms are usually referred to the suprasternal notch. When a patient points to the suprasternal notch, the impaction can be found anywhere in the esophagus.

Regurgitation

Regurgitation is the effortless movement of stomach contents into the esophagus and mouth. It is not associated with distress, and infants with regurgitation are often hungry immediately after an episode. The lower esophageal sphincter prevents reflux of gastric contents into the esophagus. Regurgitation is a result of gastroesophageal reflux through an incompetent or, in infants, immature lower esophageal sphincter. This is often a developmental process, and regurgitation or “spitting” resolves with maturity. Regurgitation should be differentiated from vomiting, which denotes an active reflex process with an extensive differential diagnosis (Table 332.4).

Table 332.4

[*] Includes malrotation, pyloric stenosis, intussusception, Hirschsprung disease, adhesions, hernias.

[†] Meningitis, sepsis.

GERD , Gastroesophageal reflux disease, inguinal hernia.

Anorexia

Anorexia means prolonged lack of appetite. Hunger and satiety centers are located in the hypothalamus; it seems likely that afferent nerves from the GI tract to these brain centers are important determinants of the anorexia that characterizes many diseases of the stomach and intestine (see Chapter 47). Satiety is stimulated by distention of the stomach or upper small bowel, the signal being transmitted by sensory afferents, which are especially dense in the upper gut. Chemoreceptors in the intestine, influenced by the assimilation of nutrients, also affect afferent flow to the appetite centers. Impulses reach the hypothalamus from higher centers, possibly influenced by pain or the emotional disturbance of an intestinal disease. Other regulatory factors include hormones, ghrelin, leptin, and plasma glucose, which, in turn, reflect intestinal function (see Chapter 47).

Vomiting

Vomiting is a highly coordinated reflex process that may be preceded by increased salivation and begins with involuntary retching. Violent descent of the diaphragm and constriction of the abdominal muscles with relaxation of the gastric cardia actively force gastric contents back up the esophagus. This process is coordinated in the medullary vomiting center, which is influenced directly by afferent innervation and indirectly by the chemoreceptor trigger zone and higher central nervous system (CNS) centers. Many acute or chronic processes can cause vomiting (see Tables 332.1 and 332.4).

Vomiting caused by obstruction of the GI tract is probably mediated by intestinal visceral afferent nerves stimulating the vomiting center (Table 332.5). If obstruction occurs below the second part of the duodenum, vomitus is usually bile stained. Emesis can also become bile stained with repeated vomiting in the absence of obstruction when duodenal contents are refluxed into the stomach. Nonobstructive lesions of the digestive tract can also cause vomiting; this includes diseases of the upper bowel, pancreas, liver, or biliary tree. CNS or metabolic derangements and cyclic vomiting syndrome (Table 332.6) can lead to severe, persistent emesis. Marijuana use among teens has also led to cannabis hyperemesis syndrome (see Chapter 140.3).

Table 332.6

Criteria for Cyclic Vomiting Syndrome

All of the criteria must be met for the consensus definition of cyclic vomiting syndrome:

- At least 5 attacks in any interval, or a minimum of 3 episodes during a 6-mo period
- Recurrent episodes of intense vomiting and nausea lasting 1 hr to 10 days and occurring at least 1 wk apart
- Stereotypical pattern and symptoms in the individual patient
- Vomiting during episodes occurs ≥4 times/hr for ≥1 hr
- Return to baseline health between episodes
- Not attributed to another disorder

From Li, B UK, Lefevre F, Chelimsky GG, et al: North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition consensus statement on the diagnosis and management of cyclic vomiting syndrome. *J Pediatr Gastroenterol Nutr* 47:379–393, 2008.

Potential complications of emesis are noted in Table 332.7 . Broad management strategies for vomiting in general and specific causes of emesis are noted in Tables 332.8 and 332.9 .

Table 332.7

Complications of Vomiting

COMPLICATION	PATHOPHYSIOLOGY	HISTORY, PHYSICAL EXAMINATION, AND LABORATORY STUDIES
Metabolic	Fluid loss in emesis	Dehydration
	HCl loss in emesis	Alkalosis; hypochloremia
	Na, K loss in emesis	Hyponatremia; hypokalemia
	Acidosis	Dehydration
Nutritional	Emesis of calories and nutrients Anorexia for calories and nutrients	Malnutrition; "failure to thrive"
Mallory-Weiss tear	Retching → tear at lesser curve of gastroesophageal junction	Forceful emesis → hematemesis
Esophagitis	Chronic vomiting → esophageal acid exposure	Heartburn; Hemoccult + stool
Aspiration	Aspiration of vomitus, especially in context of obtundation	Pneumonia; neurologic dysfunction
Shock	Severe fluid loss in emesis or in accompanying diarrhea	Dehydration (accompanying diarrhea can explain acidosis?)
	Severe blood loss in hematemesis	Blood volume depletion
Pneumomediastinum, pneumothorax	Increased intrathoracic pressure	Chest x-ray
Petechiae, retinal hemorrhages	Increased intrathoracic pressure	Normal platelet count

Table 332.8

Pharmacologic Therapies for Vomiting Episodes

DISORDER/THERAPEUTIC DRUG CLASS	DRUG	DOSAGE
REFLUX		
Dopamine antagonist	Metoclopramide (Reglan)	0.1-0.2 mg/kg PO or IV qid
GASTROPARESIS		
Dopamine antagonist	Metoclopramide (Reglan)	0.1-0.2 mg/kg PO or IV qid
Motilin agonist	Erythromycin	3-5 mg/kg PO or IV tid-qid
INTESTINAL PSEUDOOBSTRUCTION		
Stimulation of intestinal migratory myoelectric complexes	Octreotide (Sandostatin)	1 μg/kg SC bid-tid
CHEMOTHERAPY		
Dopamine antagonist	Metoclopramide	0.5-1.0 mg/kg IV qid, with antihistamine prophylaxis of extrapyramidal side effects
Serotoninergic 5-HT_3 antagonist	Ondansetron (Zofran)	0.15-0.3 mg/kg IV or PO tid
Phenothiazines (extrapyramidal, hematologic side effects)	Prochlorperazine (Compazine)	≈0.3 mg/kg PO bid-tid

	Chlorpromazine (Thorazine)	>6 mo of age: 0.5 mg/kg PO or IV tid-qid
Steroids	Dexamethasone (Decadron)	0.1 mg/kg PO tid
Cannabinoids	Tetrahydrocannabinol (Nabilone)	0.05-0.1 mg/kg PO bid-tid
POSTOPERATIVE		
	Ondansetron, phenothiazines	See under chemotherapy
MOTION SICKNESS, VESTIBULAR DISORDERS		
Antihistamine	Dimenhydrinate (Dramamine)	1 mg/kg PO tid-qid
Anticholinergic	Scopolamine (Transderm Scop)	Adults: 1 patch/3 days
ADRENAL CRISIS		
Steroids	Cortisol	2 mg/kg IV bolus followed by 0.2-0.4 mg/kg/hr IV (±1 mg/kg IM)

ECG , Electrocardiogram; *GI* , gastrointestinal.

Table 332.9

Supportive and Nonpharmacologic Therapies for Vomiting Episodes

DISEASE	**THERAPY**
All	Treat cause • Obstruction: operate • Allergy: change diet (±steroids) • Metabolic error: Rx defect • Acid peptic disease: H2RAs, PPIs, etc.
COMPLICATIONS	
Dehydration	IV fluids, electrolytes
Hematemesis	Transfuse, correct coagulopathy
Esophagitis	H_2 RAs, PPIs
Malnutrition	NG or NJ drip feeding useful for many chronic conditions
Meconium ileus	Gastrografin enema
DIOS	Gastrografin enema; balanced colonic lavage solution (e.g., GoLYTELY)
Intussusception	Barium enema; air reduction enema
Hematemesis	Endoscopic: injection sclerotherapy or banding of esophageal varices; injection therapy, fibrin sealant application, or heater probe electrocautery for selected upper GI tract lesions
Sigmoid volvulus	Colonoscopic decompression
Reflux	Positioning; dietary measures (infants: rice cereal, 1 tbs/oz of formula)
Psychogenic components	Psychotherapy; tricyclic antidepressants; anxiolytics (e.g., diazepam: 0.1 mg/kg PO tid-qid)

DIOS , Distal intestinal obstruction syndrome; *GI* , gastrointestinal; *H_2 RA* , H_2 -receptor antagonist; *NG* , nasogastric; *NJ* , nasojejunal; *PPIs* , proton pump inhibitors; *tbs* , tablespoon.

From Kliegman RM, Greenbaum LA, Lye PS, editors: *Practical strategies in pediatric diagnosis and therapy* , ed 2, Philadelphia, 2004, Elsevier, p 319.

Diarrhea

Diarrhea is best defined as excessive loss of fluid and electrolyte in the stool. Acute diarrhea is defined as sudden onset of excessively loose stools of >10 mL/kg/day in infants and >200 g/24 hr in older children, which lasts <14 days. When the episode lasts longer than 14 days, it is called *chronic* or *persistent diarrhea.*

Normally, a young infant has approximately 5 mL/kg/day of stool output; the volume increases to 200 g/24 hr in an adult. The greatest volume of intestinal water is absorbed in the small bowel; the colon concentrates intestinal contents against a high osmotic gradient. The small intestine of an adult can absorb 10-11 L/day of a combination of ingested and secreted fluid, whereas the colon absorbs approximately 0.5 L. Disorders that interfere with absorption in the small bowel tend to produce voluminous diarrhea, whereas disorders compromising colonic absorption produce lower-volume diarrhea. **Dysentery** (small-volume, frequent bloody stools with mucus, tenesmus, and urgency) is the predominant symptom of colitis.

The basis of all diarrheas is disturbed intestinal solute transport and water absorption. Water movement across intestinal membranes is passive and is determined by both active and passive fluxes of solutes, particularly sodium, chloride, and glucose. The pathogenesis of most episodes of diarrhea can be explained by secretory, osmotic, or motility abnormalities or a combination of these (Table 332.10).

Table 332.10

Mechanisms of Diarrhea

PRIMARY MECHANISM	DEFECT	STOOL EXAMINATION	EXAMPLES	COMMENT
Secretory	Decreased absorption, increased secretion, electrolyte transport	Watery, normal osmolality with ion gap <100 mOsm/kg	Cholera, toxigenic *Escherichia coli* ; carcinoid, VIP, neuroblastoma, congenital chloride diarrhea, *Clostridium difficile* , cryptosporidiosis (AIDS)	Persists during fasting; bile salt malabsorption can also increase intestinal water secretion; no stool leukocytes

Osmotic	Maldigestion, transport defects ingestion of unabsorbable substances	Watery, acidic, and reducing substances; increased osmolality with ion gap >100 mOsm/kg	Lactase deficiency, glucose-galactose malabsorption, lactulose, laxative abuse	Stops with fasting; increased breath hydrogen with carbohydrate malabsorption; no stool leukocytes
Increased motility	Decreased transit time	Loose to normal-appearing stool, stimulated by gastrocolic reflex	Irritable bowel syndrome, thyrotoxicosis, postvagotomy dumping syndrome	Infection can also contribute to increased motility
Decreased motility	Defect in neuromuscular unit(s) stasis (bacterial overgrowth)	Loose to normal-appearing stool	Pseudoobstruction, blind loop	Possible bacterial overgrowth
Decreased surface area (osmotic, motility)	Decreased functional capacity	Watery	Short bowel syndrome, celiac disease, rotavirus enteritis	Might require elemental diet plus parenteral alimentation
Mucosal invasion	Inflammation, decreased colonic reabsorption, increased motility	Blood and increased WBCs in stool	*Salmonella, Shigella* infection; amebiasis; *Yersinia, Campylobacter* infection	Dysentery evident in blood, mucus, and WBCs

VIP , Vasoactive intestinal peptide; *WBC* , white blood cell.

From Kliegman RM, Greenbaum LA, Lye PS, editors: *Practical strategies in pediatric diagnosis and therapy,* ed 2, Philadelphia, 2004, Elsevier, p 274.

Secretory diarrhea occurs when the intestinal epithelial cell solute transport system is in an active state of secretion. It is often caused by a secretagogue, such as cholera toxin, binding to a receptor on the surface epithelium of the bowel and thereby stimulating intracellular accumulation of cyclic adenosine monophosphate or cyclic guanosine monophosphate. Some intraluminal fatty acids and bile salts cause the colonic mucosa to secrete through this mechanism. Diarrhea not associated with an exogenous secretagogue can also have a secretory component (congenital microvillus inclusion disease). Secretory diarrhea is usually of large volume and persists even with fasting. The stool osmolality is predominantly indicated by the electrolytes and the ion gap is 100 mOsm/kg or less. The ion gap is calculated by subtracting the concentration of electrolytes from total osmolality:

$$\text{Ion gap} = \text{Stool osmalality} - [(\text{Stool Na} + \text{stool K}) \times 2]$$

Osmotic diarrhea occurs after ingestion of a poorly absorbed solute. The solute may be one that is normally not well absorbed (magnesium, phosphate, lactulose, or sorbitol) or one that is not well absorbed because of a disorder of the small bowel (lactose with lactase deficiency or glucose with rotavirus diarrhea). Malabsorbed carbohydrate is fermented in the colon, and short-chain fatty acids are produced. Although short-chain fatty acids can be absorbed in the colon and used as an energy source, the net effect is increase in the osmotic solute load. This form of diarrhea is usually of lesser volume than a secretory diarrhea and stops with fasting. The osmolality of the stool will not be explained by the electrolyte content, because another osmotic component is present and so the anion gap is >100 mOsm.

Motility disorders can be associated with rapid or delayed transit and are not generally associated with large-volume diarrhea. Slow motility can be associated with bacterial overgrowth leading to diarrhea. The differential diagnosis of common causes of acute and chronic diarrhea is noted in Table 332.11 .

Table 332.11

Differential Diagnosis of Diarrhea

INFANT	CHILD	ADOLESCENT
ACUTE		
Common		
Gastroenteritis (viral > bacterial > protozoal) Systemic infection Antibiotic associated Overfeeding	Gastroenteritis (viral > bacterial > protozoal) Food poisoning Systemic infection Antibiotic associated	Gastroenteritis (viral > bacterial > protozoal) Food poisoning Antibiotic associated
Rare		
Primary disaccharidase deficiency Hirschsprung toxic colitis Adrenogenital syndrome Neonatal opiate withdrawal	Toxic ingestion Hemolytic uremic syndrome Intussusception	Hyperthyroidism Appendicitis
CHRONIC		
Common		
Postinfectious secondary lactase deficiency Cow's milk or soy protein intolerance (allergy) Chronic nonspecific diarrhea of infancy Excessive fruit juice (sorbitol) ingestion Celiac disease Cystic fibrosis AIDS enteropathy	Postinfectious secondary lactase deficiency Irritable bowel syndrome Celiac disease Cystic fibrosis Lactose intolerance Excessive fruit juice (sorbitol) ingestion Giardiasis Inflammatory bowel disease AIDS enteropathy	Irritable bowel syndrome Inflammatory bowel disease Lactose intolerance Giardiasis Laxative abuse (anorexia nervosa) Constipation with encopresis
Rare		

Primary immune defects Autoimmune enteropathy IPEX and IPEX-like syndromes Glucose-galactose malabsorption Microvillus inclusion disease (microvillus atrophy) Congenital transport defects (chloride, sodium) Primary bile acid malabsorption Factitious syndrome by proxy Hirschsprung disease Shwachman syndrome Secretory tumors Acrodermatitis enteropathica Lymphangiectasia Abetalipoproteinemia Eosinophilic gastroenteritis Short bowel syndrome	Primary and acquired immune defects Secretory tumors Pseudoobstruction Sucrase-isomaltase deficiency Eosinophilic gastroenteritis Secretory tumors	Secretory tumor Primary bowel tumor Parasitic infections and venereal diseases Appendiceal abscess Addison disease

IPEX, Immunodysregulation polyendocrinopathy enteropathy X-linked.

Constipation

Any definition of constipation is relative and depends on stool consistency, stool frequency, and difficulty in passing the stool. A normal child might have a soft stool only every second or third day without difficulty; this is not constipation. A hard stool passed with difficulty every third day should be treated as constipation. Constipation can arise from defects either in filling or emptying the rectum (Table 332.12).

Table 332.12

Causes of Constipation

NONORGANIC (FUNCTIONAL)—RETENTIVE
Anatomic
Anal stenosis, atresia with fistula Imperforate anus Anteriorly displaced anus Intestinal stricture (postnecrotizing enterocolitis) Anal stricture
Abnormal Musculature
Prune-belly syndrome Gastroschisis Down syndrome Muscular dystrophy

Intestinal Nerve or Muscle Abnormalities
Hirschsprung disease Pseudoobstruction (visceral myopathy or neuropathy) Intestinal neuronal dysplasia Spinal cord lesions Tethered cord Autonomic neuropathy Spinal cord trauma Spina bifida Chagas disease
Drugs
Anticholinergics Narcotics Methylphenidate Phenytoin Antidepressants Chemotherapeutic agents (vincristine) Pancreatic enzymes (fibrosing colonopathy) Lead, arsenic, mercury Vitamin D intoxication Calcium channel blocking agents
Metabolic Disorders
Hypokalemia Hypercalcemia Hypothyroidism Diabetes mellitus, diabetes insipidus Porphyria
Intestinal Disorders
Celiac disease Cow's milk protein intolerance Cystic fibrosis (meconium ileus equivalent) Inflammatory bowel disease (stricture) Tumor Connective tissue disorders Systemic lupus erythematosus Scleroderma
Psychiatric Diagnosis
Anorexia nervosa

A nursing infant might have very infrequent stools of normal consistency; this is usually a normal pattern. True constipation in the neonatal period is most likely secondary to Hirschsprung disease, intestinal pseudoobstruction, or hypothyroidism.

Defective rectal filling occurs when colonic peristalsis is ineffective (in cases of hypothyroidism or opiate use and when bowel obstruction is caused either by a structural anomaly or by Hirschsprung disease). The resultant colonic stasis leads to excessive drying of stool and a failure to initiate reflexes from the rectum that normally trigger evacuation. Emptying the rectum by spontaneous evacuation depends on a defecation reflex initiated by pressure receptors in the rectal muscle. Therefore stool retention can also result from lesions involving these rectal muscles, the sacral spinal cord afferent and efferent fibers, or the muscles of the abdomen and pelvic floor. Disorders of anal sphincter relaxation can also contribute to fecal retention.

Constipation tends to be self-perpetuating, whatever its cause. Hard, large stools in the rectum become difficult and even painful to evacuate; thus more retention occurs and a vicious circle ensues. Distention of the rectum and colon lessens the sensitivity of the defecation reflex and the effectiveness of peristalsis. Fecal impaction is common and leads to other problems. Eventually, watery content from the proximal colon might percolate around hard retained stool and pass per rectum unperceived by the child. This involuntary **encopresis** may be mistaken for diarrhea. Constipation itself does not have deleterious systemic organic effects, but urinary tract stasis with increased risk of urinary tract infections can accompany severe long-standing cases and constipation can generate anxiety, having a marked emotional impact on the patient and family.

Abdominal Pain

There is considerable variation among children in their perception and tolerance for abdominal pain. This is one reason the evaluation of chronic abdominal pain is difficult. A child with **functional abdominal pain** (no identifiable organic cause) may be as uncomfortable as one with an organic cause. It is very important to distinguish between organic and nonorganic (functional) abdominal pain because the approach for the management is based on this. Normal growth and physical examination (including a rectal examination) and the absence of anemia or hematochezia are reassuring in a child who is suspected of having functional pain.

A specific cause may be difficult to find, but the nature and location of a pain-provoking lesion can usually be determined from the clinical description. Two types of nerve fibers transmit painful stimuli in the abdomen. In skin and muscle, A fibers mediate sharp localized pain; C fibers from viscera, peritoneum, and muscle transmit poorly localized, dull pain. These afferent fibers have cell bodies in the dorsal root ganglia, and some axons cross the midline and ascend to the medulla, midbrain, and thalamus. Pain is perceived in the cortex of the postcentral gyrus, which can receive impulses arising from both sides of the body. In the gut, the usual stimulus provoking pain is tension or stretching. Inflammatory lesions can lower the pain threshold, but the mechanisms producing pain or inflammation are not clear. Tissue metabolites released near nerve endings probably account for the pain caused by ischemia. Perception of these painful stimuli can be modulated by input from both cerebral and peripheral sources. Psychologic factors are particularly important. Tables 332.13 and 332.14 list features of abdominal pain. Pain that suggests a potentially serious organic etiology is associated with age younger than 5 yr; fever; weight loss; bile- or blood-stained emesis; jaundice; hepatosplenomegaly; back or flank pain or pain in a location other than the umbilicus; awakening from sleep in pain; referred pain to shoulder, groin or back; elevated erythrocyte sedimentation rate, white blood cell count, or C-reactive protein; anemia; edema; hematochezia; or a strong family history of inflammatory bowel disease or celiac disease.

Table 332.13

Chronic Abdominal Pain in Children

DISORDER	CHARACTERISTICS	KEY EVALUATIONS
NONORGANIC		
Functional abdominal pain	Nonspecific pain, often periumbilical	Hx and PE; tests as indicated
Irritable bowel syndrome	Intermittent cramps, diarrhea, and constipation	Hx and PE
Nonulcer dyspepsia	Peptic ulcer–like symptoms without abnormalities on evaluation of the upper GI tract	Hx; esophagogastroduodenoscopy
GASTROINTESTINAL TRACT		
Chronic constipation	Hx of stool retention, evidence of constipation on examination	Hx and PE; plain x-ray of abdomen
Lactose intolerance	Symptoms may be associated with lactose ingestion; bloating, gas, cramps, and diarrhea	Trial of lactose-free diet; lactose breath hydrogen test
Parasite infection (especially *Giardia*)	Bloating, gas, cramps, and diarrhea	Stool evaluation for O&P; specific immunoassays for *Giardia*
Excess fructose or sorbitol ingestion	Nonspecific abdominal pain, bloating, gas, and diarrhea	Large intake of apples, fruit juice, or candy or chewing gum sweetened with sorbitol
Crohn disease	See Chapter 362	
Peptic ulcer	Burning or gnawing epigastric pain; worse on awakening or before meals; relieved with antacids	Esophagogastroduodenoscopy, upper GI contrast x-rays, or MRI enteroscopy
Esophagitis	Epigastric pain with substernal burning	Esophagogastroduodenoscopy
Meckel diverticulum	Periumbilical or lower abdominal pain; may have blood in stool (usually painless)	Meckel scan or enteroclysis
Recurrent intussusception	Paroxysmal severe cramping abdominal pain; blood may be present in stool with episode	Identify intussusception during episode or lead point in intestine between episodes with contrast studies of GI tract
Internal, inguinal, or abdominal wall hernia	Dull abdomen or abdominal wall pain	PE, CT of abdominal wall

Chronic appendicitis or appendiceal mucocele	Recurrent RLQ pain; often incorrectly diagnosed, may be rare cause of abdominal pain	Barium enema, CT
GALLBLADDER AND PANCREAS		
Cholelithiasis	RUQ pain, might worsen with meals	Ultrasound of gallbladder
Choledochal cyst	RUQ pain, mass ± elevated bilirubin	Ultrasound or CT of RUQ
Recurrent pancreatitis	Persistent boring pain, might radiate to back, vomiting	Serum amylase and lipase ± serum trypsinogen; ultrasound, CT, or MRI-ERCP of pancreas
GENITOURINARY TRACT		
Urinary tract infection	Dull suprapubic pain, flank pain	Urinalysis and urine culture; renal scan
Hydronephrosis	Unilateral abdominal or flank pain	Ultrasound of kidneys
Urolithiasis	Progressive, severe pain; flank to inguinal region to testicle	Urinalysis, ultrasound, IVP, CT
Other genitourinary disorders	Suprapubic or lower abdominal pain; genitourinary symptoms	Ultrasound of kidneys and pelvis; gynecologic evaluation
MISCELLANEOUS CAUSES		
Abdominal migraine	See text; nausea, family Hx migraine	Hx
Abdominal epilepsy	Might have seizure prodrome	EEG (can require >1 study, including sleep-deprived EEG)
Gilbert syndrome	Mild abdominal pain (causal or coincidental?); slightly elevated unconjugated bilirubin	Serum bilirubin
Familial Mediterranean fever	Paroxysmal episodes of fever, severe abdominal pain, and tenderness with other evidence of polyserositis	Hx and PE during an episode, DNA diagnosis
Sickle cell crisis	Anemia	Hematologic evaluation
Lead poisoning	Vague abdominal pain ± constipation	Serum lead level
Henoch-Schönlein purpura	Recurrent, severe crampy abdominal pain, occult blood in stool, characteristic rash, arthritis	Hx, PE, urinalysis
Angioneurotic edema	Swelling of face or airway, crampy pain	Hx, PE, upper GI contrast x-rays, serum C1 esterase inhibitor
Acute intermittent porphyria	Severe pain precipitated by drugs, fasting, or infections	Spot urine for porphyrins
Anterior cutaneous nerve entrapment syndrome (ACNES)	Exquisite localized (~2 × 2 cm) tenderness that is replicable, most often right lower quadrant	Pain relief within 15 min of abdominal wall injection of local anesthetic; may need surgery

ERCP, Endoscopic retrograde cholangiopancreatography.*EEG* , Electroencephalogram; *GI* , gastrointestinal; *Hx* , history; *IVP* , intravenous pyelography; *O&P* , ova and parasites; *PE* , physical exam; *RLQ* , right lower quadrant; *RUQ* , right upper quadrant.

Table 332.14

Distinguishing Features of Acute Abdominal Pain in Children

DISEASE	ONSET	LOCATION	REFERRAL	QUALITY	COMMENTS
Pancreatitis	Acute	Epigastric, left upper quadrant	Back	Constant, sharp, boring	Nausea, emesis, tenderness

Intestinal obstruction	Acute or gradual	Periumbilical-lower abdomen	Back	Alternating cramping (colic) and painless periods	Distention, obstipation, emesis, increased bowel sounds
Appendicitis	Acute (1-3 days)	Periumbilical, then localized to lower right quadrant; generalized with peritonitis	Back or pelvis if retrocecal	Sharp, steady	Anorexia, nausea, emesis, local tenderness, fever with peritonitis
Intussusception	Acute	Periumbilical-lower abdomen	None	Cramping, with painless periods	Hematochezia, knees in pulled-up position
Urolithiasis	Acute, sudden	Back (unilateral)	Groin	Sharp, intermittent, cramping	Hematuria
Urinary tract infection	Acute	Back	Bladder	Dull to sharp	Fever, costovertebral angle tenderness, dysuria, urinary frequency
Pelvic inflammatory disease	Acute	Pelvis, lower quadrant	Upper thigh	Aching, peritoneal signs	Vaginal discharge, fever
Small bowel obstruction	Acute to subacute	Periumbilical	None	Cramping diffuse	Emesis and obstipation
Ruptured ectopic pregnancy	Acute sudden	Pelvis, lower quadrant	None	Sharp, intense, localized	Vaginal bleeding, shock

Visceral pain tends to be dull and aching and is experienced in the dermatome from which the affected organ receives innervations. So, most often, the pain and tenderness are not felt over the site of the disease process. Painful stimuli originating in the liver, pancreas, biliary tree, stomach, or upper bowel are felt in the epigastrium; pain from the distal small bowel, cecum, appendix, or proximal colon is felt at the umbilicus; and pain from the distal large bowel, urinary tract, or pelvic organs is usually suprapubic. The pain from the cecum, ascending colon, and descending colon sometimes is felt at the site of the lesion because of the short mesocecum and corresponding mesocolon. The pain caused by appendicitis is initially felt in the periumbilical region, and pain from the transverse colon is usually felt in the supra pubic region. The shifting (localization) of pain is a pointer toward diagnosis; for example, periumbilical pain of a few hours localizing to the right lower quadrant suggests appendicitis. Radiation of pain can be helpful in diagnosis; for example, in biliary colic the radiation of pain is toward the inferior angle of the right scapula, pancreatic pain radiated to the back, and the renal colic pain is radiated to the inguinal region on the same side.

Somatic pain is intense and usually well localized. When the inflamed viscus comes in contact with a somatic organ such as the parietal peritoneum or the abdominal wall, pain is localized to that site. Peritonitis gives rise to generalized abdominal pain with rigidity, involuntary guarding, rebound tenderness, and cutaneous hyperesthesia on physical examination.

Referred pain from extraintestinal locations, from shared central projections with the sensory pathway from the abdominal wall, can give rise to abdominal pain, as in pneumonia when the parietal pleural pain is referred to the abdomen.

Gastrointestinal Hemorrhage

Bleeding can occur anywhere along the GI tract, and identification of the site may be challenging (Table 332.15). Bleeding that originates in the esophagus, stomach, or duodenum can cause **hematemesis.** When exposed to gastric or intestinal juices, blood quickly darkens to resemble coffee grounds; massive bleeding is likely to be red. Red or maroon blood in stools, **hematochezia,** signifies either a distal bleeding site or massive hemorrhage above the distal ileum. Moderate to mild bleeding from sites above the distal ileum tends to cause blackened stools of tarry consistency **(melena);** major hemorrhages in the duodenum or above can also cause melena.

Table 332.15

Differential Diagnosis of Gastrointestinal Bleeding in Childhood

INFANT	CHILD	ADOLESCENT
COMMON		
Bacterial enteritis Milk protein allergy intolerance Intussusception Swallowed maternal blood Anal fissure Lymphonodular hyperplasia	Bacterial enteritis Anal fissure Colonic polyps Intussusception Peptic ulcer/gastritis Swallowed epistaxis Prolapse (traumatic) gastropathy secondary to emesis Mallory-Weiss syndrome	Bacterial enteritis Inflammatory bowel disease Peptic ulcer/gastritis Prolapse (traumatic) gastropathy secondary to emesis Mallory-Weiss syndrome Colonic polyps Anal fissure
RARE		
Volvulus Necrotizing enterocolitis Meckel diverticulum Stress ulcer, gastritis Coagulation disorder (hemorrhagic disease of newborn) Esophagitis	Esophageal varices Esophagitis Meckel diverticulum Lymphonodular hyperplasia Henoch-Schönlein purpura Foreign body Hemangioma, arteriovenous malformation	Hemorrhoids Esophageal varices Esophagitis Pill ulcer Telangiectasia-angiodysplasia Graft versus host disease Duplication cyst • Angiodysplasia

	Sexual abuse Hemolytic-uremic syndrome Inflammatory bowel disease Coagulopathy Duplication cyst • Angiodysplasia • Angiodysplasia with von Willebrand disease • Blue rubber bleb nevus syndrome	• Angiodysplasia with von Willebrand disease • Blue rubber bleb nevus syndrome

Erosive damage to the mucosa of the GI tract is the most common cause of bleeding, although variceal bleeding secondary to portal hypertension occurs often enough to require consideration. Prolapse gastropathy producing subepithelial hemorrhage and Mallory-Weiss lesions secondary to mucosal tears associated with emesis are causes of upper intestinal bleeds. Vascular malformations are a rare cause in children; they are difficult to identify (Figs. 332.1 and 332.2). Upper intestinal bleeding is evaluated with esophagogastroduodenoscopy. Evaluation of the small intestine is facilitated by capsule endoscopy. The capsule-sized imaging device is swallowed in older children or placed endoscopically in younger children. Lower GI bleeding is investigated with a colonoscopy. In brisk intestinal bleeding of unknown location, a tagged red blood cell scan is helpful in locating the site of the bleeding, although CT angiography is usually diagnostic. Occult blood in stool is usually detected by using commercially available fecal occult blood testing cards, which are based on a chemical reaction between the chemical guaiac and oxidizing action of a substrate (hemoglobin), giving a blue color. The guaiac test is very sensitive, but random testing can miss chronic blood loss, which can lead to iron-deficiency anemia. GI hemorrhage can produce hypotension and tachycardia but rarely causes GI symptoms; brisk duodenal or gastric bleeding can lead to nausea, vomiting, or diarrhea. The breakdown products of intraluminal blood might tip patients into hepatic coma if liver function is already compromised and can lead to elevation of serum bilirubin.

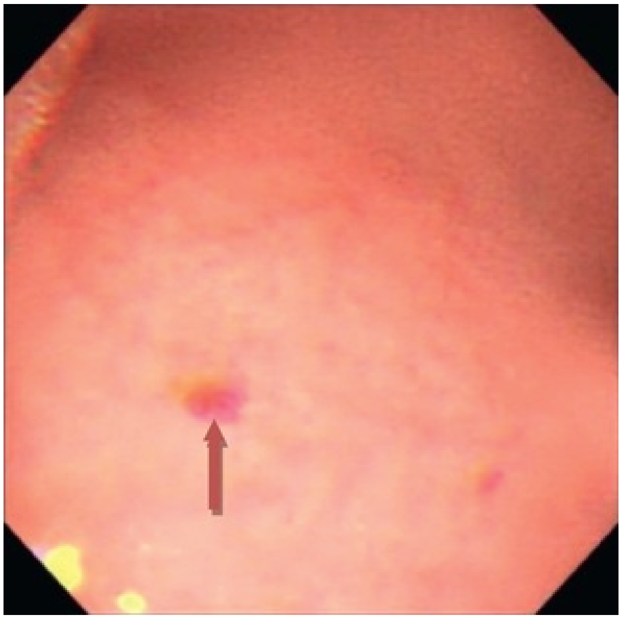

FIG. 332.1 A 7 yr old boy had tarry stool for days. Panendoscopy showed multiple cherry red flat spots in the gastric mucosa, compatible with the findings of angiodysplasia in computed tomographic angiography. (From Chuang F, Lin JS, Yeung C, et al: Intestinal angiodysplasia: an uncommon cause of gastrointestinal bleeding in children. *Pediatr Neonatol* 52:214–218, 2011. Fig. 2.)

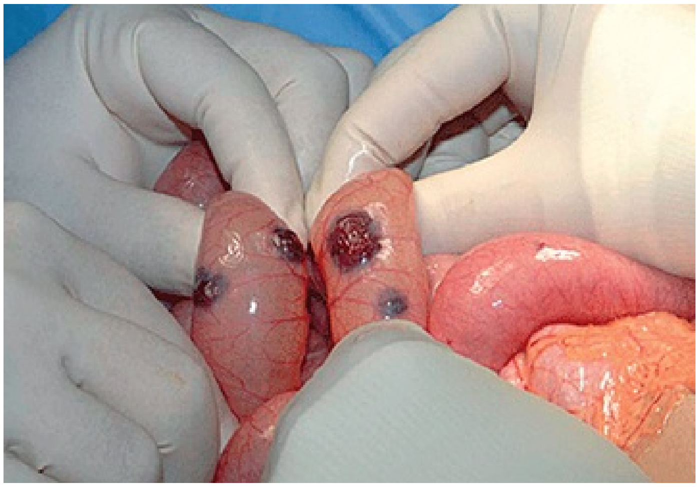

FIG. 332.2 Operative features of blue rubber bleb nevus syndrome: these lesions are similar to cutaneous lesions. (From Hasosah MY, Abdul-Wahab AA, Bin-Yahab SA, et al: Blue rubber bled nevus syndrome: extensive small bowel vascular lesions responsible for gastrointestinal bleeding. *J Pediatr Child Health* 46:63–65, 2010. Fig 3.)

Abdominal Distention and Abdominal Masses

Enlargement of the abdomen can result from diminished tone of the wall musculature or from increased content: fluid, gas, or solid. Ascites, the accumulation of fluid in the peritoneal cavity, distends the abdomen both in the flanks and anteriorly when it is large in volume. This fluid shifts with movement of the patient and conducts a percussion wave. Ascitic fluid is usually a transudate with a low protein concentration resulting from reduced plasma colloid osmotic pressure of hypoalbuminemia and/or from raised portal venous pressure. In cases of portal hypertension, the fluid leak probably occurs from lymphatics on the liver surface and from visceral peritoneal capillaries, but ascites does not usually develop until the serum albumin level falls. Sodium excretion in the urine decreases greatly as the ascitic fluid accumulates, and thus additional dietary sodium goes directly to the peritoneal space, taking with it more water. When ascitic fluid contains a high protein concentration, it is usually an exudate caused by an inflammatory or neoplastic lesion.

When fluid distends the gut, either obstruction or imbalance between absorption and secretion should be suspected. The factors causing fluid accumulation in the bowel lumen often cause gas to accumulate too. The result may be audible gurgling noises. The source of gas is usually swallowed air, but endogenous flora can increase considerably in malabsorptive states and produce excessive gas when substrate reaches the lower intestine. Gas in the peritoneal cavity (pneumoperitoneum) is usually caused by a perforated viscus and can cause abdominal distention depending on the amount of gas leak. A tympanitic percussion note, even over solid organs such as the liver, indicates a large collection of gas in the peritoneum.

An abdominal organ can enlarge diffusely or be affected by a discrete mass. In the digestive tract, such discrete masses can occur in the lumen, wall, omentum, or mesentery. In a constipated child, mobile, nontender fecal masses are often found. Congenital anomalies, cysts, or inflammatory processes can affect the wall of the gut. Gut wall neoplasms are extremely rare in children. The pathologic enlargement of liver, spleen, bladder, and kidneys can give rise to abdominal distention.

CHAPTER 333

Development and Developmental Anomalies of the Teeth

Vineet Dhar

Newborn infants do not have teeth for about first 6 mo after birth (predentate period). At this stage, the upper and lower alveolar ridges in the mouth, also known as gum pads, house the primary (deciduous) and some permanent tooth buds. The primary dentition period starts with eruption of the first primary tooth; all 20 primary teeth erupt by 3 yr of age. The permanent teeth start erupting around age of 6 yr, and the transition to full permanent dentition is completed by 13 yr of age. The transition time between primary and permanent dentition, when a mix of primary and permanent teeth are present, is referred to as mixed dentition.

Development of Teeth

Initiation

The primary teeth form in dental crypts that arise from a band of epithelial cells incorporated into each developing jaw. By 12 wk of fetal life, each of these epithelial bands **(dental laminae)** has 5 areas of rapid growth on each side of the maxilla and the mandible, seen as rounded, budlike enlargements. Organization of adjacent mesenchyme takes place in each area of epithelial growth, and the 2 elements together are the beginning of a tooth.

After the formation of these crypts for the 20 primary teeth, another generation of tooth buds forms lingually (toward the tongue); these will develop into the succeeding permanent incisors, canines, and premolars that eventually replace the primary teeth. This process takes place from approximately 5 mo of gestation for the central incisors to approximately 10 mo of age for the second premolars. On the other hand, the permanent first, second, and third molars arise from extension of the dental laminae distal to the second primary molars; buds for these teeth develop at approximately 4 mo of gestation, 1 yr of age, and 4-5 yr of age, respectively.

Histodifferentiation–Morphodifferentiation

As the epithelial bud proliferates, the deeper surface invaginates and a mass of mesenchyme becomes partially enclosed. The epithelial cells differentiate into the ameloblasts that lay down an organic matrix that forms enamel; the mesenchyme forms the dentin and dental pulp.

Calcification

After the organic matrix has been laid down, the deposition of the inorganic mineral crystals takes place from several sites of calcification that later coalesce. The characteristics of the inorganic portions of a tooth can be altered by disturbances in formation of the matrix, decreased availability of minerals, or the incorporation of foreign materials. Such disturbances can affect the color, texture, or thickness of the tooth surface. Calcification of primary teeth begins at 3-4 mo in utero and concludes postnatally at approximately 12 mo, with mineralization of the second primary molars (Table 333.1).

Table 333.1

Calcification, Crown Completion, and Eruption

TOOTH	FIRST EVIDENCE OF CALCIFICATION	CROWN COMPLETED	ERUPTION
PRIMARY DENTITION			
Maxillary			
Central incisor	3-4 mo in utero	4 mo	7.5 mo
Lateral incisor	4.5 mo in utero	5 mo	8 mo
Canine	5.5 mo in utero	9 mo	16-20 mo
First molar	5 mo in utero	6 mo	12-16 mo
Second molar	6 mo in utero	10-12 mo	20-30 mo
Mandibular			
Central incisor	4.5 mo in utero	4 mo	6.5 mo
Lateral incisor	4.5 mo in utero	4¼ mo	7 mo
Canine	5 mo in utero	9 mo	16-20 mo
First molar	5 mo in utero	6 mo	12-16 mo
Second molar	6 mo in utero	10-12 mo	20-30 mo
PERMANENT DENTITION			

Maxillary			
Central incisor	3-4 mo	4-5 yr	7-8 yr
Lateral incisor	10 mo	4-5 yr	8-9 yr
Canine	4-5 mo	6-7 yr	11-12 yr
First premolar	1.5- 1¾ yr	5-6 yr	10-11 yr
Second premolar	2- 2¼ yr	6-7 yr	10-12 yr
First molar	At birth	2.5-3 yr	6-7 yr
Second molar	2.5-3 yr	7-8 yr	12-13 yr
Third molar	7-9 yr	12-16 yr	17-21 yr
Mandibular			
Central incisor	3-4 mo	4-5 yr	6-7 yr
Lateral incisor	3-4 mo	4-5 yr	7-8 yr
Canine	4-5 mo	6-7 yr	9-10 yr
First premolar	1¾ -2 yr	5-6 yr	10-12 yr
Second premolar	2¼ -2.5 yr	6-7 yr	11-12 yr
First molar	At birth	2.5-3 yr	6-7 yr
Second molar	2.5-3 yr	7-8 yr	11-13 yr
Third molar	8-10 yr	12-16 yr	17-21 yr

Eruption

At the time of tooth bud formation, each tooth begins a continuous movement toward the oral cavity. Table 333.1 lists the times of eruption of the primary and permanent teeth.

Anomalies Associated With Eruption Pattern: Delayed eruption of the 20 primary teeth can be familial or indicate systemic or nutritional disturbances such as hypopituitarism, hypothyroidism, cleidocranial dysplasia, trisomy 21, and multiple other syndromes. Failure of eruption of single or small groups of teeth can arise from local causes such as malpositioned teeth, supernumerary teeth, cysts, or retained primary teeth. Premature *loss* of primary teeth is most commonly caused by premature *eruption* of the permanent teeth. If the entire dentition is advanced for age and sex, precocious puberty or hyperthyroidism should be considered.

Natal teeth are observed in approximately 1 in 2,000 newborn infants, usually in the position of the mandibular central incisors. Natal teeth are present at birth, whereas **neonatal teeth** erupt in the first mo of life. Attachment of natal and neonatal teeth is generally limited to the gingival margin, with little root formation or bony support. They may be a supernumerary or a prematurely erupted primary tooth. A radiograph can easily differentiate between the 2 conditions. Natal teeth are associated with cleft palate, Pierre Robin syndrome, Ellis-van Creveld syndrome, Hallermann-Streiff syndrome, pachyonychia congenita, and other anomalies. A family history of natal teeth or premature eruption is present in 15–20% of affected children.

Natal or neonatal teeth occasionally result in pain and refusal to feed and can produce maternal discomfort because of abrasion or biting of the nipple during nursing. If the tooth is mobile, there is a danger of detachment, with aspiration of the tooth. Because the tongue lies between the alveolar processes during birth, it can become lacerated (**Riga-Fede disease**). Decisions regarding extraction of prematurely erupted primary teeth must be made on an individual basis.

Exfoliation failure occurs when a primary tooth is not shed before the eruption of its permanent successor. Most often the primary tooth exfoliates eventually, but in some cases the primary tooth needs to be extracted. This occurs most commonly in the mandibular incisor region.

Anomalies Associated With Tooth Development

Both failures and excesses of tooth initiation are observed. Developmentally missing teeth can result from environmental insult, a genetic defect involving only teeth, or the manifestation of a syndrome.

Anomalies of Number: Anodontia, or absence of teeth, occurs when no tooth buds form (ectodermal dysplasia, or familial missing teeth) or when there is a disturbance of a normal site of initiation (the area of a palatal cleft). The teeth that are most commonly absent are the third molars, the maxillary lateral incisors, and the mandibular second premolars.

If the dental lamina produces more than the normal number of buds, **supernumerary teeth** occur, most often in the area between the maxillary central incisors. Because they tend to disrupt the position and eruption of the adjacent normal teeth, their identification by radiographic examination is important. Supernumerary teeth also occur with cleidocranial dysplasia (see Chapter 337) and in the area of cleft palates.

Anomalies of Size: Twinning, in which 2 teeth are joined together, is most often observed in the mandibular incisors of the primary dentition. It can result from gemination, fusion, or concrescence. **Gemination** is the result of the division of one tooth germ to form a bifid crown on a single root with a common pulp canal; an extra tooth appears to be present in the dental arch. **Fusion** is the joining of incompletely developed teeth that, owing to pressure, trauma, or crowding, continue to develop as 1 tooth. Fused teeth are sometimes joined along their entire length; in other cases a single wide crown is supported on 2 roots. **Concrescence** is the attachment of the roots of closely approximated adjacent teeth by an excessive deposit of cementum. This type of twinning, unlike the others, is found most often in the maxillary molar region.

Disturbances during differentiation can result in alterations in dental morphology, such as **macrodonti** a (large teeth) or **microdontia** (small teeth). The maxillary lateral incisors can assume a slender, tapering shape **(peg-shaped laterals).**

Anomalies of Shape: Dens in Dente or **Dens Invaginatus** presents as *tooth within tooth* appearance, which results from invagination of inner enamel epithelium caused by disruption during morphodifferentiation,

Dens Evaginatus presents as an extra cusp on anterior or posterior teeth, which contains enamel, dentin, and sometimes even pulp tissue. In the anterior teeth the cusp is talon shaped and presents in the cingulum area.

Taurodontism is more common in permanent molars and is characterized by elongated pulp chamber with short stunted roots due to failure or late invagination of Hertwig epithelial root sheath. It may be associated with several syndromic conditions such as Down syndrome, trichodento-osseous syndrome, ectodermal dysplasia (hypohidrotic), and amelogenesis imperfecta (hypomaturation-hypoplastic type).

Dilaceration is an abnormal bend or curve in root possibly due to trauma. It may be subsequent to injury to the primary predecessor tooth.

Anomalies of Structure: Amelogenesis imperfecta represents a group of hereditary conditions that manifest in enamel defects of the primary and permanent teeth without evidence of systemic disorders (Fig. 333.1). The teeth are covered by only a thin layer of abnormally formed enamel through which the yellow underlying dentin is seen. The primary teeth are generally affected more than the permanent teeth. Susceptibility to caries is low, but the enamel is subject to destruction from abrasion. Complete coverage of the crown may be indicated for dentin protection, to reduce tooth sensitivity, and for improved appearance.

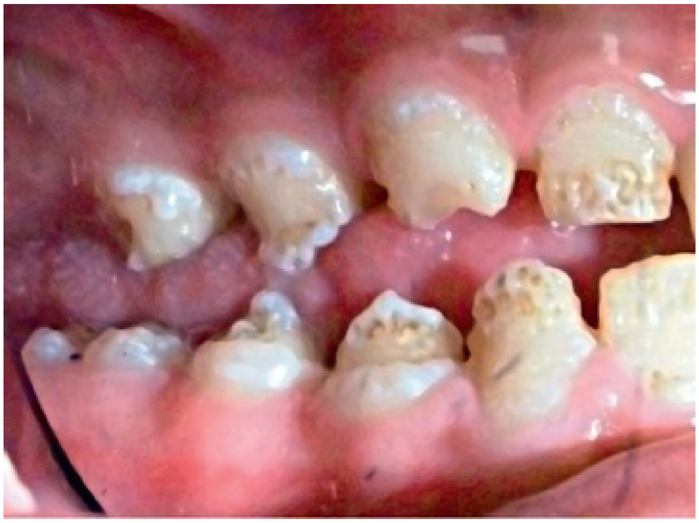

FIG. 333.1 **Amelogenesis imperfecta, hypoplastic type. The enamel defect results in areas of missing or thin enamel, as well as grooves and pits.**

Dentinogenesis imperfecta, or hereditary opalescent dentin, is a condition analogous to amelogenesis imperfecta in which the odontoblasts fail to differentiate normally, resulting in poorly calcified dentin (Fig. 333.2). This autosomal dominant disorder can also occur in patients with **osteogenesis imperfecta.** The enamel-dentin junction is altered, causing enamel to break away. The exposed dentin is then susceptible to abrasion, in some cases worn to the gingiva. The teeth are opaque and pearly, and the pulp chambers are generally obliterated by calcification. Both primary and permanent teeth are usually involved. If there is excessive wear of the teeth, selected complete coverage of the teeth may be indicated to prevent further tooth loss and improve appearance.

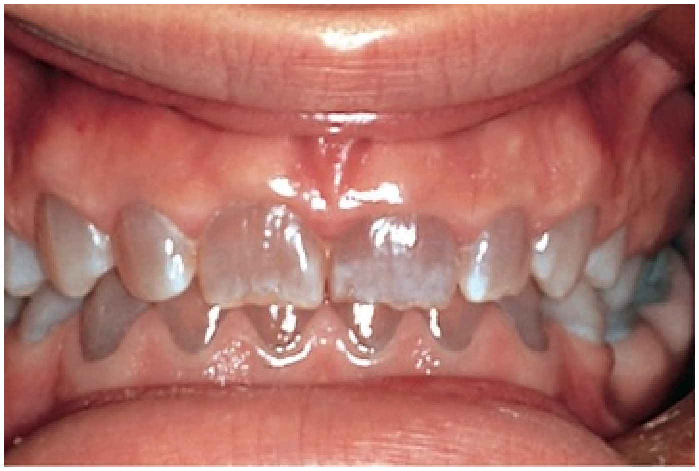

FIG. 333.2 Dentinogenesis imperfecta. The bluish, opalescent sheen on several of these teeth results from genetically defective dentin. This condition may be associated with osteogenesis imperfecta. (From Nazif MM, Martin BS, McKibben DH, et al: Oral disorders. In Zitelli BJ, Davis HW, editors: *Atlas of pediatric physical diagnosis,* ed 4, Philadelphia, 2002, Mosby, p 703.)

Localized disturbances of calcification that correlate with periods of illness, malnutrition, premature birth, or birth trauma are common. **Hypocalcification** appears as opaque white patches or horizontal lines on the tooth; **hypoplasia** is more severe and manifests as pitting or areas devoid of enamel. Systemic conditions, such as renal failure and cystic fibrosis, are associated with enamel defects. Local trauma to the primary incisors can also affect calcification of permanent incisors.

Fluorosis (mottled enamel) can result from systemic fluoride consumption >0.05 mg/kg/day during enamel formation. This high fluoride consumption can be caused by residing in an area of high fluoride content of the drinking water (>2.0 ppm), swallowing excessive fluoridated toothpaste, or inappropriate fluoride prescriptions. Excessive fluoride during enamel formation affects ameloblastic function, resulting in inconspicuous white, lacy patches on the enamel to severe brownish discoloration and hypoplasia. The latter changes are usually seen with fluoride concentrations in the drinking water >5.0 ppm.

Anomalies of Color: Discolored teeth can result from incorporation of foreign substances into developing enamel. Neonatal hyperbilirubinemia can produce blue to black discoloration of the primary teeth. Porphyria produces a red-brown discoloration. Tetracyclines are extensively incorporated into bones and teeth and, if administered during the period of formation of enamel, can result in brown-yellow discoloration and hypoplasia of the enamel. Such teeth fluoresce under ultraviolet light. The period at risk extends from approximately 4 mo of gestation to 7 yr of life. Repeated or prolonged therapy with tetracycline carries the highest risk.

Teething is associated with primary tooth eruption and may manifest with benign symptoms such as gingival hyperemia, irritability, sucking fingers, and drooling; some infants have no symptoms or symptoms not identified by their parents. Low-grade fever is an inconsistent finding. The treatment of symptoms of teething is often unnecessary but could include oral analgesics and iced teething rings. “Natural” (homeopathic) teething remedies may contain toxic additives and should be avoided.

CHAPTER 334

Disorders of the Oral Cavity Associated With Other Conditions

Vineet Dhar

Disorders of the teeth and surrounding structures can occur in isolation or in combination with other systemic conditions (Table 334.1). Most commonly, medical conditions that occur during tooth development can affect tooth formation or appearance. Damage to teeth during their development is permanent.

Table 334.1

Dental Problems Associated With Selected Medical Conditions

MEDICAL CONDITION	COMMON ASSOCIATED DENTAL OR ORAL FINDINGS
Cleft lip and palate	Missing teeth, extra (supernumerary) teeth, shifting of arch segments, feeding difficulties, speech problems
Kidney failure	Mottled enamel (permanent teeth), facial dysmorphology
Cystic fibrosis	Stained teeth with extensive medication, mottled enamel
Immunosuppression	Oral candidiasis with potential for systemic candidiasis, cyclosporine-induced gingival hyperplasia
Low birthweight	Palatal groove, narrow arch with prolonged oral intubation; enamel defects of primary teeth
Heart defects with susceptibility to bacterial endocarditis	Bacteremia from dental procedures or trauma
Neutrophil chemotactic deficiency	Aggressive periodontitis (loss of supporting bone around teeth)
Diabetes mellitus type I (uncontrolled)	Aggressive periodontitis
Neuromotor dysfunction	Oral trauma from falling; malocclusion (open bite); gingivitis from lack of hygiene
Prolonged illness (generalized) during tooth formation	Enamel hypoplasia of crown portions forming during illness
Seizures	Gingival enlargement if phenytoin is used
Maternal infections	Syphilis: abnormally shaped teeth
Vitamin D–dependent rickets	Enamel hypoplasia

CHAPTER 335

Malocclusion

Vineet Dhar

The oral cavity is essentially a masticatory instrument. The purpose of the anterior teeth is to bite off large portions of food. The posterior teeth reduce foodstuff to a soft, moist bolus. The cheeks and tongue force the food onto the areas of tooth contact. Establishing a proper relationship between the mandibular and maxillary teeth is important for both physiologic and cosmetic reasons.

Variations in Growth Patterns

Growth patterns are classified into 3 main types of occlusion, determined when the jaws are closed and the teeth are held together (Fig. 335.1). According to the Angle classification of malocclusion, in **class I occlusion** (normal), the cusps of the posterior mandibular teeth interdigitate ahead of and inside of the corresponding cusps of the opposing maxillary teeth. This relationship provides a normal facial profile.

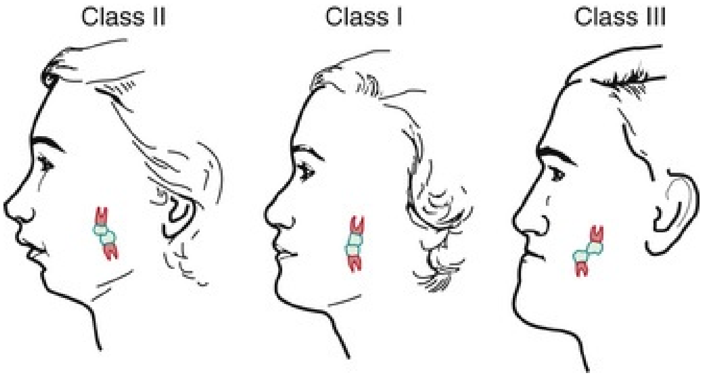

FIG. 335.1 **Angle classification of occlusion. The typical correspondence between the facial-jaw profile and molar relationship is shown. (Data from Borrie FR, Bearn DR,**

Innes NP, Iheozor-Ejiofor Z: Interventions for the cessation of non-nutritive sucking habits in children. *Cochrane Database Syst Rev* 31(3):CD008694, 2015. doi: 10.1002/14651858.CD008694.pub2.)

In **class II malocclusion,** *buck teeth* , the cusps of the posterior mandibular teeth are behind and inside the corresponding cusps of the maxillary teeth. This common occlusal disharmony is found in approximately 45% of the population. The facial profile can give the appearance of a *receding chin* (retrognathia) (mandibular deficiency) or protruding front teeth. The resultant increased space between upper and lower anterior teeth encourage finger sucking and tongue-thrust habits. In addition, children with pronounced class II malocclusions are at greater risks of damage to the incisors as a consequence of trauma. Treatment includes orthodontic retraction of the maxilla or stimulation of the mandible.

In **class III malocclusion,** *underbite* , the cusps of the posterior mandibular teeth interdigitate a tooth or more ahead of their opposing maxillary counterparts. The anterior teeth appear in crossbite with the mandibular incisors protruding beyond the maxillary incisors. The facial profile gives the appearance of a *protruding chin* **(prognathia)** with or without an appearance of maxillary deficiency. If necessary, treatment includes mandibular excess reduction osteotomy or orthodontic maxillary facial protrusion.

Crossbite

Normally, the mandibular teeth are in a position just inside the maxillary teeth, so that the outside mandibular cusps or incisal edges meet the central portion of the opposing maxillary teeth. A reversal of this relation is referred to as a crossbite. Crossbites can be anterior, involving the incisors; can be posterior, involving the molars; or can involve single or multiple teeth.

Open and Closed Bites

If the posterior mandibular and maxillary teeth make contact with each other, but the anterior teeth are still apart, the condition is called an *open bite*. Open bites can result from skeletal growth pattern or digit sucking. If digit sucking is terminated before skeletal and dental growth is complete, the open bite might resolve naturally. If mandibular anterior teeth occlude inside the maxillary anterior teeth in an overclosed position, the condition is referred to as a *closed* or *deep bite*.

Treatment of open and closed bites consists of orthodontic correction, generally performed in the preteen or teenage years. Some cases require orthognathic surgery to position the jaws optimally in a vertical direction.

Dental Crowding

Overlap of incisors can result when the jaws are too small or the teeth are too large for adequate alignment of the teeth. Growth of the jaws is mostly in the posterior aspects of the mandible and maxilla, and therefore inadequate space for the teeth at 7 or 8 yr of age will not resolve with growth of the jaws. Spacing in the primary dentition is normal and favorable for adequate alignment of successor teeth.

Digit Sucking

Various and conflicting etiologic theories and recommendations for correction have been proposed for digit sucking in children. Prolonged digit sucking can cause flaring of the maxillary incisor teeth, an open bite, and a posterior crossbite. The prevalence of digit sucking decreases steadily from the age of 2 yr to approximately 10% by the age of 5 yr. The earlier the habit is discontinued after the eruption of the permanent maxillary incisors (age 7-8 yr), the greater the likelihood that there will be lessening effects on the dentition.

A variety of treatments have been suggested, from behavioral modification to insertion of an appliance with extensions that serves as a reminder when the child attempts to insert the digit. Unfortunately, a systematic review has found only low-quality evidence of the effectiveness of interventions such as orthodontic appliances and psychological interventions. The greatest likelihood of success occurs in cases in which the child desires to stop. Stopping of the habit will not rectify a malocclusion caused by a prior deviant growth pattern.

CHAPTER 336

Cleft Lip and Palate

Vineet Dhar

Clefts of the lip and palate are distinct entities which are closely related embryologically, functionally, and genetically. It is thought that cleft of the lip appears because of hypoplasia of the mesenchymal layer, resulting in a failure of the medial nasal and maxillary processes to join. Cleft of the palate results from failure of palatal shelves to approximate or fuse.

Incidence and Epidemiology

The incidence of cleft lip with or without cleft palate is approximately 1 in 750 white births; the incidence of cleft palate alone is approximately 1 in 2,500 white births. Clefts of the lip are more common in males. Possible causes include maternal drug exposure, a syndrome-malformation complex, or genetic factors. Although clefts of lips and palates appear to occur sporadically, the presence of susceptible genes appears important. There are approximately 400 syndromes associated with cleft lip and palates. There are families in which a cleft lip or palate, or both, is inherited in a dominant fashion (**van der Woude syndrome**), and careful examination of parents is important to distinguish this type from others, because the recurrence risk is 50%. Ethnic factors also affect the incidence of cleft lip and palate; the incidence is highest among Asians (~1 in 500) and Native Americans (~1 in 300) and lowest among blacks (~1 in 2,500). Cleft lip may be associated with other cranial facial anomalies, whereas cleft palate may be associated with central nervous system anomalies.

Clinical Manifestations

Cleft lip can vary from a small notch in the vermilion border to a complete separation involving skin, muscle, mucosa, tooth, and bone. Clefts of the lip may be unilateral (more often on the left side) or bilateral and can involve the alveolar ridge (Fig. 336.1).

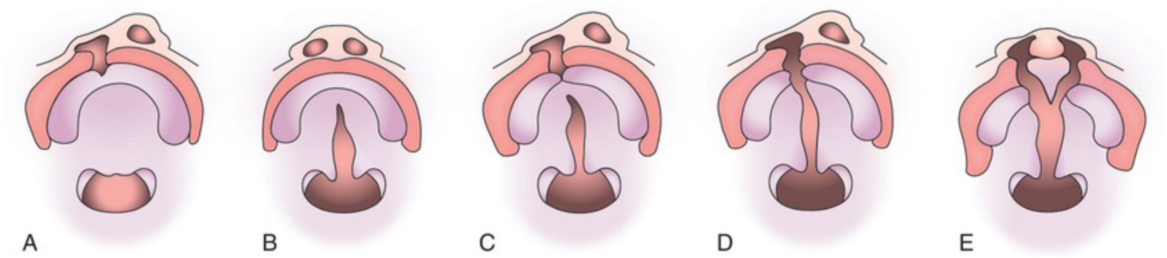

FIG. 336.1 **Nonsyndromic orofacial clefts. A, Cleft lip and alveolus. B, Cleft palate. C, Incomplete unilateral cleft lip and palate. D, Complete unilateral cleft lip and palate. E, Complete bilateral cleft lip and palate. (From Shaw WC: *Orthodontics and occlusal management* . Oxford, UK, 1993, Butterworth-Heinemann.)**

Isolated cleft palate occurs in the midline and might involve only the uvula or can extend into or through the soft and hard palates to the incisive foramen. When associated with cleft lip, the defect can involve the midline of the soft palate and extend into the hard palate on one or both sides, exposing one or both of the nasal cavities as a unilateral or bilateral cleft palate. The palate can also have a **submucosal cleft** indicated by a bifid uvula, partial separation of muscle with intact mucosa, or a palpable notch at the posterior of the palate (see Fig. 336.1).

Treatment

A complete program of habilitation for the child with a cleft lip or palate can require years of special treatment by a team consisting of a pediatrician, plastic surgeon, otolaryngologist, oral and maxillofacial surgeon, pediatric dentist, prosthodontist, orthodontist, speech therapist, geneticist, medical social worker, psychologist, and public health nurse.

The immediate problem in an infant born with a cleft lip or palate is feeding. Although some advocate the construction of a plastic obturator to assist in feedings, most believe that, with the use of soft artificial nipples with large openings, a squeezable bottle, and proper instruction, feeding of infants with clefts can be achieved.

Surgical closure of a cleft lip is usually performed by 3 mo of age, when the infant has shown satisfactory weight gain and is free of any oral, respiratory, or systemic infection. Modification of the Millard rotation–advancement technique is the most commonly used technique; a staggered suture line minimizes notching of the lip from retraction of scar tissue. The initial repair may be revised at 4 or 5 yr of age. Corrective surgery on the nose may be delayed until adolescence. Nasal surgery can also be performed at the time of the lip repair. Cosmetic results depend on the extent of the original deformity, healing potential of the individual patient, absence of infection, and the skill of the surgeon.

Because clefts of the palate vary considerably in size, shape, and degree of deformity, the timing of surgical correction should be individualized. Criteria such as width of the cleft, adequacy of the existing palatal segments, morphology of the surrounding areas (width of the oropharynx), and neuromuscular function of the soft palate and pharyngeal walls affect the decision. The goals of surgery are the union of the cleft segments, intelligible and pleasant speech, reduction of nasal regurgitation, and avoidance of injury to the growing maxilla.

In an otherwise healthy child, closure of the palate is usually done before 1 yr of age to enhance normal speech development. When surgical correction is delayed beyond the 3rd yr, a contoured speech bulb can be attached to the posterior of a maxillary denture so that contraction of the pharyngeal and velopharyngeal muscles can bring tissues into contact with the bulb to accomplish occlusion of the nasopharynx and help the child to develop intelligible speech.

A cleft palate usually crosses the alveolar ridge and interferes with the formation of teeth in the maxillary anterior region. Teeth in the cleft area may be displaced, malformed, or missing. Missing teeth or teeth that are nonfunctional are replaced by prosthetic devices.

Postoperative Management

During the immediate postoperative period, special nursing care is essential. Gentle aspiration of the nasopharynx minimizes the chances of the common complications of atelectasis or pneumonia. The primary considerations in postoperative care are maintenance of a clean suture line and avoidance of tension on the sutures. The infant is fed with a specially designed bottle and the arms are restrained with elbow cuffs. A fluid or semifluid diet is maintained for 3 wk. The patient's hands, toys, and other foreign bodies must be kept away from the surgical site.

Sequelae

Recurrent otitis media and subsequent hearing loss are frequent with cleft palate. Displacement of the maxillary arches and malposition of the teeth usually require orthodontic correction. Misarticulations and velopharyngeal dysfunction are often associated with cleft lip and palate and may be present or persist because of physiologic dysfunction, anatomic insufficiency, malocclusion, or inadequate surgical closure of the palate. Such speech is characterized by the emission of air from the nose and by a hypernasal quality with certain sounds, or by compensatory misarticulations (glottal stops). Before and sometimes after palatal surgery, the speech defect is caused by inadequacies in function of the palatal and pharyngeal muscles. The muscles of the soft palate and the lateral and posterior walls of the nasopharynx constitute a valve that separates the nasopharynx from the oropharynx during swallowing and in the production of certain sounds. If the valve does not function adequately, it is difficult to build up enough pressure in the mouth to make such explosive sounds as p, b, d, t, h, y, or the sibilants s, sh, and ch, and such words as “cats,” “boats,” and “sisters” are not intelligible. After operation or the insertion of a speech appliance, speech therapy is necessary.

Velopharyngeal Dysfunction

The speech disturbance characteristic of the child with a cleft palate can also be produced by other osseous or neuromuscular abnormalities where there is an inability to form an effective seal between oropharynx and nasopharynx during swallowing or phonation. In a child who has the potential for abnormal speech, adenoidectomy can precipitate overt hypernasality. If the neuromuscular function is adequate, compensation in palatopharyngeal movement might take place and the speech defect might improve, although speech therapy is necessary. In other cases, slow involution of the adenoids can allow gradual compensation in palatal and pharyngeal muscular function. This might explain why a speech defect does not become apparent in some children who have a submucous cleft palate or similar anomaly predisposing to palatopharyngeal incompetence.

Clinical Manifestations

Although clinical signs vary, the symptoms of velopharyngeal dysfunction are similar to those of a cleft palate. There may be hypernasal speech (especially noted in the articulation of pressure consonants such as p, b, d, t, h, v, f, and s); conspicuous constricting movement of the nares during speech; inability to whistle, gargle, blow out a candle, or inflate a balloon; loss of liquid through the nose when drinking with the head down; otitis media; and hearing loss. Oral inspection might reveal a cleft palate or a relatively short palate with a large oropharynx; absent, grossly asymmetric, or minimal muscular activity of the soft palate and pharynx during phonation or gagging; or a submucous cleft.

Velopharyngeal dysfunction may also be demonstrated radiographically. The head should be carefully positioned to obtain a true lateral view; one film is obtained with the patient at rest and another during continuous phonation of the vowel u as in “boom.” The soft palate contacts the posterior pharyngeal wall in normal function, whereas in velopharyngeal dysfunction such contact is absent.

In selected cases of velopharyngeal dysfunction, the palate may be retropositioned or pharyngoplasty may be performed using a flap of tissue from the posterior pharyngeal wall. Dental speech appliances have also been used successfully. The type of surgery used is best tailored to the findings on nasoendoscopy.

CHAPTER 337

Syndromes With Oral Manifestations

Vineet Dhar

Many syndromes have distinct or accompanying facial, oral, and dental manifestations (see Apert syndrome, Chapter 609.11 ; Crouzon disease, Chapter 609.11 ; Down syndrome, Chapter 98.2).

Osteogenesis imperfecta is often accompanied by effects on the teeth, termed **dentinogenesis imperfecta** (see Chapter 333 , Fig. 333.2). Depending on the severity of presentation, treatment of the dentition varies from routine preventive and restorative monitoring to covering affected posterior teeth with stainless steel crowns, to prevent further tooth loss and improve appearance. Dentinogenesis imperfecta can also occur in isolation without the bony effects.

Another syndrome, **cleidocranial dysplasia,** has orofacial features such as frontal bossing, hypoplastic maxilla, and supernumerary teeth. The primary teeth can be overretained, and the permanent teeth remain unerupted. Supernumerary teeth are common, especially in the premolar area. Extensive dental rehabilitation may be needed to correct severe tooth crowding and unerupted and supernumerary teeth.

Ectodermal dysplasias are a heterogeneous group of conditions in which oral manifestations range from little or no involvement (the dentition is completely normal) to cases in which the teeth can be totally or partially absent or malformed (Chapter 668). Because alveolar bone does not develop in the absence of teeth, the alveolar processes can be either totally or partially absent, and the resultant overclosure of the mandible causes the lips to protrude. Facial development is otherwise not disturbed. Teeth, when present, can range from normal to small and conical. If aplasia of the buccal and labial salivary glands is present, dryness and irritation of the oral mucosa can occur. People with ectodermal dysplasia might need partial or full dentures, even at a very young age. The vertical height between the jaws is thus restored, improving the position of the lips and facial contours, as well as restoring masticatory function.

Pierre Robin syndrome consists of micrognathia and is usually accompanied by a high arched or cleft palate (Fig. 337.1). The tongue is usually of normal size, but the floor of the mouth is foreshortened. The air passages can become obstructed, particularly on inspiration, usually requiring treatment to prevent suffocation. The infant should be maintained in a prone or partially prone position so that the tongue falls forward to relieve respiratory obstruction. Some patients require tracheostomy. Mandibular distraction procedures in the neonate can improve mandibular size, enhance respiration, and facilitate oral feedings.

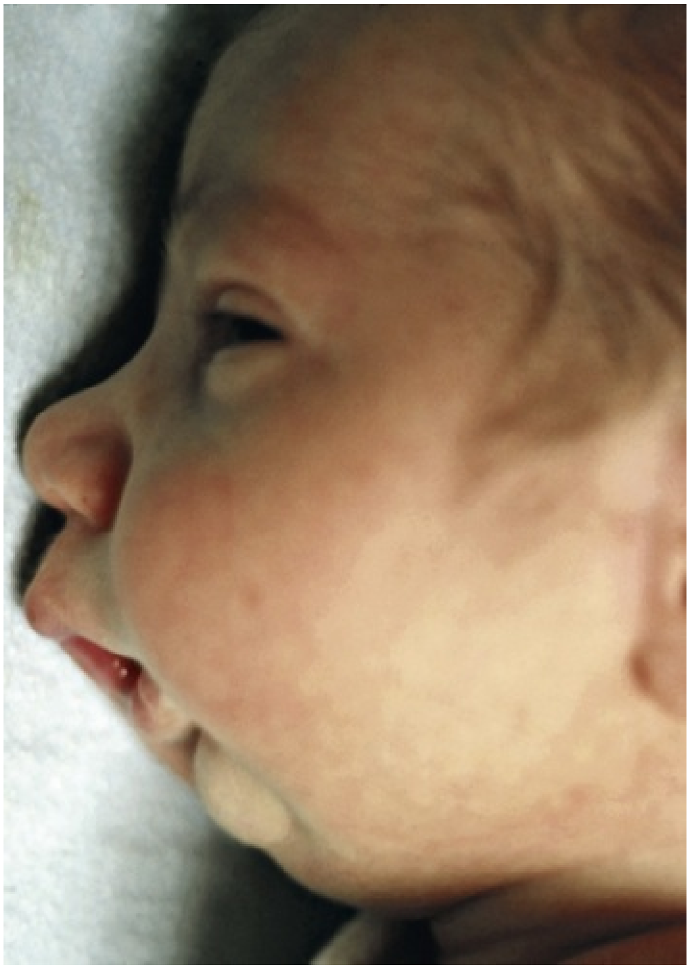

FIG. 337.1 Pierre Robin syndrome. (From Clark DA: *Atlas of neonatology,* ed 7, Philadelphia, 2000, WB Saunders, p 144.)

Sufficient spontaneous mandibular growth can take place within a few months to relieve the potential airway obstruction. Often the growth of the mandible achieves a normal profile in 4-6 yr. Of children with Pierre Robin syndrome, 30–50% have **Stickler syndrome** (types I-VI), an autosomal dominant condition that includes other findings such as prominent joints, arthritis, hypotonia, hypermobile joints, mitral valve prolapse, hearing loss, spine problems (scoliosis, kyphosis, platyspondyly), and ocular problems (high myopia, glaucoma, cataracts, retinal detachment). Symptoms may vary greatly even with a family. Mutations are noted in the genes that produce collagen (*COL2A1* in most; *COL11A1* in others) in many, but not all, patients with Stickler syndrome. Other syndromes are associated with Pierre Robin syndrome, including 22Q11.2 deletion syndrome (velocardiofacial syndrome).

Mandibulofacial dysostosis (Treacher Collins syndrome or Franceschetti syndrome) is an autosomal dominant syndrome that primarily affects the face. The facial appearance varies but is characterized by downward-sloping palpebral fissures, colobomas of the lower eyelids, sunken cheekbones, blind fistulas opening between the angles of the mouth and the ears, deformed pinnae, atypical hair growth extending toward the cheeks, receding chin, and large mouth. Facial clefts, abnormalities of the ears, and deafness are common. The mandible is usually hypoplastic; the ramus may be deficient, and the coronoid and condylar processes are flat or even aplastic. The palatal vault may be either high or cleft. Dental malocclusions are common. The teeth may be missing, hypoplastic, or displaced or be in an open bite position. Initially, the primary concern is breathing and feeding problems. Surgery to restore normal structure of the face can be performed, which may include repair of cleft palate, zygomatic and orbit reconstruction, reconstruction of the lower eyelid, external ear reconstruction, and orthognathic surgery.

Hemifacial microsomia presentation can be quite variable but is usually characterized by unilateral hypoplasia of the mandible and can be associated with partial paralysis of the facial nerve, underdeveloped ear, and blind fistulas between the angles of the mouth and the ears. Severe facial asymmetry and malocclusion can develop because of the absence or hypoplasia of the mandibular condyle on the affected side. Congenital condylar deformity tends to increase with age. Early craniofacial surgery may be indicated to minimize the deformity. This disorder can be associated with ocular and vertebral anomalies (oculoauriculovertebral spectrum, including Goldenhar syndrome); therefore radiographs of the vertebrae and ribs should be considered to determine the extent of skeletal involvement.

CHAPTER 338

Dental Caries

Vineet Dhar

Etiology

The development of dental caries depends on interrelationships among the tooth surface, dietary carbohydrates, and specific oral bacteria. Organic acids produced by bacterial fermentation of dietary carbohydrates reduce the pH of dental plaque adjacent to the tooth to a point where demineralization occurs. The initial demineralization appears as an opaque **white spot lesion** on the enamel, and with progressive loss of tooth mineral, cavitation of the tooth occurs (Fig. 338.1).

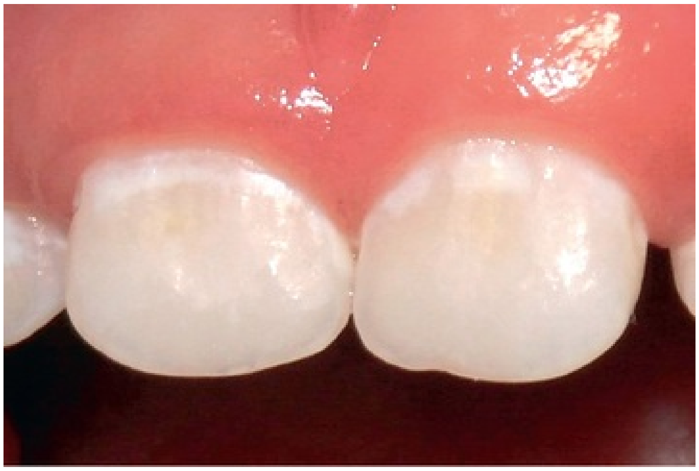

FIG. 338.1 Initial carious lesions (white spot lesions) around the necks of the maxillary central incisors.

The group of microorganisms, mutans streptococci, is associated with the development of dental caries. These bacteria have the ability to adhere to enamel, produce abundant acid, and survive at low pH. Once the enamel surface cavitates, other oral bacteria (lactobacilli) can colonize the tooth, produce acid, and foster further tooth demineralization. Demineralization from bacterial acid production is determined by the frequency of carbohydrate consumption and by the type of carbohydrate. Sucrose is the most cariogenic sugar because one of its by-products during bacterial metabolism is glucan, a polymer that enables bacteria to adhere more readily to tooth structures. Dietary behaviors, such as consuming sweetened beverages in a nursing bottle or frequently consuming sticky candies, increase the cariogenic potential of foods because of the long retention of sugar in the mouth.

Epidemiology

As per the 2011–2012 National Health and Nutrition Examination Survey (NHANES), approximately 15% of children ranging from 2 to 8 yr of age had one or more primary teeth affected by dental caries (Fig. 338.2). In the permanent dentition, over 10% of children aged 12-15 yr had dental caries and one-fourth of children were affected by age 16-19 yr (Fig. 338.3).

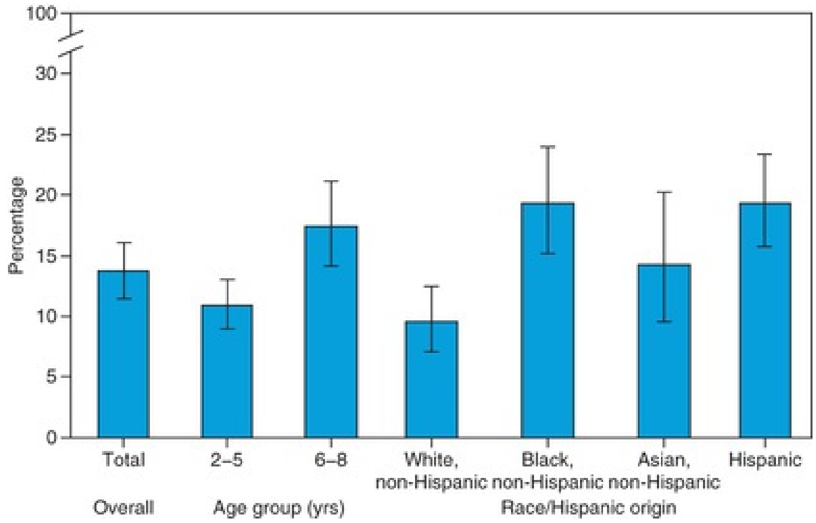

FIG. 338.2 Prevalence* of untreated dental caries† in primary teeth§ among children aged 2-8 yr, by age group and race/Hispanic origin—National Health and Nutrition Examination Survey, 2011-2014. *With 95% confidence intervals indicated with error bars. † Untreated dental caries is defined as tooth decay (dental cavities) that have not received appropriate treatment. Clinical Manifestations

Dental caries of the primary dentition usually begins in the pits and fissures.

Small lesions may be difficult to diagnose by visual inspection, but larger lesions are evident as darkened or cavitated lesions on the tooth surfaces (Fig. 338.4). Rampant dental caries in infants and toddlers, referred to as **early childhood caries** , is the result of early colonization of the child with cariogenic bacteria and the frequent ingestion of sugar, either in the bottle or in solid foods. The carious process in this situation is initiated earlier and consequently can affect the maxillary incisors first and then progress to the molars as they erupt.

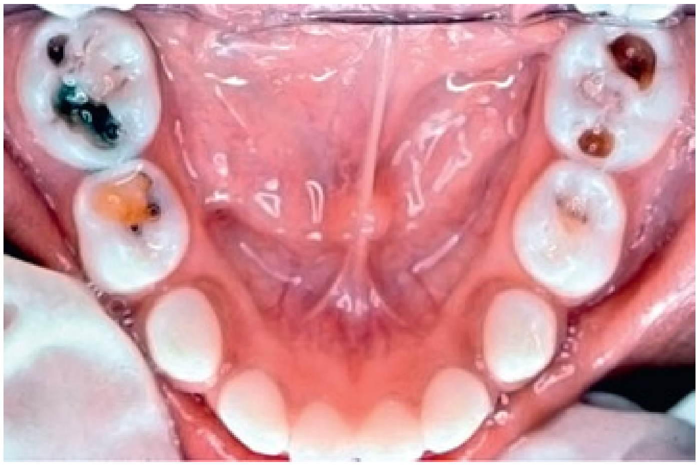

FIG. 338.4 **Rampant caries in a 3 yr old child. Note darkened and cavitated lesions on the fissure surfaces of mandibular molars.**

The prevalence of untreated caries was significantly higher in children between 3 and 9 yr of age living at or below 100% of federal poverty level compared with those above the poverty level. Besides high frequency of sugar consumption and colonization with cariogenic bacteria, other enabling factors include low socioeconomic status of the family, other family member with carious teeth, recent immigrant status of the child, and the visual presence of dental plaque on the child's teeth. Children who develop caries at a young age are known to be at high risk for developing further caries as they get older. Therefore the appropriate prevention of early childhood caries can result in the elimination of major dental problems in toddlers and less decay in later childhood.

Among adolescents, the prevalence of dental caries experience was higher in age group 16-19 yr (67%) compared with age group 12-15 yr (50%). Overall, the caries experience did not significantly differ by race, Hispanic origin, and poverty levels.

Complications

Left untreated, dental caries usually destroy most of the tooth and invade the dental pulp (Fig. 338.5), leading to an inflammation of the pulp **(pulpitis)** and significant pain. Pulpitis can progress to pulp necrosis, with bacterial invasion of the alveolar bone causing a **dental abscess** (Fig. 338.6). Red flags for serious spreading of dental infection are noted in Table 338.1 . Infection of a primary tooth can disrupt normal development of the successor permanent tooth. In some cases, this process leads to spread of infection to other facial spaces (Fig. 338.7).

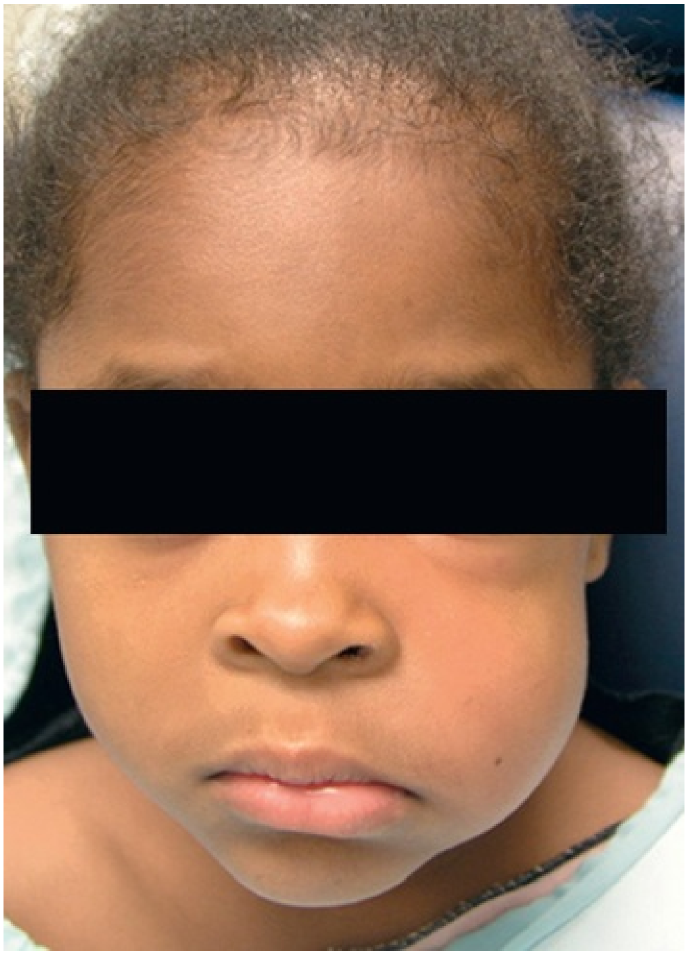

FIG. 338.6 **Facial swelling from an abscessed primary molar. Resolution of the inflammation can be achieved by a course of antibiotics, followed by either extraction or root canal of the offending tooth.**

Table 338.1

Red Flags Suggestive of a Spreading Dental Infection

• Pyrexia
• Tachycardia or tachypnea
• Trismus; may be relative due to pain or absolute due to a collection within the muscle causing muscle spasm in cases of masticator space involvement
• Raised tongue and floor of mouth, drooling
• Periorbital cellulitis
• Difficulty with speaking, swallowing, and breathing
• Hypotension
• Increased white blood cell count
• Lymphadenopathy
• Dehydration

FIG. 338.7 Spread of infection in the maxillofacial region is complicated by the variety of vital structures. Routes of spread are determined by fascial planes and this affects the presentation and management of each subdivision of cervicofacial infection. (From Robertson DP, Keys W, Rautemaa-Richardson R, et al: Management of severe acute dental infections. *BMJ* 350:h1300, 2015. Fig. 3, p. 151.)

Treatment

The age at which dental caries occurs is important in dental management. Children younger than 3 yr of age lack the developmental ability to cooperate with dental treatment and often require sedation or general anesthesia to repair carious teeth. After age 4 yr, children can generally cope with dental restorative care with the use of local anesthesia. Children with neurologic impairment or developmental delay may require general anesthesia for dental procedures at older ages.

Dental treatment, using silver amalgam, plastic composite, or stainless-steel crowns, can restore most teeth affected with dental caries. If caries involves the dental pulp, a partial removal of the pulp (pulpotomy) or complete removal of the pulp (pulpectomy) may be required. If a tooth requires extraction, a space maintainer may be indicated to prevent migration of teeth, which subsequently leads to malposition of permanent successor teeth.

Clinical management of the pain and infection associated with untreated dental caries varies with the extent of involvement and the medical status of the patient. Dental infection localized to the dentoalveolar unit can be managed by local measures (extraction, pulpectomy). Oral antibiotics are indicated for dental infections associated with fever, cellulitis, and facial swelling or if it is difficult to anesthetize the tooth in the presence of inflammation. Penicillin is the antibiotic of choice, except in patients with a history of allergy to this agent. Clindamycin and erythromycin are suitable alternatives. Oral analgesics, such as ibuprofen, are usually adequate for pain control.

Prevention

Dental caries screening, risk assessment, and preventive management in young children needs to be part of the scope of medical providers because children younger than 3 yr often are not under the care of a dentist. Prevention of early childhood caries is critical because, if primary dental care is not initiated or does not succeed, teeth may develop dental caries requiring restorative care. Dental restorative care to treat caries in young children may require the use of sedation or general anesthesia with its associated high costs and possible health risks, and there is high recurrence of carious lesions once they develop.

Because they are seeing infants and toddlers on a periodicity schedule, physicians have an important role in screening children younger than 3 yr of age for dental caries; providing preventive instructions; applying preventive measures, such as fluoride varnish; and referring the child to a dentist if problems exist.

Fluoride

The most effective preventive measure against dental caries is communal water supplies with optimal fluoride content. Water fluoridation at the level of 0.7-1.2

mg fluoride per liter (ppm F) was introduced in the United States in the 1940s. Because fluoride from water supplies is now one of several sources of fluoride, the Department of Health and Human Services proposes to not have a fluoride range, but instead to limit the recommendation to the lower limit of 0.7 ppm F. The rationale is to balance the benefits of preventing dental caries with reducing the chance of fluorosis. Children who reside in areas with fluoride-deficient water supplies or who consume primarily bottled water, and are at risk for caries, benefit from dietary fluoride supplements (Table 338.2). If the patient uses a private water supply, it is necessary to get the water tested for fluoride levels before prescribing fluoride supplements. To avoid potential overdoses, no fluoride prescription should be written for more than a total of 120 mg of fluoride. However, because of confusion regarding fluoride supplements among practitioners and parents, association of supplements with fluorosis, and lack of parent compliance with the daily administration, supplements may no longer be the first-line approach for preventing caries in preschool-aged children.

Table 338.2

Supplemental Fluoride Dosage Schedule

AGE	FLUORIDE IN HOME WATER		
	<0.3 (PPM)	**0.3-0.6 (PPM)**	**>0.6 (PPM)**
6 mo-3 yr	0.25*	0	0
3-6 yr	0.50	0.25	0
6-16 yr	1.00	0.50	0

* Milligrams of fluoride per day.

Topical fluoride on a daily basis can be achieved by using fluoridated toothpaste. Supervised use of less than a *pea-sized* amount of toothpaste (approximately 0.25 g) on the toothbrush in children between 3 and 6 yr of age reduces the risk of fluorosis. Children younger than 3 yr of age should brush with less than a *smear or grain-sized* amount of fluoridated toothpaste. Professional topical fluoride applications performed semiannually reportedly reduce caries by approximately 30%. Fluoride varnish is ideal for professional applications in preschool children because of ease of use, even with non–dental health providers, and its safety because of single-dose dispensers. Products that are available come in containers of 0.25, 0.4, or 0.6 mL of varnish, corresponding to 5.6, 9.0, and 13.6 mg fluoride, respectively. Fluoride varnish should be administered twice a year for preschool children at moderate caries risk and 4 times a year for children at high caries risk.

Oral Hygiene

Daily brushing, especially with fluoridated toothpaste, helps to prevent dental caries. Most children younger than 8 yr of age do not have the coordination required for adequate tooth brushing. Accordingly, parents should assume responsibility for the child's oral hygiene, with the degree of parental involvement appropriate to the child's changing abilities.

Diet

Frequent consumption of sweetened fruit drinks is not generally recognized by parents for its high cariogenic potential. Consuming sweetened beverages in a nursing bottle or sippy cup should be discouraged and special efforts made to instruct parents that their child should consume sweetened beverages only at meal times and not exceed 6 oz/day.

Dental Sealant

Plastic dental sealants have been shown to be effective in preventing caries on the pit and fissure of the primary and permanent molars. Sealants are most effective when placed soon after teeth erupt and used in children with deep grooves and fissures in the molar teeth. Sealants have been shown to reduce caries incidence by 85% over 7 yr.

CHAPTER 339

Periodontal Diseases

Vineet Dhar

The periodontium includes the gingiva, alveolar bone, cementum, and periodontal ligament (see Fig. 338.5).

Gingivitis

Poor oral hygiene results in the accumulation of dental plaque at the tooth-gingival interface that activates an inflammatory response, expressed as localized or generalized reddening and swelling of the gingiva. More than half of American school children experience gingivitis. In severe cases, the gingiva spontaneously bleeds and there is oral malodor. Treatment is proper oral hygiene (careful tooth brushing and flossing); complete resolution can be expected. Fluctuations in hormonal levels during the onset of puberty can increase inflammatory responses to plaque. Gingivitis in healthy children is unlikely to progress to periodontitis (inflammation of the periodontal ligament resulting in loss of alveolar bone).

Aggressive Periodontitis in Children (Prepubertal Periodontitis)

Periodontitis in children before puberty is a rare disease that often begins between the time of eruption of the primary teeth and the age of 4 or 5 yr. The disease occurs in localized and generalized forms. There is rapid bone loss, often leading to premature loss of primary teeth. It is often associated with systemic problems, including neutropenia, leukocyte adhesion or migration defects, hypophosphatasia, Papillon-Lefèvre syndrome, leukemia, and Langerhans cell histiocytosis. However, in many cases, there is no apparent underlying medical problem. Nonetheless, diagnostic workups are necessary to rule out underlying systemic disease.

Treatment includes aggressive professional teeth cleaning, strategic extraction of affected teeth, and antibiotic therapy. There are few reports of long-term successful treatment to reverse bone loss surrounding primary teeth.

Aggressive Periodontitis in Adolescents

Localized aggressive periodontitis (LAgP) in adolescents is characterized by rapid attachment and alveolar bone loss, on at least 2 first molars and incisors. Overall prevalence in the United States is <1%, but the prevalence among African Americans is reportedly 2.5%. This form of periodontitis is associated with a strain of *Aggregatibacter (Actinobacillus)* bacteria. In addition, the neutrophils of patients with aggressive periodontitis can have chemotactic or phagocytic defects. If left untreated, affected teeth lose their attachment and can exfoliate. Treatment varies with the degree of involvement. Patients whose disease is diagnosed at onset are usually managed by surgical or nonsurgical debridement in conjunction with antibiotic therapy. Prognosis depends on the degree of initial involvement and compliance with therapy.

Generalized aggressive periodontitis (GAgP) occurs more in adolescents and young adults and is characterized by generalized interproximal attachment loss and bone loss, including 3 teeth that are not first molars and incisors.

Cyclosporine- or Phenytoin-Induced Gingival Overgrowth

The use of cyclosporine to suppress organ rejection or phenytoin for anticonvulsant therapy, and in some cases calcium channel blockers, is associated with generalized enlargement of the gingiva. Phenytoin and its metabolites have a direct stimulatory action on gingival fibroblasts, resulting in accelerated synthesis of collagen. Phenytoin induces less gingival hyperplasia in patients who maintain meticulous oral hygiene.

Gingival hyperplasia occurs in 10–30% of patients treated with phenytoin. Severe manifestations can include gross enlargement of the gingiva, sometimes covering the teeth; edema and erythema of the gingiva; secondary infection, resulting in abscess formation; migration of teeth; and inhibition of exfoliation of primary teeth and subsequent impaction of permanent teeth. Treatment should be directed toward prevention and, if possible, discontinuation of cyclosporine or phenytoin. Patients undergoing long-term treatment with these drugs should receive frequent dental examinations and oral hygiene care. Severe forms of gingival overgrowth are treated by gingivectomy, but the lesion recurs if drug use is continued.

Acute Pericoronitis

Acute inflammation of the flap of gingiva that partially covers the crown of an incompletely erupted tooth is common in mandibular permanent molars. Accumulation of debris and bacteria between the gingival flap and tooth precipitates the inflammatory response. A variant of this condition is a gingival abscess caused by entrapment of bacteria because of orthodontic bands or crowns. Trismus and severe pain may be associated with the inflammation. Untreated cases can result in facial space infections and facial cellulitis.

Treatment includes local debridement and irrigation, warm saline rinses, and antibiotic therapy. When the acute phase has subsided, resection of the gingival flap prevents recurrence. Early recognition of the partial impaction of mandibular 3rd molars and their subsequent extraction prevents these areas from developing pericoronitis.

Necrotizing Periodontal Disease (Acute Necrotizing Ulcerative Gingivitis)

Necrotizing periodontal disease, in the past sometimes referred to as “trench mouth,” is a distinct periodontal disease associated with oral spirochetes and fusobacteria. However, it is not clear whether bacteria initiate the disease or are secondary. It rarely develops in healthy children in developed countries, with a prevalence in the United States of <1%, but is seen more often in children and adolescents from developing areas of Africa, Asia, and South America. In certain African countries, where affected children usually have protein malnutrition, the lesion can extend into adjacent tissues, causing necrosis of facial structures (cancrum oris, or noma).

Clinical manifestations of necrotizing periodontal disease include necrosis and ulceration of gingiva between the teeth, an adherent grayish pseudomembrane over the affected gingiva, oral malodor, cervical lymphadenopathy, malaise, and fever. The condition may be mistaken for acute herpetic gingivostomatitis. Dark-field microscopy of debris obtained from necrotizing lesions demonstrates dense spirochete populations.

Treatment of necrotizing periodontal disease is divided into an acute management with local debridement, oxygenating agents (direct application of 10% carbamide peroxide in anhydrous glycerol qid), and analgesics. Dramatic resolution usually occurs within 48 hr. If a patient is febrile, antibiotics (penicillin or metronidazole) may be an important adjunctive therapy. A second phase of treatment may be necessary if the acute phase of the disease has caused irreversible morphologic damage to the periodontium. The disease is not contagious.

CHAPTER 340

Dental Trauma

Vineet Dhar

Traumatic oral injuries may be categorized into 3 groups: injuries to teeth, injuries to soft tissue (contusions, abrasions, lacerations, punctures, avulsions, and burns), and injuries to jaw (mandibular and/or maxillary fractures).

Injuries to Teeth

Approximately 10% of children between 18 mo and 18 yr of age sustain significant tooth trauma. Oral injuries are second most common, covering 18% of all somatic injuries in the age group 0-6 yr. Among oral injuries, injuries to teeth are most common, followed by soft tissue injuries. There appear to be 3 age periods of greatest predilection: toddlers (1-3 yr), usually from falls or child abuse; school-age children (7-10 yr), usually from bicycle and playground accidents; and adolescents (16-18 yr), often the result of fights, athletic injuries, and automobile accidents. Injuries to teeth are more common among children with protruding front teeth. Children with craniofacial abnormalities or neuromuscular deficits are also at increased risk for dental injury. Injuries to teeth can involve the hard dental tissues, the dental pulp (nerve), and injuries to the periodontal structure (surrounding bone and attachment apparatus) (Fig. 340.1 ; Table 340.1).

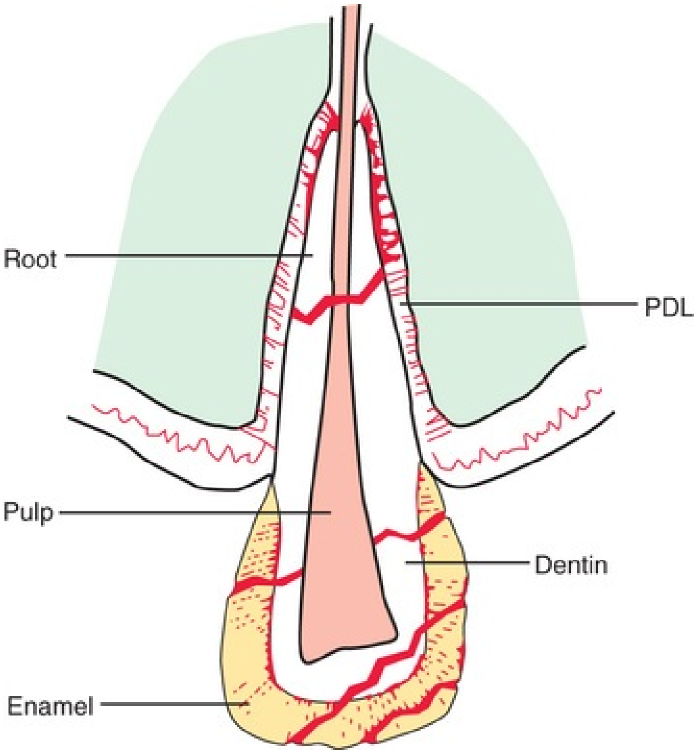

FIG. 340.1 Tooth fractures can involve enamel, dentin, or pulp and can occur in the crown or root of a tooth. *PDL,* periodontal ligament. (From Pinkham JR: *Pediatric dentistry: infancy through adolescence,* Philadelphia, 1988, WB Saunders, p. 172.)

Table 340.1

Injuries to Crowns of Teeth

TYPE OF TRAUMA	DESCRIPTION	TREATMENT AND REFERRAL
Enamel infraction (crazing)	Incomplete fracture of enamel without loss of tooth structure	Initially might not require therapy but should be assessed periodically by dentist
Enamel fractures	Fracture of only the tooth enamel	Tooth may be smoothed or treated to replace fragment
Enamel and dentin fracture	Fracture of enamel and dentinal layer of the tooth. Tooth may be sensitive to cold or air. Pulp may become necrotic, leading to periapical abscess	Refer as soon as possible. Area should be treated to preserve the integrity of the underlying pulp
Enamel, dentin fracture involving the pulp	Bacterial contamination can lead to pulpal necrosis and periapical abscess. The tooth might have the appearance of bleeding or might display a small red spot	Refer immediately. The dental therapy of choice depends on the extent of injury, the condition of the pulp, the development of the tooth, time elapsed from injury, and any other injuries to the supporting structures. Therapy is directed toward minimizing contamination in an effort to improve the prognosis

From Josell SD, Abrams RG: Managing common dental problems and emergencies. *Pediatr Clin North Am* 38:1325–1342, 1991.

Fractures of teeth may be uncomplicated (confined to the hard dental tissues) or complicated (involving the pulp). Exposure of the pulp results in its bacterial contamination, which can lead to infection and pulp necrosis. Such pulp exposure complicates therapy and can lower the likelihood of a favorable outcome.

The teeth most often affected are the maxillary incisors. Uncomplicated crown fractures are treated by covering exposed dentin and by placing an aesthetic restoration. Complicated crown fractures involving the tooth pulp usually require **endodontic therapy** (root canal). Crown-root fractures and root fractures usually require extensive dental therapy. Such injuries in the primary dentition can interfere with normal development of the permanent dentition, and therefore significant injuries of the primary incisor teeth are usually managed by extraction.

Traumatic oral injuries should be referred to a dentist as soon as possible. Even when the teeth appear intact, a dentist should promptly evaluate the patient. Baseline data (radiographs, mobility patterns, responses to specific stimuli) enable the dentist to assess the likelihood of future complications.

Injuries to Periodontal Structures

Trauma to teeth with associated injury to periodontal structures that hold the teeth usually manifests as mobile or displaced teeth. Such injuries are more common in the primary than in the permanent dentition. Categories of trauma to the periodontium include concussion, subluxation, intrusive luxation, extrusive luxation, and avulsion.

Concussion

Injuries that produce minor damage to the periodontal ligament are termed *concussions*. Teeth sustaining such injuries are not mobile or displaced but react markedly to percussion (gentle hitting of the tooth with an instrument). This type of injury usually requires no therapy and resolves without complication. Primary incisors that sustain concussion can change color, indicating pulpal degeneration, and should be evaluated by a dentist.

Subluxation

Subluxated teeth exhibit mild to moderate horizontal mobility and/or vertical mobility. Hemorrhage is usually evident around the neck of the tooth at the gingival margin. There is no displacement of the tooth. Many subluxated teeth need to be immobilized by splints to ensure adequate repair of the periodontal ligament. Some of these teeth develop pulp necrosis.

Intrusion

Intruded teeth are pushed up into their socket, sometimes to the point where they are not clinically visible. Intruded primary incisors can give the false appearance of being avulsed (knocked out). To rule out avulsion, a dental radiograph is indicated (Figs. 340.2 and 340.3).

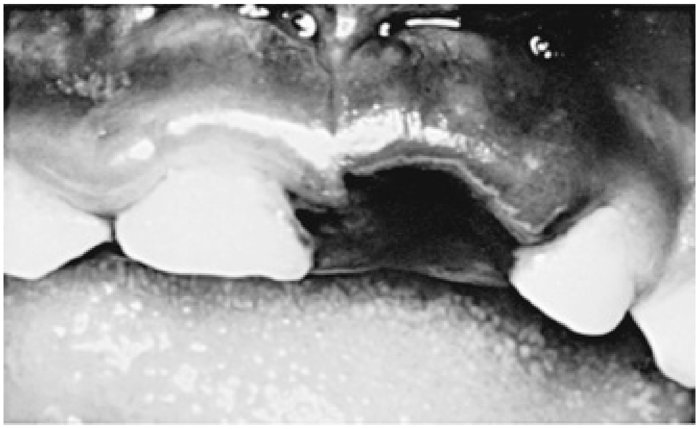

FIG. 340.2 Intruded primary incisor that appears avulsed (knocked out).

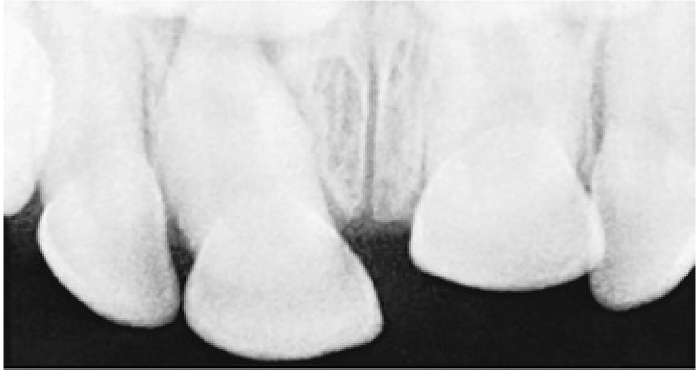

FIG. 340.3 Occlusal radiograph documents intrusion of "missing tooth" presented in Fig. 340.2 .

Extrusion

Extrusion injury is characterized by displacement of the tooth from its socket. The tooth is usually displaced to the lingual (tongue) side, with fracture of the wall of the alveolar socket. These teeth need immediate treatment; the longer the delay, the more likely the tooth will be fixed in its displaced position. Therapy is directed at reduction (repositioning the tooth) and fixation (splinting). The pulp of such teeth often becomes necrotic and requires endodontic therapy. Extrusive luxation in the primary dentition is usually managed by extraction because complications of reduction and fixation can result in problems with development of permanent teeth.

Avulsion

If avulsed permanent teeth are replanted as soon as possible after injury, there is a good chance that normal reattachment will follow and the tooth will have a good prognosis. However, if the tooth is in a dry environment for longer than 1 hr, the ligament that holds the tooth in place has little chance for survival and failure (root resorption, ankylosis) is common. Parents confronted with this emergency situation can be instructed to do the following:

◆ Find the tooth.
◆ Briefly rinse the tooth. (Do not scrub the tooth. Do not touch the root. After plugging the sink drain, hold

the tooth by the crown and rinse it under running tap water.)

- Insert the tooth into the socket. (Gently place it back into its normal position. Do not be concerned if the tooth extrudes slightly. If the parent or child is too apprehensive for replantation of the tooth, the tooth should be placed in cold cow's milk or other cold isotonic solution.)
- Go directly to the dentist. (In transit, the child should hold the tooth in its socket with a finger. The parent should place the child in an age-appropriate child seat, buckle a seatbelt around the child, and drive safely.)

After the tooth is replanted, it must be immobilized to facilitate reattachment; endodontic therapy is always required. The initial signs of complications associated with replantation can appear as early as 1 wk after trauma or as late as several years later. Close dental follow-up is indicated for at least 1 yr.

Prevention

To minimize the likelihood of dental injuries:

- Every child or adolescent who engages in contact sports should wear a **mouth guard** , which may be constructed by a dentist or purchased at any athletic goods store.
- Helmets with face guards should be worn by children or adolescents with neuromuscular problems

or seizure disorders to protect the head and face during falls.

- Helmets should also be used during biking, skiing, skating, and skateboarding.
- All children or adolescents with protruding incisors should be evaluated by a pediatric dentist or orthodontist.

Additional Considerations

Children who experience dental trauma might also have sustained head or neck trauma, and therefore neurologic assessment is warranted. Tetanus prophylaxis should be considered with any injury that disrupts the integrity of the oral tissues. The possibility of child abuse should always be considered.

CHAPTER 341

Common Lesions of the Oral Soft Tissues

Vineet Dhar

Oropharyngeal Candidiasis

Oropharyngeal infection with *Candida albicans* (thrush, moniliasis) (see Chapter 261.1) is common in neonates from contact with the organism in the birth canal or contact with the breast during breastfeeding. The lesions of oropharyngeal candidiasis (OPC) appear as white plaques covering all or part of the oropharyngeal mucosa. These plaques are removable from the underlying surface, which is characteristically inflamed and has pinpoint hemorrhages. The diagnosis is confirmed by direct microscopic examination on potassium hydroxide smears and culture of scrapings from lesions. OPC is usually self-limited in the healthy newborn infant, but topical application of nystatin to the oral cavity of the baby and to the nipples of breastfeeding mothers will hasten recovery.

OPC is also a major problem during myelosuppressive therapy. **Systemic candidiasis** , a major cause of morbidity and mortality during myelosuppressive therapy, develops almost exclusively in patients who have had prior oropharyngeal, esophageal, or intestinal candidiasis. This observation implies that prevention of OPC should reduce the incidence of systemic candidiasis. The use of oral rinses of 0.2% chlorhexidine gluconate solution along with systemic antifungals may be effective in preventing OPC, systemic candidiasis, or candidal esophagitis.

Aphthous Ulcers

The aphthous ulcer (canker sore) is a distinct oral lesion (Fig. 341.1), prone to recurrence; Table 341.1 notes the differential diagnosis. Aphthous ulcers are reported to develop in 20% of the population. Their etiology is unclear, but allergic or immunologic reactions, emotional stress, genetics, and injury to the soft tissues in the mouth have been implicated. Aphthous-like lesions may be associated with inflammatory bowel disease, Behçet disease, gluten-sensitive enteropathy, periodic fever-aphthae-pharyngitis-adenitis syndrome, Sweet syndrome, HIV infection (especially if ulcers are large and slow to heal), and cyclic neutropenia. Clinically, these ulcers are characterized by well-circumscribed, ulcerative lesions with a white necrotic base surrounded by a red halo. The lesions generally last 10-14 days and heal without scarring. Nonprescription palliative therapies, such as benzocaine and topical lidocaine, are effective, as are topical steroids. Tetracycline has benefit with severe outbreaks, but caution is necessary in pregnant women, since it is classified as FDA pregnancy category D. In younger children (≤8 yr), tetracycline can affect developing teeth and cause permanent staining of the teeth.

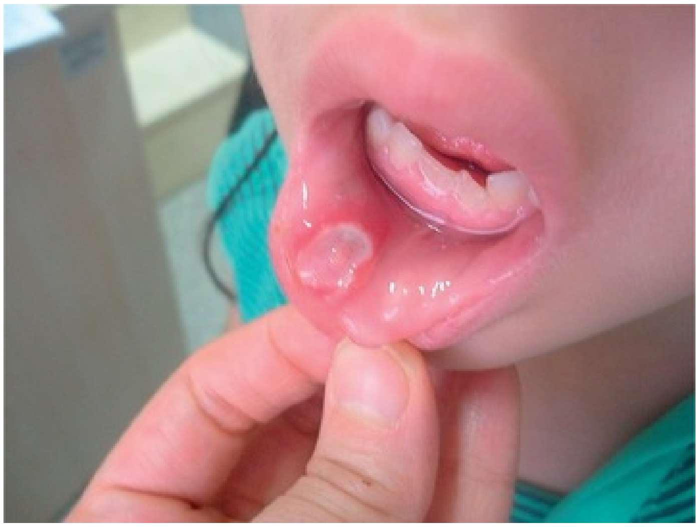

FIG. 341.1 **Major aphthous in a child. (From Gürkan A, Özlü SG, Altiaylik-Özer P, et al: Recurrent aphthous stomatitis in childhood and adolescence: a single-center experience. *Pediatr Dermatol* 32(4):476–480, 2015. Fig. 1.)**

Table 341.1

Differential Diagnosis of Oral Ulceration

CONDITION	COMMENT
Common	
Aphthous ulcers (canker sores)	Painful circumscribed lesions; recurrences
Traumatic ulcers	Accidents, chronic cheek biter, after dental local anesthesia
Hand, foot, and mouth disease	Painful; lesions on tongue, anterior oral cavity, hands, and feet
Herpangina	Painful; lesions confined to soft palate and oropharynx
Herpetic gingivostomatitis	Vesicles on mucocutaneous borders; painful, febrile
Recurrent herpes labialis	Vesicles on lips; painful
Chemical burns	Alkali, acid, aspirin; painful
Heat burns	Hot food, electrical
Uncommon	
Neutrophil defects	Agranulocytosis, leukemia, cyclic neutropenia; painful
Systemic lupus erythematosus	Recurrent; may be painless
Behçet syndrome	Resembles aphthous lesions; associated with genital ulcers, uveitis
Necrotizing ulcerative gingivostomatitis	Vincent stomatitis; painful
Syphilis	Chancre or gumma; painless
Oral Crohn disease	Aphthous-like; painful
Histoplasmosis	Lingual
Pemphigus	May be isolated to the oral cavity
Stevens-Johnson syndrome	May be isolated to or appear initially in the oral cavity

Herpetic Gingivostomatitis

After an initial incubation period of approximately 1 wk, the primary infection with herpes simplex virus manifests as fever and malaise, usually in a child younger than 5 yr (see Chapter 279). The oral cavity can show various expressions, including the gingiva becoming erythematous, mucosal hemorrhages, and clusters of small vesicles erupting throughout the mouth. There is often involvement of the mucocutaneous margin and perioral skin (Fig. 341.2). The oral symptoms generally are accompanied by fever, lymphadenopathy, and difficulty eating and drinking. The symptoms usually regress within 2 wk without scarring. Fluids should be encouraged because the child may become dehydrated. Analgesics and anesthetic rinses can make the child more comfortable. Oral acyclovir, if taken within the first 3 days of symptoms in immunocompetent patients, is beneficial in shortening the duration of symptoms. Caution should be exercised to prevent autoinoculation, especially of the eyes.

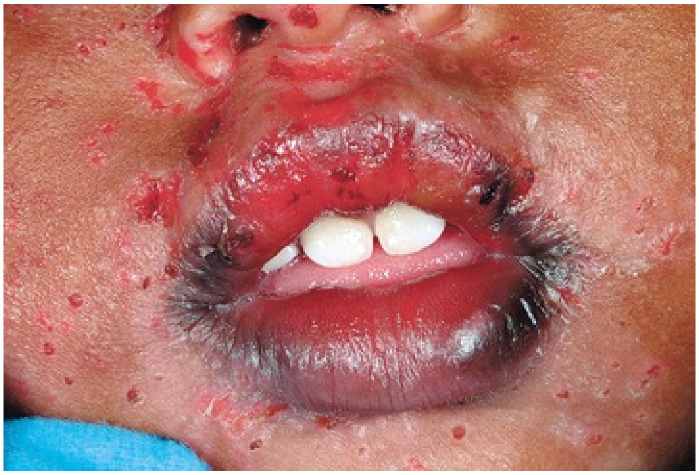

FIG. 341.2 Herpetic gingivostomatitis. Lip erosions with multiple perioral herpetic lesions involving the mucotaneous borders. (From Paller AS, Mancini AJ, editors: *Hurwitz clinical pediatric dermatology,* ed 3, Philadelphia, 2006, WB Saunders, p. 398.)

Recurrent Herpes Labialis

Approximately 90% of the worldwide population develops antibodies to herpes simplex virus. In periods of quiescence, the virus is thought to remain latent in sensory neurons. Unlike primary herpetic gingivostomatitis which manifests as multiple painful vesicles on the lips, tongue, palate, gingiva, and mucosa, recurrent herpes is generally limited to the lips. Other than the annoyance of causing pain and being a cosmetic issue, recurrent episodes generally do not involve systemic symptoms. Reactivation of the virus is thought to be the result of exposure to ultraviolet light, tissue trauma, stress, or fevers. There is little advantage of antiviral therapy over palliative therapies in an otherwise healthy patient affected by recurrent herpes.

Parulis

The parulis (gum boil) is a soft reddish papule located adjacent to the root of a chronically abscessed tooth. It occurs at the end-point of a draining dental sinus tract. Treatment consists of diagnosing which tooth is abscessed and extracting it or performing root canal treatment on the offending tooth.

Cheilitis

Cheilitis, dryness of the lips followed by scaling and cracking and accompanied by a characteristic burning sensation, is common in children. Cheilitis may be caused by sensitivity to contact substances, lip licking, vitamin deficiency, weakened immune system, or fungal or bacterial infections, and often occurs in association with fever. Treatment may include antifungal or antibacterial agents and frequent application of petroleum jelly.

Ankyloglossia

Ankyloglossia, or tongue-tie, is characterized by an abnormally short lingual frenum that can hinder the tongue movement, but rarely interferes with feeding or speech. It is possible that the frenum could spontaneously lengthen as the child gets older. If, in the rare event that the extent of the ankyloglossia is severe, speech may be affected and surgical correction may be indicated.

Geographic Tongue

Geographic tongue (migratory glossitis) is a benign and asymptomatic lesion that is characterized by one or more smooth bright red patches, often showing a yellow, gray, or white membranous margin on the dorsum of an otherwise normally roughened tongue. The condition has no known cause, and no treatment is indicated (see Chapter 684).

Fissured Tongue

The fissured tongue (scrotal tongue) is a malformation manifested clinically by numerous small furrows or grooves on the dorsal surface (see Chapter 684). If the tongue is painful, brushing the tongue or irrigating with water can reduce the bacteria in the fissures.

Developmental (Normal) Variations

Bohn Nodules

Bohn nodules are small developmental anomalies located along the buccal and lingual aspects of the mandibular and maxillary ridges and in the hard palate of the neonate. These lesions arise from remnants of mucous gland tissue. Treatment is not necessary as the nodules usually disappear within a few weeks.

Dental Lamina Cysts

Dental lamina cysts are small cystic lesions located along the crest of the mandibular and maxillary ridges of the neonate. These lesions arise from epithelial remnants of the dental lamina. Treatment is not necessary; they disappear within a few weeks.

Epstein Pearls

Epstein pearls are small developmental lesions located in the median palatal raphe region due to entrapment of epithelial remnants along the line of fusion of the palatal halves. Treatment is not necessary as these slough off on their own within a few weeks.

Fordyce Granules

Fordyce granules are common and almost 80% of adults have these yellow-white granules in clusters or plaque-like areas on the oral mucosa, most commonly on the buccal mucosa or lips. They are aberrant sebaceous glands. The glands are present at birth, but they can undergo hypertrophy and first appear as discrete yellowish papules during the preadolescent period in approximately 50% of children. No treatment is necessary.

CHAPTER 342

Diseases of the Salivary Glands and Jaws

Vineet Dhar

With the exception of mumps (see Chapter 275), diseases of the salivary glands are rare in children. Bilateral enlargement of the submaxillary glands can occur in HIV/AIDS, cystic fibrosis, Epstein-Barr virus infection, malnutrition, and transiently during acute asthmatic attacks. Chronic vomiting can be accompanied by enlargement of the parotid glands. Benign salivary gland hypertrophy has been associated with endocrinopathies: thyroid disease, diabetes, and Cushing syndrome. Infiltrative disease or tumors are uncommon; red flags include facial nerve palsy, rapid growth, fixed skin, paresthesias, ulceration, or a history of radiation to the head or neck region.

Parotitis

Acute parotitis is often caused by blockage, with further inflammation due to bacterial infection. The blockage may be due to a salivary stone or mucous plug. Stones can be removed by physical manipulation, surgery, or lithotripsy. **Recurrent parotitis** is an idiopathic swelling of the parotid gland that can occur in otherwise healthy children. The swelling is usually unilateral, but both glands can be involved simultaneously or alternately. There is little pain; the swelling is limited to the gland and usually lasts 2-3 wk. Treatment may include local heat, massaging the gland, and antibiotics. **Suppurative parotitis** is usually caused by *Staphylococcus aureus* . It is usually unilateral and may be accompanied by fever. The gland becomes swollen, tender, and painful. Suppurative parotitis responds to antibacterial therapy based on culture obtained from the Stensen duct or by surgical drainage. Viral causes of parotitis include mumps (often in epidemics), Epstein-Barr virus, human herpesvirus 6, enteroviruses, and HIV.

Ranula

A ranula is a cyst associated with a major salivary gland in the sublingual area. It is a large, soft, mucus-containing swelling in the floor of the mouth. It occurs at any age, including infancy. The cyst should be excised, and the severed duct should be exteriorized.

Mucocele

Mucocele is a salivary gland lesion caused by a blockage of a salivary gland duct. It is most common on the lower lip and has the appearance of a fluid-filled vesicle, or a fluctuant nodule with the overlying mucosa being normal in color. Treatment is surgical excision, with removal of the involved accessory salivary gland.

Congenital Lip Pits

Congenital lip pits are caused by fistulous tracts that lead to embedded mucous glands in the lower lip. They leak saliva, especially with salivary stimulation. Lip pits can be isolated anomalies, or they can be found in patients with cleft lip or palate. Treatment is surgical excision of the glandular tissue.

Eruption Cyst

Eruption cyst is a smooth painless swelling over the erupting tooth. If bleeding occurs in the cyst space, it may appear blue or blue-black. In most cases, no treatment is indicated and the cyst resolves with the full eruption of the tooth.

Xerostomia

Also known as dry mouth, xerostomia may be associated with fever, dehydration, anticholinergic drugs, chronic graft-versus-host disease, Mikulicz disease (leukemic infiltrates), Sjögren syndrome, or tumoricidal doses of radiation when the salivary glands are within the field. Long-term xerostomia is a high-risk factor for dental caries.

Salivary Gland Tumors

See Chapter 527 .

Histiocytic Disorders

See Chapter 534 .

Tumors of the Jaw

Ossifying fibroma is a common benign tumor of the jaw. It is often asymptomatic, being discovered on routine radiographic examinations. Treatment is resection due to the possibility of recurrence. **Central giant cell granuloma** is another common lesion thought to be reactive, rather than neoplastic. Although usually asymptomatic, it can be expansile, with or without resorption of the roots of teeth and perforation of the cortical plate. Treatment is complete curettage or surgical excision. **Dentigerous cysts** are common lesions associated with the crown of an impacted or unerupted tooth. Although usually asymptomatic, they can become large and destructive. Treatment is surgical removal.

The malignant primary tumors of the jaw in children include Burkitt lymphoma, osteogenic sarcoma, lymphosarcoma, ameloblastoma, and, more rarely, fibrosarcoma.

CHAPTER 343

Diagnostic Radiology in Dental Assessment

Vineet Dhar

Diagnostic dental radiology in children follows the As Low As Reasonably Achievable (ALARA) principle. In children, intraoral radiographs such as bitewings and select periapical radiographs are taken during routine dental visits, and repeated every 6 mo to 2 yr based on the caries risk assessment. Additional radiographs such as panoramic views, cephalometric radiographs, and dental cone beam computed tomography (CBCT) are taken when indicated. In general, the cumulative radiation exposure due to routine dental radiographs is minimal. In addition, precautions such as use of high-speed film, collimated beam, protective aprons and thyroid collars, proper technique, and minimizing number of exposures, are all taken to keep radiation exposure minimal.

Intraoral dental radiographs are highly detailed, direct-exposure films that demonstrate sections of the child's teeth and supporting bone structures. The film or image receptor is placed lingual to the teeth, and the x-ray beam is directed through the teeth and supporting structures. The resulting images are used to detect dental caries, loss of alveolar bone (periodontal disease), abscesses at the roots of the teeth, and trauma to the teeth and alveolar bone. These radiographs are also used to demonstrate the developmental status of permanent teeth within the bone.

The **panoramic radiograph** provides a single tomographic image of the upper and lower jaw, including all teeth and supporting structures. The x-ray tube rotates about the patient's head with reciprocal movement of the film or image receptor during the exposure. The panoramic image shows the teeth, mandibular bodies, rami, and condyles; maxillary sinuses; and a majority of the facial buttresses. Such images are used to show abnormalities of tooth number, development and eruption pattern, cystic and neoplastic lesions, bone infections, and fracture, as well as dental caries and periodontal disease (see Fig. 343.1).

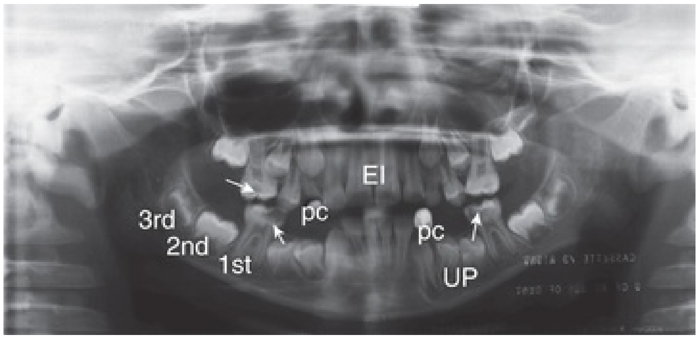

FIG. 343.1 **A panoramic radiograph of a 10 yr old child showing extensive dental caries of the 1st permanent molars *(arrows),* as well as normal structures: erupted 1st permanent molar, unerupted 2nd molar, and unerupted 3rd molar; erupted incisors *(EI)* , unerupted premolars *(UP),* and erupted primary canines *(pc).***

Cephalometric radiographs are posteroanterior and lateral skull films that are taken using a **cephalostat** (head positioner) and employ techniques that clearly demonstrate the facial skeleton and soft facial tissues. Similar protocols for positioning children are used throughout the world. From these images, cranial and facial points and planes can be determined and compared with standards derived from thousands of images. A child's facial growth can be assessed serially when cephalometric radiographs are taken sequentially. Relationships among the maxilla, mandible, cranial base, and facial skeleton can be determined in a quantitative manner. Additionally, the alignment of the teeth and the relation of the teeth to the supporting bone can be serially measured.

Dental CBCT is a variation of traditional computed tomography (CT), used mainly to evaluate oral and maxillofacial regions and teeth. Dental CBCT generally delivers lower radiation exposure than traditional CT, but higher than conventional dental radiography. There are several indications for CBCT, such as evaluation of oral-maxillofacial pathologies, diagnosis of dental trauma, endodontic treatment, visualization of abnormal teeth, orthodontic assessment, or cleft palate assessment, among others.

CHAPTER 344

Embryology, Anatomy, and Function of the Esophagus

Seema Khan, Sravan Kumar Reddy Matta

The esophagus is a hollow muscular tube, separated from the pharynx above and the stomach below by two tonically closed sphincters. Its primary function is to convey ingested material from the mouth to the stomach. Largely lacking digestive glands and enzymes, and exposed only briefly to nutrients, it has no active role in digestion.

Embryology

The esophagus develops from the postpharyngeal foregut and can be distinguished from the stomach in the 4 wk old embryo. At the same time, the trachea begins to bud just anterior to the developing esophagus; the resulting laryngotracheal groove extends and becomes the lung. Disturbance of this stage can result in congenital anomalies such as **tracheoesophageal fistula.** The length of the esophagus is 8-10 cm at birth and doubles in the first 2-3 yr of life, reaching approximately 25 cm in the adult. The abdominal portion of the esophagus is as large as the stomach in an 8 wk old fetus but gradually shortens to a few millimeters at birth, attaining a final length of approximately 3 cm by a few years of age. This intraabdominal location of both the distal esophagus and the **lower esophageal sphincter** (LES) is an important antireflux mechanism, because an increase in intraabdominal pressure is also transmitted to the sphincter, augmenting its defense. Swallowing can be seen in utero as early as 16-20 wk of gestation, helping to circulate the amniotic fluid; **polyhydramnios** is a hallmark of lack of normal swallowing or of esophageal or upper gastrointestinal tract obstruction. Sucking and swallowing are not fully coordinated before 34 wk of gestation, a contributing factor for feeding difficulties in premature infants.

Anatomy

The luminal aspect of the esophagus is covered by thick, protective, nonkeratinized stratified squamous epithelium, which abruptly changes to simple columnar epithelium at the stomach's upper margin at the **gastroesophageal junction (GEJ).** This squamous epithelium is relatively resistant to damage by gastric secretions (in contrast to the ciliated columnar epithelium of the respiratory tract), but chronic irritation by gastric contents can result in morphometric changes (thickening of the basal cell layer and lengthening of papillary ingrowth into the epithelium) and subsequent metaplasia of the cells lining the lower esophagus from squamous to columnar. Deeper layers of the esophageal wall are composed successively of lamina propria, muscularis mucosae, submucosa, and the two layers of muscularis propria (circular surrounded by longitudinal). The two delimiting sphincters of the esophagus, the **upper esophageal sphincter (UES)** at the cricopharyngeus muscle and the **LES** at the **GEJ,** constrict the esophageal lumen at its proximal and distal boundaries. The muscularis propria of the upper third of the esophagus is predominantly striated, and that of the lower two-thirds is smooth muscle. Clinical conditions involving striated muscle (cricopharyngeal dysfunction, cerebral palsy) affect the upper esophagus, whereas those involving smooth muscle (achalasia, reflux esophagitis) affect the lower esophagus. The muscular LES and the mucosal “Z-line” of the GEJ may be discrepant up to several centimeters.

Function

The esophagus can be divided into 3 areas: the UES, the esophageal body, and the LES. At rest, the tonic LES pressure is normally approximately 20 mm Hg; values <10 mm Hg are usually considered abnormal, although it seems that competence against retrograde flow of gastric material is maintained if the LES pressure is >5 mm Hg. The LES pressure rises during intragastric pressure amplifications, whether caused by gastric contractions, abdominal wall muscle contractions (“straining”), or external pressure applied to the abdominal wall. It also rises in response to cholinergic stimuli, gastrin, gastric alkalization, and certain drugs (bethanechol, metoclopramide, cisapride). The UES pressure is more variable and often higher than that of the LES; it decreases almost to zero during deep sleep and it increases markedly during stress and straining. The UES and LES relax briefly to allow material to pass through during swallowing, belching, reflux, and vomiting. They can contract in response to subthreshold levels of reflux (esophagoglottal closure reflex).

Swallowing is initiated by elevation of the tongue, propelling the bolus into the pharynx. The larynx elevates and moves anteriorly, pulling open the relaxing UES, while the opposed aryepiglottic folds close. The epiglottis drops back to cover the larynx and direct the bolus over the larynx and into the UES. The soft palate occludes the nasopharynx. The primary peristalsis thus initiated is a contraction originating in the oropharynx that clears the esophagus aborally (Fig. 344.1). Oropharyngeal swallowing related dysfunction may occur at multiple levels (Table 344.1). The LES, tonically contracted as a barrier against gastroesophageal reflux (GER), relaxes as swallowing is initiated, at nearly the same time as the UES relaxation. The LES relaxation persists considerably longer, until the peristaltic wave traverses it and closes it. The normal esophageal peristaltic speed is approximately 3 cm/sec; the wave takes 4 sec or longer to traverse the 12 cm esophagus of a young infant and considerably longer in a larger child. Facial stimulation by a puff of air can induce swallowing and esophageal peristalsis in healthy young infants, a reflex termed the **Santmyer swallow.**

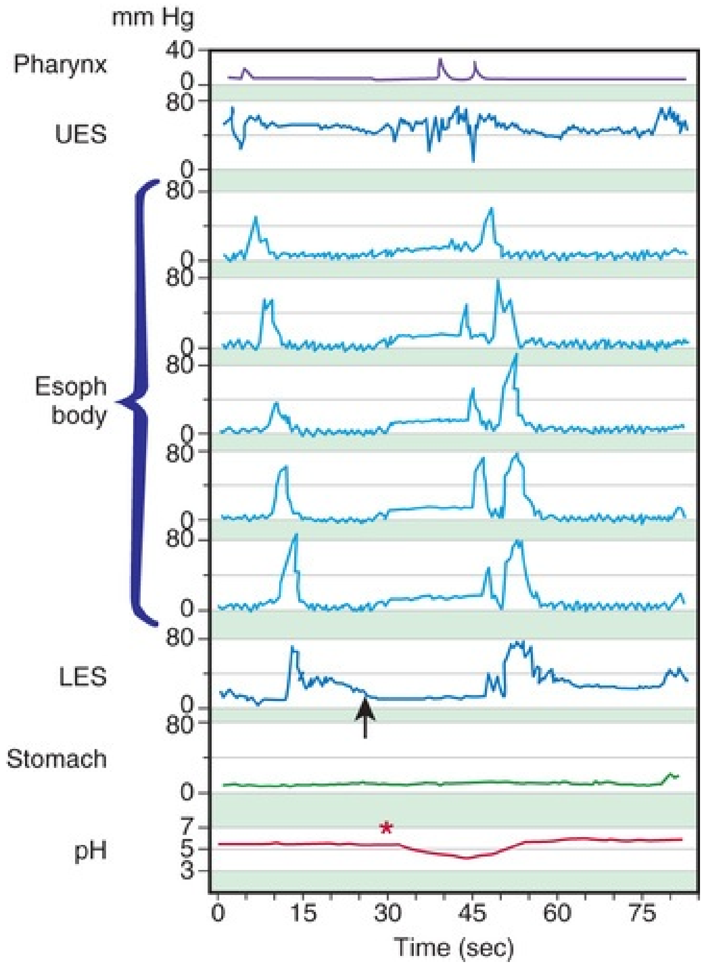

FIG. 344.1 A continuous tracing of esophageal motility showing 2 swallows, as indicated by the pharyngeal contraction associated with relaxation of the upper esophageal sphincter *(UES)* and followed by peristalsis in the body of the esophagus. The lower esophageal sphincter *(LES)* also displays a transient relaxation *(arrow)* unassociated with a swallow. There is an episode of gastroesophageal reflux *(*)* recorded by a *pH* probe at the time of the transient *LES* relaxation. (Courtesy John Dent, FRACP, PhD and Geoffrey Davidson, MD.)

Table 344.1

Mechanical Events of the Oropharyngeal Swallow and Evidence of Dysfunction

MECHANICAL EVENT	EVIDENCE OF DYSFUNCTION
Nasopharyngeal closure	Nasopharyngeal regurgitation Nasal voice
Laryngeal closure	Aspiration during bolus transit
Upper esophageal sphincter opening	Dysphagia Post-swallow residue/aspiration Diverticulum formation

Tongue loading and bolus propulsion	Sluggish misdirected bolus
Pharyngeal clearance	Post-swallow residue in hypopharynx/aspiration

Modified from Pandolfino JE, Kahrilas PJ: Esophageal neuromuscular function and motility disorders. In Feldman M, Friedman LS, Brandt LJ, editors: *Sleisenger and Fordtran's gastrointestinal and liver disease* , ed 10, New York, 2016, Elsevier (Table 43.1).

In addition to relaxing to move swallowed material past the GEJ into the stomach, the LES normally relaxes to vent swallowed air or to allow retrograde expulsion of material from the stomach. Perhaps as an extension of these functions, the normal LES also permits physiologic reflux episodes, brief events that occur approximately 5 times in the first postprandial hour, particularly in the awake state, but are otherwise uncommon. **Transient LES relaxation,** not associated with swallowing, is the major mechanism underlying **pathologic reflux** (see Fig. 344.1).

The close linkage of the anatomy of the upper digestive and respiratory tracts has mandated intricate functional protections of the respiratory tract during retrograde movement of gastric contents as well as during swallowing. The protective functions include the LES tone, the bolstering of the LES by the surrounding diaphragmatic crura, and the *backup protection* of the UES tone. Secondary peristalsis, akin to primary peristalsis but without an oral component, originates in the upper esophagus, triggered mainly by GER, and thereby also clears refluxed gastric contents from the esophagus. Another protective reflex is the *pharyngeal swallow* (initiated above the esophagus, but without lingual participation). Multiple levels of protection against aspiration include the rhythmic coordination of swallowing and breathing and a series of protective reflexes with esophagopharyngeal afferents and efferents that close the UES or larynx. These reflexes include the esophago-UES contractile reflex, the pharyngo-UES contractile reflex, the esophagoglottal closure reflex, and 2 pharyngoglottal adduction reflexes. The last 2 reflexes have chemoreceptors on the laryngeal surface of the epiglottis and mechanoreceptors on the aryepiglottic folds as their sites of stimulus. It is likely that interactions between the esophagus and the respiratory tract, which cause extraesophageal manifestations of gastroesophageal reflux disease (GERD), will be explained by subtle abnormalities in these protective reflexes.

344.1

Common Clinical Manifestations and Diagnostic Aids

Seema Khan, Sravan Kumar Reddy Matta

Keywords

dysphagia
radionuclide scintigraphy
high-resolution esophageal manometry
common clinical manifestations

Manifestations of esophageal disorders include pain, obstruction or difficulty swallowing, abnormal retrograde movement of gastric contents (reflux, regurgitation, or vomiting), or bleeding; esophageal disease can also engender respiratory symptoms. Pain in the chest unrelated to swallowing **(heartburn)** can be a sign of esophagitis, but similar pain might also represent cardiac, pulmonary, or musculoskeletal disease or visceral hyperalgesia. Pain during swallowing **(odynophagia)** localizes the disease more discretely to the pharynx and esophagus and often represents inflammatory mucosal disease. Complete esophageal obstruction can be produced acutely by esophageal foreign bodies, including food impactions; can be congenital, as in esophageal atresia; or can evolve over time as a peptic stricture occludes the esophagus. Difficulty swallowing **(dysphagia)** can be produced by incompletely occlusive esophageal obstruction (by extrinsic compression, intrinsic narrowing, or foreign bodies) but can also result from dysmotility of the esophagus (whether primary/idiopathic or secondary to systemic disease). Inflammatory lesions of the esophagus without obstruction or dysmotility are a third cause of dysphagia; eosinophilic esophagitis, most often afflicting older boys, is relatively common.

The most common esophageal disorder in children is **GERD,** which is from retrograde return of gastric contents into the esophagus. **Esophagitis** can be caused by GERD, by eosinophilic disease, by infection, or by caustic substances.

Esophageal **bleeding** can result from severe esophagitis that produces erosions or ulcerations and can manifest as anemia or Hemoccult-positive stools. More acute or severe bleeding can be from ruptured **esophageal varices.** The resulting hematemesis must be differentiated from more distal bleeding (gastric ulcer) and from more proximal bleeding (a nosebleed or hemoptysis). Respiratory symptoms of esophageal disease can result from luminal contents incorrectly being directed into the respiratory tract or to reflexive respiratory responses to esophageal stimuli.

Diagnostic Aids

The esophagus can be evaluated by radiography, endoscopy, histology, scintigraphy, manometry, pH-metry (linked as indicated with other polysomnography), and multichannel intraluminal impedance. Contrast (usually barium) radiographic study of the esophagus usually incorporates fluoroscopic imaging over time so that motility and anatomy can be assessed. Although most often requested to evaluate for GERD, it is neither sensitive nor specific for this purpose; it can detect complications of GERD (stricture) or conditions mimicking GERD (pyloric stenosis or malrotation with intermittent volvulus), or concurrent hiatal hernia complicating GERD.

Barium fluoroscopy is optimal for evaluating for structural anomalies, such as duplications, strictures, hiatal hernia, congenital esophageal stenosis or external esophageal compression by an aberrant blood vessel, or for causes of dysmotility, such as achalasia. Modifications of the routine barium fluoroscopic study are used in special situations. When an *H-type* tracheoesophageal fistula is suspected, the test is most sensitive if the radiologist, with the patient prone, distends the esophagus with barium via a nasogastric tube. The videofluoroscopic evaluation of swallowing performed with varying consistencies of barium (modified barium swallow, oropharyngeal videoesophagram, or cookie swallow) optimally evaluates children with dysphagia by demonstrating incoordination of the pharyngeal and esophageal phases of swallowing and any associated aspiration.

In some centers, fiberoptic endoscopic evaluation of swallowing uses nasopharyngeal endoscopy to visualize the pharynx and larynx during swallowing of dye-enhanced foods when dysphagia, laryngeal penetration, or aspiration is suspected. This is often combined with sensory testing of the laryngeal adductor reflex in response to a calibrated puff of air through the endoscope to the arytenoids, generating the composite fiberoptic endoscopic evaluation of swallowing sensory testing that examines the mechanisms of any aspiration that is present. Endoscopy allows direct visualization of esophageal mucosa and helps therapeutically in the removal of foreign bodies and treatment of esophageal varices. Endoscopy also allows biopsy samples to be taken, thus improving the diagnosis of **endoscopy-negative GERD** , differentiating GERD from eosinophilic esophagitis, and identifying viral or fungal causes of esophagitis.

Radionuclide scintigraphy scans are helpful in evaluating the efficiency of peristalsis and demonstrating reflux episodes. They can be specific, although not very sensitive, for aspiration and can quantify gastric emptying, thus hinting at a cause for GERD. The related radionuclide salivagram can demonstrate aspiration of even minute amounts of saliva.

Esophageal manometry evaluates for dysmotility from the pharynx to the stomach; by synchronized quantitative pressure measurements along the esophagus, it detects and characterizes dysfunctions sometimes missed radiographically. Manometry is often challenging in young infants, and sphincters are optimally evaluated with special Dent sleeves, rather than the simple ports available for the esophageal body. High-resolution esophageal manometry (HRM) along with video fluoroscopic swallowing study (VFSS) to evaluate UES relaxation, pharyngeal and peristaltic pressures is now available at a few centers of expertise.

Extended pH monitoring of the distal esophagus is a sensitive test for acidic GER episodes that can quantify duration and degree of acidity, but not volume, of the reflux episodes. It is linked with polysomnography (a pneumogram) when GER is suspected to cause apnea or similar symptoms. Multichannel intraluminal impedance is a method for pH-independent detection of bolus movements in the esophagus; with a pH probe incorporated, it can distinguish between acid and nonacid liquid and gaseous reflux, the proximal extent of reflux, and several aspects of esophageal function, such as direction of bolus flow, duration of bolus presence, and bolus clearance.

CHAPTER 345

Congenital Anomalies

345.1

Esophageal Atresia and Tracheoesophageal Fistula

Seema Khan, Sravan Kumar Reddy Matta

Keywords

VACTERL
polyhydramnios

Esophageal atresia (EA) is the most common congenital anomaly of the esophagus, with a prevalence of 1.7 per 10,000 live births. Of these, >90% have an associated tracheoesophageal fistula (TEF). In the most common form of EA, the upper esophagus ends in a blind pouch and the TEF is connected to the distal esophagus (type C). Fig. 345.1 shows the types of EA and TEF and their relative frequencies. The exact cause is still unknown; associated features include advanced maternal age, European ethnicity, obesity, low socioeconomic status, and tobacco smoking. This defect has survival rates of >90%, owing largely to improved neonatal intensive care, earlier recognition, and appropriate intervention. Infants weighing <1,500 g at birth and those with severe associated cardiac anomalies have the highest risk for mortality. Fifty percent of infants are nonsyndromic without other anomalies, and the rest have associated anomalies, most often associated with the vertebral, anorectal, (cardiac), tracheal, esophageal, renal, radial, (limb) (VACTERL) syndrome. Cardiac and vertebral anomalies are seen in 32% and 24%, respectively. VACTERL is generally associated with normal intelligence. Despite low concordance among twins and the low incidence of familial cases, genetic factors have a role in the pathogenesis of TEF in some patients as suggested by discrete mutations in syndromic cases: Feingold syndrome *(N-MYC)*, CHARGE syndrome (*c* oloboma of the eye; *c* entral nervous system anomalies; *h* eart defects; *a* tresia of the choanae; *r* etardation of growth and/or development; *g* enital and/or urinary defects [hypogonadism]; *e* ar anomalies and/or deafness) *(CHD7)*, and anophthalmia-esophageal-genital syndrome *(SOX2)*.

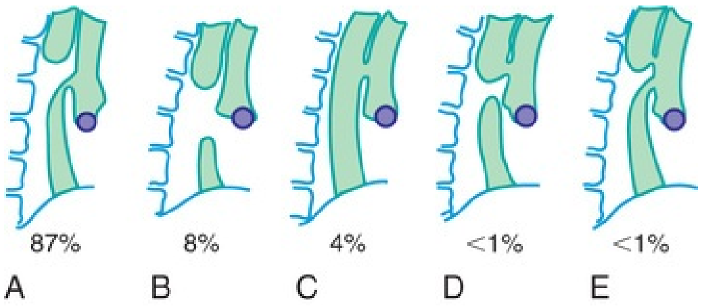

FIG. 345.1 Diagrams of the 5 most commonly encountered forms of esophageal atresia and tracheoesophageal fistula, shown in order of frequency.

Presentation

The neonate with EA typically has frothing and bubbling at the mouth and nose after birth as well as episodes of coughing, cyanosis, and respiratory distress. Feeding exacerbates these symptoms, causes regurgitation, and can precipitate aspiration. Aspiration of gastric contents via a distal fistula causes more damaging pneumonitis than aspiration of pharyngeal secretions from the blind upper pouch. The infant with an isolated TEF in the absence of EA (“H-type” fistula) might come to medical attention later in life with chronic respiratory problems, including refractory bronchospasm and recurrent pneumonias.

Diagnosis

In the setting of early-onset respiratory distress, the inability to pass a nasogastric or orogastric tube in the newborn suggests EA. Imaging findings of absence of the fetal stomach bubble and maternal polyhydramnios might alert the physician to EA before birth. Plain radiography in the evaluation of respiratory distress might reveal a coiled feeding tube in the esophageal pouch and/or an air-distended stomach, indicating the presence of a coexisting TEF (Fig. 345.2). Conversely, pure EA can manifest as an airless scaphoid abdomen. In isolated TEF (H type), an esophagogram with contrast medium injected under pressure can demonstrate the defect (Fig. 345.3). Alternatively, the orifice may be detected at bronchoscopy or when methylene blue dye injected into the endotracheal tube during endoscopy is observed in the esophagus during forced inspiration. The differential diagnosis of congenital esophageal lesions is noted in Table 345.1 .

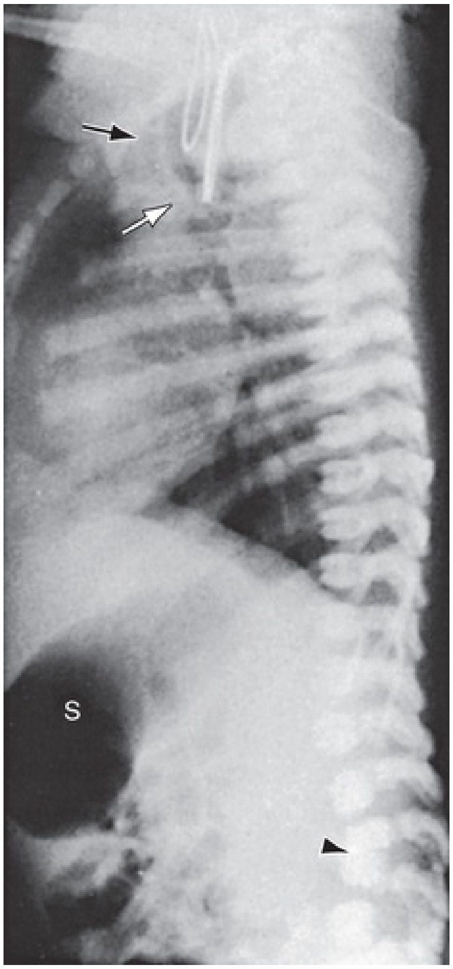

FIG. 345.2 Tracheoesophageal fistula. Lateral radiograph demonstrating a nasogastric tube coiled *(arrows)* in the proximal segment of an atretic esophagus. The distal fistula is suggested by gaseous dilation of the stomach *(S)* and small intestine. The *arrowhead* depicts vertebral fusion, whereas a heart murmur and cardiomegaly suggest the presence of a ventricular septal defect. This patient demonstrated elements of the vertebral, anorectal, tracheal, esophageal, renal, and radial anomalad. (From Balfe D, Ling D, Siegel M: The esophagus. In Putman CE, Ravin CE, editors: *Textbook of diagnostic imaging,* Philadelphia, 1988, WB Saunders.)

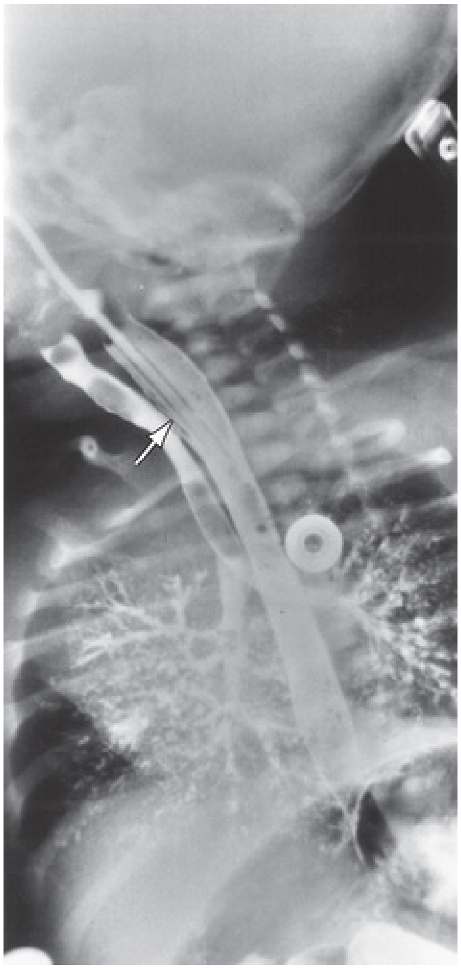

FIG. 345.3 H-type fistula *(arrow)* demonstrated in an infant after barium swallow on frontal-oblique chest x-ray. The tracheal aspect of the fistula is characteristically superior to the esophageal aspect. Barium is seen to outline the tracheobronchial tree. (From Wyllie R, Hyams JS, editors: *Pediatric gastrointestinal and liver disease,* ed 3, Philadelphia, 2006, Saunders Elsevier, p. 299.)

TEF, tracheoesophageal fistula.

From Madanick R, Orlando RC: Anatomy, histology, embryology, and developmental anomalies of the esophagus. In Feldman M, Friedman LS, Brandt LJ, editors: *Sleisenger and Fordtran's gastrointestinal and liver disease* , ed 10, New York, 2016, Elsevier, Table 42.2.

Management

Initially, maintaining a patent airway, pre-operative proximal pouch decompression to prevent aspiration of secretions, and use of antibiotics to prevent consequent pneumonia are paramount. Prone positioning minimizes movement of gastric secretions into a distal fistula, and esophageal suctioning minimizes aspiration from a blind pouch. Endotracheal intubation with mechanical ventilation is to be avoided if possible because it can worsen distention of the stomach. Surgical ligation of the TEF and primary end-to-end anastomosis of the esophagus via right-sided thoracotomy constitute the current standard surgical approach. In the premature or otherwise complicated infant, a primary closure may be delayed by temporizing with fistula ligation and gastrostomy tube placement. If the gap between the atretic ends of the esophagus is >3 to 4 cm (>3 vertebral bodies), primary repair cannot be done; options include using gastric, jejunal, or colonic segments interposed as a neoesophagus. Careful search must be undertaken for the common associated cardiac and other anomalies. Thoracoscopic surgical repair is feasible and associated with favorable long-term outcomes.

Outcome

The majority of children with EA and TEF grow up to lead normal lives, but complications are often challenging, particularly during the first 5 yr of life. Complications of surgery include anastomotic leak, refistulization, and anastomotic stricture. Gastroesophageal reflux disease, resulting from intrinsic abnormalities of esophageal function, often combined with delayed gastric emptying, contributes to management challenges in many cases. Gastroesophageal reflux disease contributes significantly to the respiratory disease **(reactive airway disease)** that often complicates EA and TEF and also worsens the frequent anastomotic strictures after repair of EA.

Many patients have an associated tracheomalacia that improves as the child grows. Hence, it is important to target on prevention of long-term complications using appropriate surveillance techniques (endoscopy, pH-Impedance).

345.2

Laryngotracheoesophageal Clefts

Seema Khan, Sravan Kumar Reddy Matta

Laryngotracheoesophageal clefts are uncommon anomalies that result when the septum between the esophagus and trachea fails to develop fully, leading to a common channel defect between the pharyngoesophagus and laryngotracheal lumen, thus making the laryngeal closure incompetent during swallowing or reflux. Other developmental anomalies, such as EA and TEF, are seen in 20% of patients with clefts. The severity of presenting symptoms depends on the type of cleft; they are commonly classified as four types (I-IV) according to the inferior extent of the cleft. Early in life, the infant presents with stridor, choking, cyanosis, aspiration of feedings, and recurrent chest infections. The diagnosis is difficult and usually requires direct endoscopic visualization of the larynx and esophagus. When contrast radiography is used, material is often seen in the esophagus and trachea. Treatment is surgical repair, which can be complex if the defects are long.

345.3

Congenital Esophageal Stenosis

Seema Khan, Sravan Kumar Reddy Matta

Keywords

total bronchial remnants (TBR)
bougie dilations

Congenital esophageal stenosis (CES) is a rare anomaly of the esophagus with clinical significance. Though the original incidence is not known, it is estimated to affect 1 : 25,000 to 50,000 live births. The defect results from incomplete separation of respiratory tract from the primitive foregut at 25th day of fetal life. CES is differentiated by histology into 3 types: esophageal membrane/web, total bronchial remnants (TBR), and fibromuscular remnants (FMR). Symptoms vary depending on the location and severity of the defect. Higher lesions present with respiratory symptoms and lower lesions present with dysphagia and vomiting. Esophagogram (Fig. 345.4), MRI, CT, and endoscopic ultrasound are used for diagnosis. Endoscopy (Fig. 345.5) is done to evaluate mucosal abnormalities like strictures, foreign bodies, and esophagitis. Treatment option (surgical correction, bougie dilation) is chosen based on the location, severity, and type of stenosis.

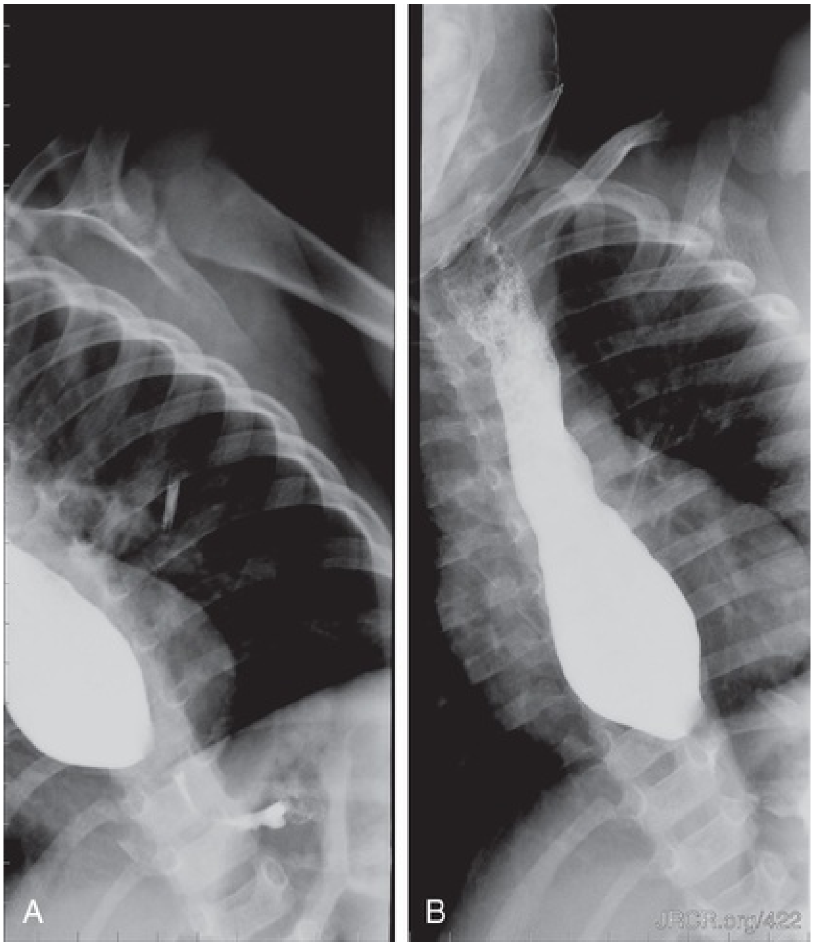

FIG. 345.4 An 18-month-old male with congenital esophageal stenosis. Esophagogram using barium as contrast media, shows an AP projection (A) and an unsuccessful attempt to obtain a lateral projection (B) , due to poor collaboration of the patient. An asymmetric short narrowing of the distal esophagus is observed, as well as proximal dilatation of the esophagus. Gastroesophageal reflux was not identified. (From Serrao E, Santos, A, Gaivao A: Congenital esophageal stenosis: a rare case of dysphagia, *J Radiol Case Rep* 4(6):8–14, 2010. Fig. 2).

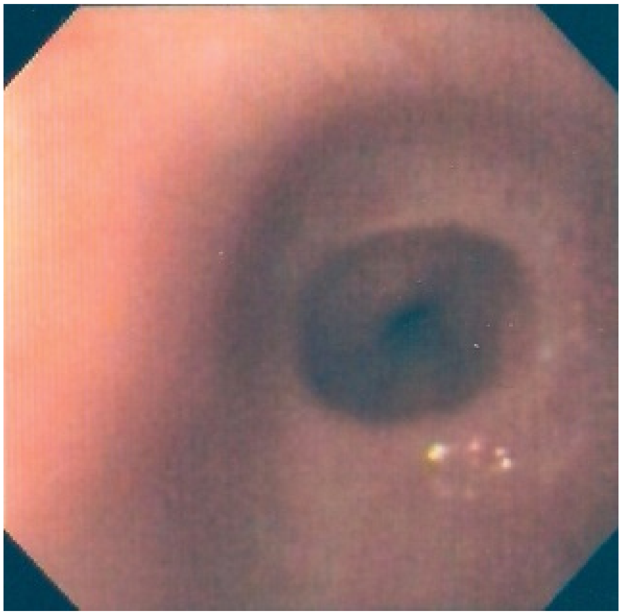

FIG. 345.5 An 18-month-old male with congenital esophageal stenosis. Esophagoscopy showed a circumferential, slightly non-central narrowing at the distal esophagus, 2 cm proximal to the esophagogastric junction. (From Serrao E, Santos, A, Gaivao A: Congenital esophageal stenosis: a rare case of dysphagia, *J Radiol Case Rep* 4(6):8–14, 2010. Fig. 3).

CHAPTER 346

Obstructing and Motility Disorders of the Esophagus

Seema Khan, Sravan Kumar Reddy Matta

Obstructing lesions classically produce **dysphagia** to *solids* earlier and more noticeably than to liquids and can manifest when the infant liquid diet begins to incorporate solids; this contrasts to **dysphagia** from **dysmotility,** in which swallowing of *liquids* is affected as early as, or earlier than, solids. In most instances of dysphagia, evaluation begins with fluoroscopy, which may include videofluoroscopic evaluation of swallowing, particularly if aspiration is a primary symptom. Secondary studies are often endoscopic if intrinsic obstruction is suspected or manometric if dysmotility is suspected; other imaging studies may be used in particular cases. Congenital lesions can require surgery, whereas webs and peptic strictures might respond adequately to endoscopic (or bougie) dilation. Peptic strictures, once dilated, should prompt consideration of fundoplication for ongoing prophylaxis.

Extrinsic

Esophageal duplication cysts are the most commonly encountered foregut duplications (see Table 345.1). These cysts are lined by intestinal epithelium, have a well-developed smooth muscle wall, and are attached to the normal gastrointestinal tract. Most of these affect the distal half of the esophagus on the right side. The most common presentation is respiratory distress caused by compression of the adjacent airways. Dysphagia is a common symptom in older children. Upper gastrointestinal bleeding can occur as a result of acid-secreting gastric mucosa in the duplication wall. **Neuroenteric cysts** might contain glial elements and are associated with **vertebral anomalies.** Diagnosis is made using modalities, such as barium swallow, chest CT, and MRI, or endosonography. Treatment is surgical; laparoscopic approach to excision is also possible.

Enlarged mediastinal or subcarinal **lymph nodes,** caused by infection (tuberculosis, histoplasmosis) or neoplasm (lymphoma), are the most common external masses that compress the esophagus and produce obstructive symptoms. **Vascular anomalies** can also compress the esophagus; *dysphagia lusoria* is a term denoting the dysphagia produced by a developmental vascular anomaly, which is often an aberrant right subclavian artery or right-sided or double aortic arch (see Chapter 459.1).

Intrinsic

Intrinsic narrowing of the esophageal lumen can be congenital or acquired. The etiology is suggested by the location, the character of the lesion, and the clinical situation. The lower esophagus is the most common location for peptic strictures, which are generally somewhat ragged and several cm long. Thin membranous rings, including the **Schatzki ring** at the squamocolumnar junction, can also occlude this area. In the midesophagus, congenital narrowing may be associated with the esophageal atresia–tracheoesophageal fistula complex, in which some of the lesions might incorporate cartilage and might be impossible to dilate safely; alternatively, reflux esophagitis can induce a ragged and extensive narrowing that appears more proximal than the usual peptic stricture, often because of an associated hiatal hernia. Congenital webs or rings can narrow the upper esophagus. The upper esophagus can also be narrowed by an inflammatory stricture occurring after a caustic ingestion or due to epidermolysis bullosa. Cricopharyngeal achalasia can appear radiographically as a cricopharyngeal bar posteriorly in the upper esophagus. **Eosinophilic esophagitis** is one of the most common causes for esophageal obstructive symptoms. Although the pathogenesis of obstructive eosinophilic esophagitis is not yet completely explained and seems to vary among individual patients, endoscopy or radiology demonstrates stricture formation in some children with eosinophilic esophagitis, and in others a noncompliant esophagus is evident, with thickened wall layers demonstrable by ultrasonography.

CHAPTER 347

Dysmotility

Seema Khan, Sravan Kumar Reddy Matta

Upper Esophageal and Upper Esophageal Sphincter Dysmotility (Striated Muscle)

Cricopharyngeal **achalasia** signifies a failure of complete relaxation of the upper esophageal sphincter (UES), whereas cricopharyngeal **incoordination** implies full relaxation of the UES but incoordination of the relaxation with the pharyngeal contraction. These entities are usually detected on videofluoroscopic evaluation of swallowing (sometimes accompanied by visible cricopharyngeal prominence, termed a *bar*), but often the most precise definition of the dysfunction is obtained with manometry. A self-limited form of cricopharyngeal incoordination occurs in infancy and remits spontaneously in the 1st yr of life if nutrition is maintained despite the dysphagia. In children, treatment options for non-self-limited cricopharyngeal achalasia consist of dilation, Botox injection, and transcervical myotomy. It is important to evaluate such children thoroughly, including cranial MRI to detect **Arnold-Chiari malformations,** which can manifest in this way but are best treated by cranial decompression rather than esophageal surgery. Cricopharyngeal spasm may be severe enough to produce posterior pharyngeal (**Zenker**) **diverticulum** above the obstructive sphincter; this entity occurs rarely in children.

Systemic causes of swallowing dysfunction that can affect the oropharynx, UES, and upper esophagus include cerebral palsy, Arnold-Chiari malformations, syringomyelia, bulbar palsy or cranial nerve defects (Möbius syndrome, transient infantile paralysis of the superior laryngeal nerve), transient pharyngeal muscle dysfunction, spinal muscular atrophy (including Werdnig-Hoffmann disease), muscular dystrophy, multiple sclerosis, infections (botulism, tetanus, poliomyelitis, diphtheria), inflammatory and autoimmune diseases (dermatomyositis, myasthenia gravis, polyneuritis, scleroderma), and familial dysautonomia. All of these can produce dysphagia. Medications (nitrazepam, benzodiazepines) and tracheostomy can adversely affect the function of the UES and thereby produce dysphagia.

Lower Esophageal and Lower Esophageal Sphincter Dysfunction (Smooth Muscle)

Causes of dysphagia resulting from more distal primary esophageal dysmotility include achalasia, diffuse esophageal spasm, nutcracker esophagus, and hypertensive lower esophageal sphincter (LES); all but achalasia are rare in children. Secondary causes include Hirschsprung disease, pseudoobstruction, inflammatory myopathies, scleroderma, and diabetes.

Achalasia is a primary esophageal motor disorder of unknown etiology characterized by loss of LES relaxation and loss of esophageal peristalsis, both contributing to a functional obstruction of the distal esophagus. Degenerative, autoimmune (antibodies to Auerbach plexus), and infectious (Chagas disease caused by *Trypanosoma cruzi*) factors are possible causes. In rare cases, achalasia is familial or part of the achalasia, alacrima, and adrenal insufficiency, known as triple A syndrome or **Allgrove syndrome** . *Pseudoachalasia* refers to achalasia caused by various forms of cancer via obstruction of the gastroesophageal junction, infiltration of the submucosa and muscularis of the LES, or as part of the paraneoplastic syndrome with formation of anti-Hu antibodies. Pathologically, in achalasia, inflammation surrounds ganglion cells, which are decreased in number. There is selective loss of postganglionic inhibitory neurons that normally lead to sphincter relaxation, leaving postganglionic cholinergic neurons unopposed. This imbalance produces high basal LES pressures and insufficient LES relaxation. The loss of esophageal peristalsis can be a secondary phenomenon.

Achalasia manifests with regurgitation and dysphagia for solids and liquids and may be accompanied by undernutrition or chronic cough; retained esophageal food can produce esophagitis. *The presentations of chronic* *regurgitation/vomiting with weight loss, and chronic cough have led to misdiagnoses of anorexia nervosa and asthma, respectively.* The mean age in children is 8.8 yr, with a mean duration of symptoms before diagnosis of 23 mo; it is uncommon before school age. Chest radiograph shows an air–fluid level in a dilated esophagus. **Barium fluoroscopy** reveals a smooth tapering of the lower esophagus leading to the closed LES, resembling a bird's beak (Fig. 347.1). Loss of primary peristalsis in the distal esophagus with retained food and poor emptying are often present. **Manometry** is the most sensitive diagnostic test and helps differentiate the three types of achalasia; it reveals the defining features of aperistalsis in the distal esophageal body and incomplete or absent LES relaxation, often accompanied by high-pressure LES and low-amplitude esophageal body contractions (Fig. 347.2).

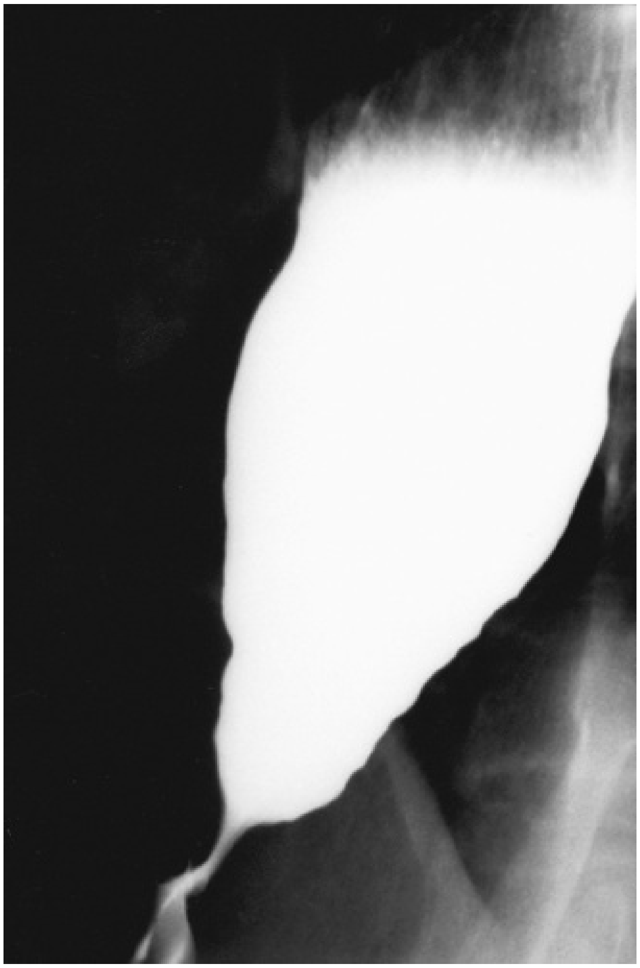

FIG. 347.1 Barium esophagogram of a patient with achalasia demonstrating dilated esophagus and narrowing at the lower esophageal

sphincter. Note retained secretions layered on top of barium in the esophagus.

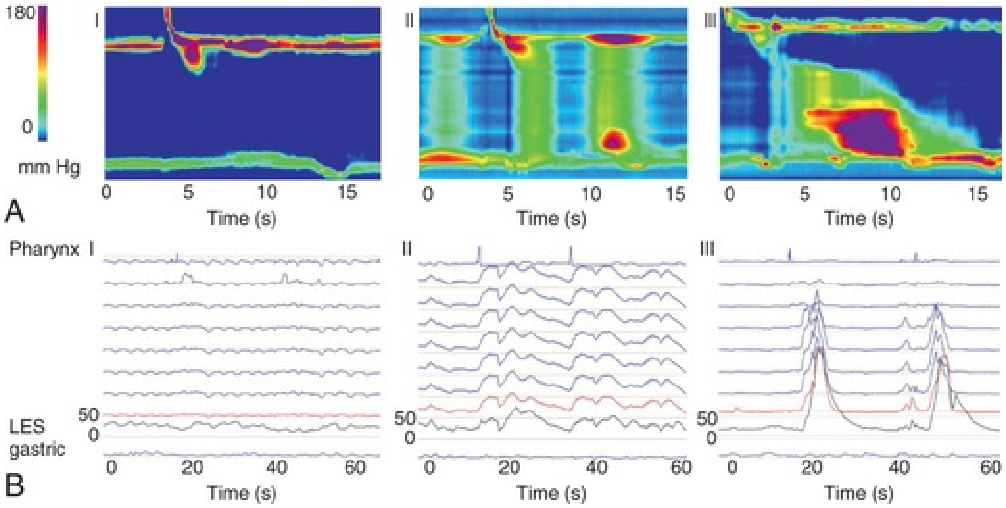

FIG. 347.2 **Based on the residual wave type on HRM, 3 subtypes of achalasia can be determined. A, No distal pressurization is observed in type I (AI), whereas panesophageal pressurizations and spastic contractions are observed in type II (AII) and type III (AIII), respectively. B, A similar classification can be made when conventional manometry is used. Note that pressure recordings in type II achalasia are similar in every line tracing, compatible with panesophageal pressurization. (From Rohof WO, Salvador R, Annese V: Outcomes of treatment for achalasia depend on manometric subtype. *Gastroenterology* 144(4): 718–725, 2013. Fig. 1).**

The goals of achalasia therapy are relief of symptoms, improvement of esophageal emptying, and prevention of megaesophagus. The two most effective treatment options are pneumatic dilation and laparoscopic or surgical (Heller) myotomy. Pneumatic dilation is the initial treatment of choice and does not preclude a future myotomy. Surgeons often supplement a myotomy with an antireflux procedure to prevent the gastroesophageal reflux disease that otherwise often ensues when the sphincter is rendered less competent. Laparoscopic myotomy is a particularly effective procedure in adolescent and young adult males. Peroral endoscopic myotomy (POEM) may be a feasible, safe, and an effective alternative to the laparoscopic method. Calcium channel blockers (nifedipine) and phosphodiesterase inhibitors offer temporary relief of dysphagia. Endoscopic injection of the LES with **botulinum toxin** counterbalances the selective loss of inhibitory neurotransmitters by inhibiting the release of acetylcholine from nerve terminals and may be an effective therapy. Botulinum toxin is effective in 50–65% of patients and is expensive;

half the patients might require a repeat injection within 1 yr. Most eventually require dilation or surgery.

Diffuse esophageal spasm causes chest pain and dysphagia and affects adolescents and adults. It is diagnosed **manometrically** and can be treated with nitrates or calcium-channel-blocking agents.

Gastroesophageal reflux disease constitutes the most common cause of nonspecific abnormalities of esophageal motor function, probably through the effect of the esophageal inflammation on the musculature.

CHAPTER 348

Hiatal Hernia

Seema Khan, Sravan Kumar Reddy Matta

Herniation of the stomach through the esophageal hiatus can occur as a common sliding hernia (type 1), in which the gastroesophageal junction slides into the thorax, or it can be paraesophageal (type 2), in which a portion of the stomach (usually the fundus) is insinuated next to the esophagus inside the gastroesophageal junction in the hiatus (Figs. 348.1 and 348.2). A combination of sliding and paraesophageal types (type 3) is present in some patients. Sliding hernias are often associated with gastroesophageal reflux, especially in developmentally delayed children. The relationship to hiatal hernias in adults is unclear. Diagnosis is usually made by an upper gastrointestinal series and upper endoscopy. Medical treatment is not directed at the hernia but at the gastroesophageal reflux, unless failure of medical therapy prompts correction of the hernia at the time of fundoplication.

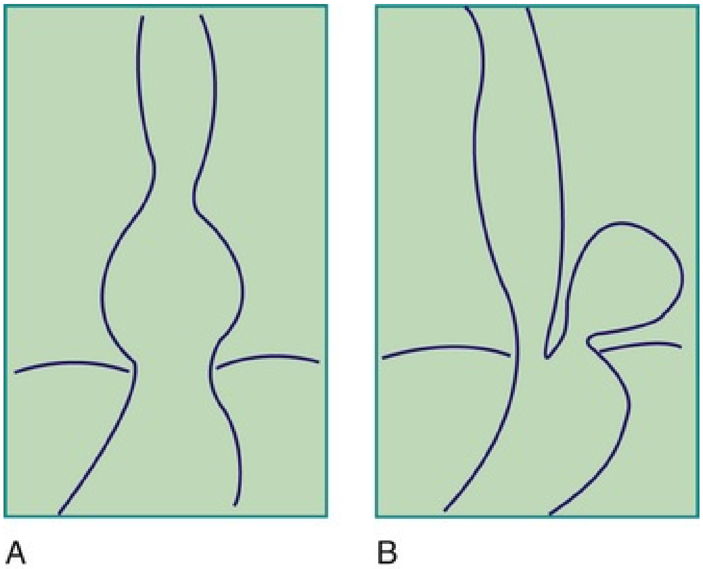

FIG. 348.1 **Types of esophageal hiatal hernia. A, Sliding hiatal hernia, the most common type. B, Paraesophageal hiatal hernia.**

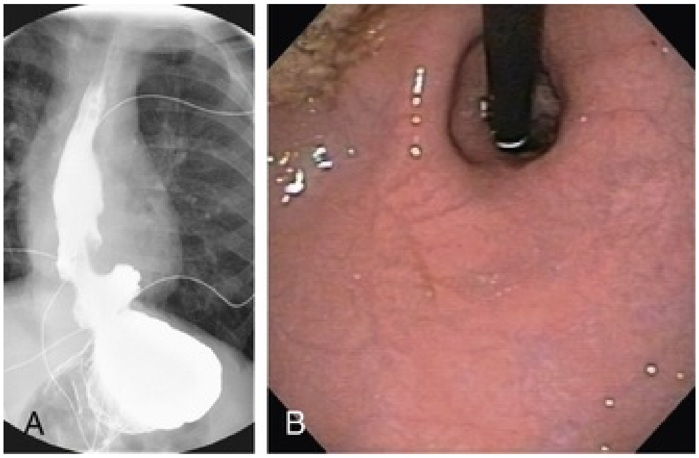

FIG. 348.2 **A,** An upper gastrointestinal series shows a large hiatal hernia that extends above the diaphragm and impedes the exit of contrast from the esophagus into the stomach. Contrast is also noted to reflux to the upper esophagus. **B,** A retroflexed view of the hernia from the stomach during an upper endoscopy.

A paraesophageal hernia can be an isolated congenital anomaly or associated with gastric volvulus, or it may be encountered after fundoplication for gastroesophageal reflux, especially if the edges of a dilated esophageal diaphragmatic hiatus have not been approximated. Fullness after eating and upper abdominal pain are the usual symptoms. Infarction of the herniated stomach is rare.

CHAPTER 349

Gastroesophageal Reflux Disease

Seema Khan, Sravan Kumar Reddy Matta

Gastroesophageal reflux disease (GERD) is the most common esophageal disorder in children of all ages. Gastroesophageal reflux (GER) signifies the retrograde movement of gastric contents across the lower esophageal sphincter (LES) into the esophagus, which occurs physiologically every day in all infants, older children, and adults. Physiologic GER is exemplified by the effortless regurgitation of normal infants. The phenomenon becomes **pathologic GERD** in infants and children who manifest or report bothersome symptoms because of frequent or persistent GER, producing esophagitis-related symptoms, or extra-esophageal presentations, such as respiratory symptoms or nutritional effects.

Pathophysiology

Factors determining the esophageal manifestations of reflux include the duration of esophageal exposure (a product of the frequency and duration of reflux episodes), the causticity of the refluxate, and the susceptibility of the esophagus to damage. The LES, defined as a high-pressure zone by manometry, is supported by the crura of the diaphragm at the gastroesophageal junction, together with valve-like functions of the esophagogastric junction anatomy, form the antireflux barrier. In the context of even the normal intraabdominal pressure augmentations that occur during daily life, the frequency of reflux episodes is increased by insufficient LES tone, by abnormal frequency of LES relaxations, and by hiatal herniation that prevents the LES pressure from being proportionately augmented by the crura during abdominal straining. Normal intraabdominal pressure augmentations may be further exacerbated by straining or respiratory efforts. The duration of reflux episodes is increased by lack of swallowing (e.g., during sleep) and by defective esophageal peristalsis. Vicious cycles ensue because chronic esophagitis produces esophageal peristaltic dysfunction (low-amplitude waves, propagation disturbances), decreased LES tone, and inflammatory esophageal shortening that induces hiatal herniation, all worsening reflux.

Transient LES relaxation (TLESR) is the primary mechanism allowing reflux to occur, and is defined as simultaneous relaxation of both LES and the surrounding crura. TLESRs occur independent of swallowing, reduce LES pressure to 0-2 mm Hg (above gastric), and last 10-60 sec; they appear by 26 wk of gestation. A vagovagal reflex, composed of afferent mechanoreceptors in the proximal stomach, a brainstem pattern generator, and efferents in the LES, regulates TLESRs. Gastric distention (postprandially, or from abnormal gastric emptying or air swallowing) is the main stimulus for TLESRs. Whether GERD is caused by a higher frequency of TLESRs or by a greater incidence of reflux during TLESRs is debated; each is likely in different persons. Straining during a TLESR makes reflux more likely, as do positions that place the gastroesophageal junction below the air–fluid interface in the stomach. Other factors influencing gastric pressure–volume dynamics, such as increased movement, straining, obesity, large-volume or hyperosmolar meals, gastroparesis, a large sliding hiatal hernia, and increased respiratory effort (coughing, wheezing) can have the same effect.

Epidemiology and Natural History

Infant reflux becomes evident in the first few mo of life, peaks at 4 mo, and resolves in up to 88% by 12 mo and in nearly all by 24 mo. *Happy spitters* are infants who have recurrent regurgitation *without* exhibiting discomfort or refusal to eat and failure to gain weight. Symptoms of GERD in **older children** tend to be chronic, waxing and waning, but completely resolving in no more than half, which resembles adult patterns (Table 349.1). The histologic findings of esophagitis persist in infants who have naturally resolving symptoms of reflux. GERD likely has genetic predispositions: family clustering of GERD symptoms, endoscopic esophagitis, hiatal hernia, Barrett esophagus, and adenocarcinoma have been identified. As a continuously variable and common disorder, complex inheritance involving multiple genes and environmental factors is likely. Genetic linkage is indicated by the strong evidence of GERD in studies with monozygotic twins. A pediatric autosomal dominant form with otolaryngologic and respiratory manifestations has been located to chromosome 13q14, and the locus is termed GERD1.

Table 349.1

Symptoms According to Age

MANIFESTATIONS	INFANTS	CHILDREN	ADOLESCENTS AND ADULTS
Impaired quality of life	+++	+++	+++
Regurgitation	++++	+	+
Excessive crying/irritability	+++	+	–
Vomiting	++	++	+
Food refusal/feeding disturbances/anorexia	++	+	+
Persisting hiccups	++	+	+
Failure to thrive	++	+	–

+++ , Very common; ++ common; + possible; (+) rare; − absent; ? unknown; *BRUE* , brief resolved unexplained event; previously called as *ALTE* , apparent life-threatening event.

From Wyllie R, Hyams JS, Kay M, editors: *Pediatric gastrointestinal and liver disease,* ed 4, Philadelphia, 2011, WB Saunders, Table 22.3, p. 235.

Clinical Manifestations

Most of the common clinical manifestations of esophageal disease can signify the presence of GERD and are generally thought to be mediated by the pathogenesis involving acid GER (Table 349.2). Although less noxious for the esophageal mucosa, nonacid reflux events are recognized to play an important role in extraesophageal disease manifestations. **Infantile reflux** manifests more often with regurgitation (especially postprandially), signs of esophagitis (irritability, arching, choking, gagging, feeding aversion), and resulting failure to thrive; symptoms resolve spontaneously in the majority of infants by 12-24 mo. **Older children** can have regurgitation during the preschool years; this complaint diminishes somewhat as children age, and complaints of abdominal and chest pain supervene in later childhood and adolescence. Occasional children present with food refusal or neck contortions (arching, turning of head) designated **Sandifer syndrome.** The respiratory presentations are also age dependent: GERD in infants may manifest as obstructive apnea or as stridor or lower airway disease in which reflux complicates primary airway disease such as laryngomalacia or bronchopulmonary dysplasia. Otitis media, sinusitis, lymphoid hyperplasia, hoarseness, vocal cord nodules, and laryngeal edema have all been associated with GERD. Airway manifestations in older children are more commonly related to asthma or to otolaryngologic disease such as laryngitis or sinusitis. Despite the high prevalence of GERD symptoms in asthmatic children, data showing direction of causality are conflicting.

Table 349.2

Symptoms and Signs That May Be Associated With Gastroesophageal Reflux

SYMPTOMS
Recurrent regurgitation with or without vomiting
Weight loss or poor weight gain
Irritability in infants
Ruminative behavior
Heartburn or chest pain
Hematemesis
Dysphagia, odynophagia
Wheezing
Stridor
Cough
Hoarseness
SIGNS
Esophagitis
Esophageal stricture
Barrett esophagus
Laryngeal/pharyngeal inflammation
Recurrent pneumonia
Anemia
Dental erosion
Feeding refusal
Dystonic neck posturing (Sandifer syndrome)

Apnea spells
Apparent life-threatening events

From Wyllie R, Hyams JS, Kay M, editors: *Pediatric gastrointestinal and liver disease,* ed 4, Philadelphia, 2011, WB Saunders, Table 22.1, p. 235.

Neurologically challenged children are one group that is recognized to be at an increased risk for GERD. It is not well established if the greater risk is conferred due to inadequate defensive mechanisms and/or inability to express symptoms. A low clinical threshold is important in the early identification and prompt treatment of GERD symptoms in these individuals.

Diagnosis

For most of the typical GERD presentations, particularly in older children, a thorough history and physical examination suffice initially to reach the diagnosis. This initial evaluation aims to identify the pertinent positives in support of GERD and its complications and the negatives that make other diagnoses unlikely. The history may be facilitated and standardized by questionnaires (e.g., the Infant Gastroesophageal Reflux Questionnaire, the I-GERQ, and its derivative, the I-GERQ-R), which also permit quantitative scores to be evaluated for their diagnostic discrimination and for evaluative assessment of improvement or worsening of symptoms. The clinician should be alerted to the possibility of other important diagnoses in the presence of any *alarm or warning signs* : bilious emesis, frequent projectile emesis, gastrointestinal bleeding, lethargy, organomegaly, abdominal distention, micro- or macrocephaly, hepatosplenomegaly, failure to thrive, diarrhea, fever, bulging fontanelle, and seizures. The important differential diagnoses to consider in the evaluation of an infant or a child with chronic vomiting are milk and other food allergies, eosinophilic esophagitis, pyloric stenosis, intestinal obstruction (especially malrotation with intermittent volvulus), nonesophageal inflammatory diseases, infections, inborn errors of metabolism, hydronephrosis, increased intracranial pressure, rumination, and bulimia. Focused diagnostic testing, depending on the presentation and the differential diagnosis, can then supplement the initial examination.

Most of the esophageal tests are of some use in particular patients with suspected GERD. **Contrast (usually barium) radiographic** study of the esophagus and upper gastrointestinal tract is performed in children with vomiting and dysphagia to evaluate for achalasia, esophageal strictures and stenosis, hiatal hernia, and gastric outlet or intestinal obstruction (Fig. 349.1). It has poor sensitivity and specificity in the diagnosis of GERD as a result of its limited duration and the inability to differentiate physiologic GER from GERD. Furthermore, contrast radiography neither accurately assesses mucosal inflammation nor correlates with severity of GERD.

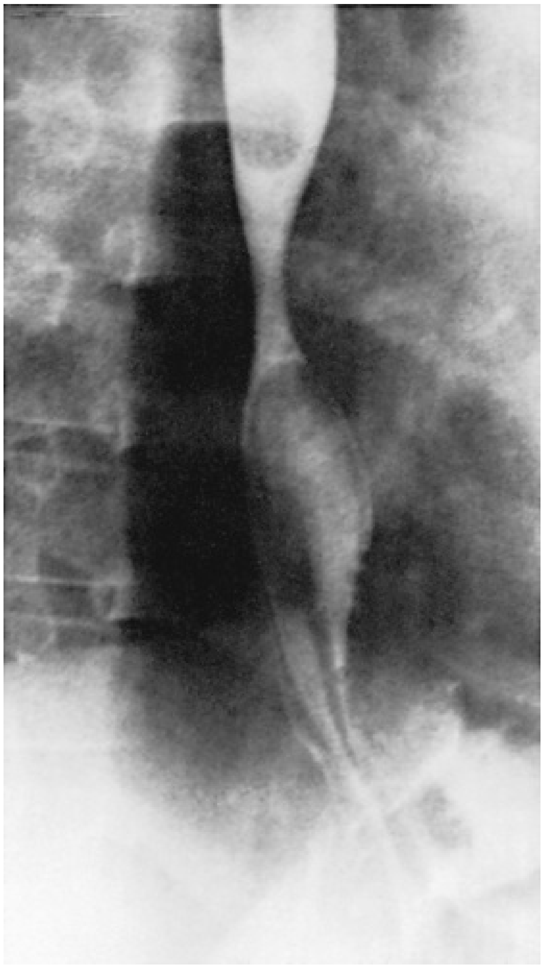

FIG. 349.1 **Barium esophagogram demonstrating free gastroesophageal reflux. Note stricture caused by peptic esophagitis. Longitudinal gastric folds above the diaphragm indicate the unusual presence of an associated hiatal hernia.**

Extended esophageal pH monitoring of the distal esophagus, no longer considered the *sine qua non* of a GERD diagnosis, provides a quantitative and sensitive documentation of acidic reflux episodes, the most important type of reflux episodes for pathologic reflux. The distal esophageal pH probe is placed at a level corresponding to 87% of the nares-LES distance, based on regression equations using the patient's height, on fluoroscopic visualization, or on manometric identification of the LES. Normal values of distal esophageal acid exposure (pH <4) are generally established as <5 to 8% of the total monitored time, but these quantitative normals are insufficient to establish or disprove a diagnosis of pathologic GERD. The most important indications for esophageal pH monitoring are for assessing efficacy of acid suppression during treatment, evaluating apneic episodes in conjunction with a pneumogram and perhaps impedance, and evaluating atypical GERD presentations such as chronic cough, stridor, and asthma. Dual pH probes, adding a proximal esophageal probe to the standard distal one, are used in the diagnosis of extraesophageal GERD, identifying upper esophageal acid exposure times of 1% of the total time as threshold values for abnormality.

Endoscopy allows diagnosis of erosive esophagitis (Fig. 349.2) and complications such as strictures or Barrett esophagus; esophageal biopsies can diagnose histologic reflux esophagitis in the absence of erosions while simultaneously eliminating allergic and infectious causes. Endoscopy is also used therapeutically to dilate reflux-induced strictures. Radionucleotide scintigraphy using technetium can demonstrate aspiration and delayed gastric emptying when these are suspected.

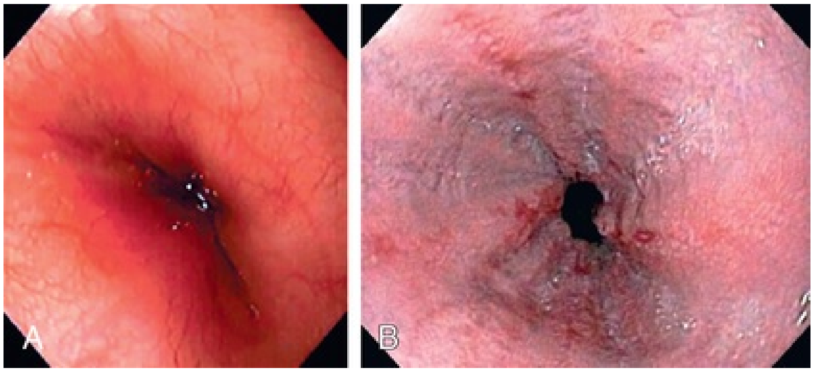

FIG. 349.2 Endoscopic image of a normal esophagus **(A)** and erosive peptic esophagitis **(B)** .

The multichannel **intraluminal impedance** is a cumbersome test, but with potential applications both for diagnosing GERD and for understanding esophageal function in terms of bolus flow, volume clearance, and (in conjunction with manometry) motor patterns associated with GERD. Owing to the multiple sensors and a distal pH sensor, it is possible to document acidic reflux (pH <4), weakly acidic reflux (pH 4-7), and weakly alkaline reflux (pH

>7) with multichannel intraluminal impedance. It is an important tool in those with respiratory symptoms, particularly for the determination of nonacid reflux, but must be cautiously applied in routine clinical evaluation because of limited evidence-based parameters for GERD diagnosis and symptom association.

Esophageal manometry is not useful in demonstrating gastroesophageal reflux but might be of use to evaluate transient LES relaxations and pressures.

Laryngotracheobronchoscopy evaluates for visible airway signs that are associated with extraesophageal GERD, such as posterior laryngeal inflammation and vocal cord nodules; it can permit diagnosis of silent aspiration (during swallowing or during reflux) by bronchoalveolar lavage with subsequent quantification of lipid-laden macrophages in airway secretions. Detection of pepsin in tracheal fluid is a marker of reflux-associated aspiration of gastric contents. Esophageal manometry permits evaluation for dysmotility, particularly in preparation for antireflux surgery.

Empirical antireflux therapy, using a time-limited trial of high-dose proton pump inhibitor (PPI), is a cost-effective strategy for diagnosis in adults; although not formally evaluated in older children, it has also been applied to this age group. Failure to respond to such empirical treatment, or a requirement for the treatment for prolonged periods, mandates formal diagnostic evaluation.

Management

Conservative therapy and lifestyle modifications that form the foundation of GERD therapy can be effectively implemented through education and reassurance for parents. Dietary measures for infants include normalization of any abnormal feeding techniques, volumes, and frequencies. Thickening of feeds or use of commercially prethickened formulas increases the percentage of infants with no regurgitation, decreases the frequency of daily regurgitation and emesis, and increases the infant's weight gain. However, caution should be exercised when managing preterm infants because of the possible association between xanthan gum-based thickened feeds and necrotizing enterocolitis. The evidence does not clearly favor 1 type of thickener over another; the addition of a Tbsp of rice or oat cereal per oz of formula results in a greater caloric density (30 kcal/oz) and reduced crying time, although it might not modify the number of nonregurgitant reflux episodes. Caution must be exercised while using rice cereal, as studies show increased risk of arsenic exposure in children with rice and rice product consumption. A short trial (2 wk) of a hypoallergenic diet in infants may be used to exclude milk or soy protein allergy before pharmacotherapy. A combination of modified feeding volumes, hydrolyzed infant formulas, proper positioning, and avoidance of smoke exposure satisfactorily improve GERD symptoms in 24–59% of infants with GERD. Older children should be counseled to avoid acidic or reflux-inducing foods (tomatoes, chocolate, mint) and beverages (juices, carbonated and caffeinated drinks, alcohol). Weight reduction for obese patients and elimination of smoke exposure are other crucial measures at all ages.

Positioning measures are particularly important for infants, who cannot control their positions independently. Seated position worsens infant reflux and should be avoided in infants with GERD. Esophageal pH monitoring demonstrates more reflux episodes in infants in supine and side positions compared with the prone position, but evidence that the supine position reduces the risk of sudden infant death syndrome has led the American Academy of Pediatrics and the North American Society of Pediatric Gastroenterology and Nutrition to recommend supine positioning during sleep. When the infant is awake and observed, prone position and upright carried position can be used to minimize reflux. Lying in the flat supine position and semi-seated positions (e.g., car seats, infant carriers) in the postprandial period are considered provocative positions for GER and therefore should be avoided. The efficacy of positioning for older children is unclear, but some evidence suggests a benefit to left side position and head elevation during sleep. The head should be elevated by elevating the head of the bed, rather than using excess pillows, to avoid abdominal flexion and compression that might worsen reflux.

Pharmacotherapy is directed at ameliorating the acidity of the gastric contents or at promoting their aboral movement and should be considered for those symptomatic infants and children who are either highly suspected or proven to have GERD. Antacids are the most commonly used antireflux therapy and are readily available over the counter. They provide rapid but transient relief of symptoms by acid neutralization. The long-term regular use of antacids cannot be recommended because of side effects of diarrhea (magnesium antacids) and constipation (aluminum antacids) and rare reports of more serious side effects of chronic use.

Histamine-2 receptor antagonists (H2RAs: cimetidine, famotidine, nizatidine, and ranitidine) are widely used antisecretory agents that act by selective inhibition of histamine receptors on gastric parietal cells. There is a definite benefit of H2RAs in treatment of mild-to-moderate reflux esophagitis.

H2RAs have been recommended as first-line therapy because of their excellent overall safety profile, but they are superseded by PPIs in this role, as increased experience with pediatric use and safety, FDA approval, and pediatric formulations and dosing are available.

PPIs (omeprazole, lansoprazole, pantoprazole, rabeprazole, and esomeprazole) provide the most potent antireflux effect by blocking the hydrogen–potassium adenosine triphosphatase channels of the final common pathway in gastric acid secretion. PPIs are superior to H2RAs in the treatment of severe and erosive esophagitis. Pharmacodynamic studies indicate that children require higher doses of PPIs than adults on a per-weight basis. The use of PPIs to treat infants and children deemed to have GERD on the basis of symptoms is common, however an important systematic review of the efficacy and safety of PPI therapy in pediatric GERD reveals no clear benefit for PPI over placebo use in suspected infantile GERD (crying, arching behavior). Limited pediatric data are available to draw definitive conclusions about potential complications implicated with PPI use, such as respiratory infections, *Clostridium difficile* infection, bone fractures (noted in adults), hypomagnesemia, and kidney damage.

Prokinetic agents available in the United States include metoclopramide (dopamine-2 and 5-HT$_3$ antagonist), bethanechol (cholinergic agonist), and erythromycin (motilin receptor agonist). Most of these increase LES pressure; some improve gastric emptying or esophageal clearance. None affects the frequency of TLESRs. The available controlled trials *have not* demonstrated much efficacy for GERD. In 2009, the FDA announced a black box warning for metoclopramide, linking its chronic use (longer than 3 mo) with tardive dyskinesia, the rarely reversible movement disorder. Baclofen is a centrally acting γ-aminobutyric acid agonist that decreases reflux by decreasing TLESRs in healthy adults and in a small number of neurologically impaired children with GERD. Other agents of interest include peripherally acting γ-aminobutyric acid agonists devoid of central side effects, and metabotropic glutamate receptor 5 antagonists that are reported to reduce TLESRs but are as yet inadequately studied for this indication in children.

Cisapride is a serotonergic-receptor agonist with prokinetic effect that is only available in the United States through a limited access program because of its cardiac side effects (QT prolongation, dysrhythmias).

Surgery, usually **fundoplication,** is effective therapy for intractable GERD in children, particularly those with refractory esophagitis or strictures and those at risk for significant morbidity from chronic pulmonary disease. It may be combined with a gastrostomy for feeding or venting. The availability of potent acid-suppressing medication mandates more-rigorous analysis of the relative risks (or costs) and benefits of this relatively irreversible therapy in comparison to long-term pharmacotherapy. Some of the risks of fundoplication include a wrap that is *too tight* (producing dysphagia or gas-bloat) or *too loose* (and thus incompetent). Surgeons may choose to perform a *tight* (360 degrees, Nissen) or variations of a *loose* (<360 degrees, Thal, Toupet, Boix-Ochoa) wrap, or to add a gastric drainage procedure (pyloroplasty) to improve gastric emptying, based on their experience and the patient's disease. Preoperative accuracy of diagnosis of GERD and the skill of the surgeon are two of the most important predictors of successful outcome. Long-term studies suggest that fundoplications often become incompetent in children, as in adults, with reflux recurrence rates of up to 14% for Nissen and up to 20% for loose wraps (the rates may be highest with laparoscopic procedures); this fact currently combines with the potency of PPI therapy that is available to shift practice toward long-term pharmacotherapy in many cases. Fundoplication procedures may be performed as open operations, by laparoscopy, or by endoluminal (gastroplication) techniques. Pediatric experience is limited with endoscopic application of radiofrequency therapy (Stretta procedure) to a 2-3 cm area of the LES and cardia to create a high-pressure zone to reduce reflux.

Total esophagogastric dissociation is performed in selective neurologically impaired children with repeated failed fundoplications and with severe life-threatening gastroesophageal reflux disease.

349.1

Complications of Gastroesophageal Reflux Disease

Seema Khan, Sravan Kumar Reddy Matta

Keywords

brief resolved unexplained event (BRUE)
Barrett's esophagitis

Esophageal: Esophagitis and Sequelae—Stricture, Barrett Esophagus, Adenocarcinoma

Esophagitis can manifest as irritability, arching, and feeding aversion in infants; chest or epigastric pain in older children; and, rarely, as hematemesis, anemia, or Sandifer syndrome at any age. Erosive esophagitis is found in approximately 12% of children with GERD symptoms and is more common in boys, older children, neurologically challenged children, children with severe chronic respiratory disease, and in those with hiatal hernia. Prolonged and severe esophagitis leads to formation of strictures, generally located in the distal esophagus, producing dysphagia, and requiring repeated esophageal dilations and often fundoplication. Long-standing esophagitis predisposes to metaplastic transformation of the normal esophageal squamous epithelium into intestinal columnar epithelium, termed **Barrett esophagus,** a precursor of esophageal adenocarcinoma. A large multicenter prospective study of 840 consecutive children who underwent elective endoscopies reported a 25.7% prevalence for reflux esophagitis, and a mere 0.12% for Barrett esophagus in children without neurologic disorders or tracheoesophageal anomalies. Both Barrett esophagus and adenocarcinoma occur more in white males and in those with increased duration, frequency, and severity of reflux symptoms. This transformation increases with age to plateau in the fifth decade; adenocarcinoma is rare in childhood. Barrett esophagus, uncommon in children, warrants periodic surveillance biopsies, aggressive pharmacotherapy, and fundoplication for progressive lesions.

Nutritional

Esophagitis and regurgitation may be severe enough to induce failure to thrive because of caloric deficits. Enteral (nasogastric or nasojejunal, or percutaneous gastric or jejunal) or parenteral feedings are sometimes required to treat such deficits.

Extraesophageal: Respiratory (“Atypical”) Presentations

GERD should be included in the differential diagnosis of children with unexplained or refractory otolaryngologic and respiratory complaints. GERD can produce respiratory symptoms by direct contact of the refluxed gastric contents with the respiratory tract (aspiration, laryngeal penetration, or microaspiration) or by reflexive interactions between the esophagus and respiratory tract (inducing laryngeal closure or bronchospasm). Often, GERD and a primary respiratory disorder, such as asthma, interact and a vicious cycle between them worsens both diseases. Many children with these extraesophageal presentations do not have typical GERD symptoms, making the diagnosis difficult. These atypical GERD presentations require a thoughtful approach to the differential diagnosis that considers a multitude of primary otolaryngologic (infections, allergies, postnasal drip, voice overuse) and pulmonary (asthma, cystic fibrosis) disorders. Therapy for the GERD must be more intense (usually incorporating a PPI) and prolonged (usually at least 3-6 mo). In these cases a multidisciplinary approach involving otolaryngology, pulmonary for airway disease and gastroenterology for reflux disease is often warranted for specialized diagnostic testing and for optimizing intensive management.

Apnea and Stridor

These upper airway presentations have been linked with GERD in case reports and epidemiologic studies; temporal relationships between them and reflux episodes have been demonstrated in some patients by esophageal pH–multichannel intraluminal impedance studies, and a beneficial response to therapy for GERD provides further support in a number of case series. An evaluation of 1,400 infants with apnea attributed the apnea to GERD in 50%, but other studies have failed to find an association. Apnea and brief resolved unexplained event-like presentation (previously called an “apparent life-threatening event”) caused by reflux is generally obstructive, owing to laryngospasm that may be conceived of as an abnormally intense protective reflex. At the time of such apnea, infants have often been provocatively positioned (supine or flexed seated), have been recently fed, and have shown signs of obstructive apnea, with unproductive respiratory efforts. *The evidence suggests that for the large majority of infants presenting with apnea and a brief resolved unexplained event, GERD is not causal.* Stridor triggered by reflux generally occurs in infants anatomically predisposed toward stridor (laryngomalacia, micrognathia). Spasmodic croup, an episodic frightening upper airway obstruction, can be an analogous condition in older children. Esophageal pH probe studies might fail to demonstrate linkage of these manifestations with reflux owing to the buffering of gastric contents by infant formula and the episodic nature of the conditions. Pneumograms can fail to identify apnea if they are not designed to identify obstructive apnea by measuring nasal airflow.

Reflux laryngitis and other otolaryngologic manifestations (also known as laryngopharyngeal reflux) can be attributed to GERD. **Hoarseness,** voice fatigue, throat clearing, chronic cough, pharyngitis, sinusitis, otitis media, and a sensation of globus have been cited. Laryngopharyngeal signs of GERD include edema and hyperemia (of the posterior surface), contact ulcers, granulomas, polyps, subglottic stenosis, and interarytenoid edema. The paucity of well-controlled evaluations of the association contributes to the skepticism with which these associations may be considered. Other risk factors irritating the upper respiratory passages can predispose some patients with GERD to present predominantly with these complaints.

Many studies have reported a strong association between asthma and reflux as determined by history, pH–multichannel intraluminal impedance, endoscopy, and esophageal histology. GERD symptoms are present in an average of 23% (19–80%) of children with asthma as observed in a systematic review of 19 studies examining the prevalence of GERD in asthmatics. The review also reported abnormal pH results in 63%, and esophagitis in 35% of asthmatic children. However, this association does not clarify the direction of causality in individual cases and thus does not indicate which patients with asthma are likely to benefit from anti-GERD therapy. Children with asthma who are particularly likely to have GERD as a provocative factor are those with symptoms of reflux disease, those with refractory or steroid-dependent asthma, and those with nocturnal worsening of asthma. Endoscopic evaluation that discloses esophageal sequelae of GERD provides an impetus to embark on the aggressive (high dose and many months’ duration) therapy of GERD.

Dental erosions constitute the most common oral lesion of GERD, the lesions being distinguished by their location on the lingual surface of the teeth. The severity seems to correlate with the presence of reflux symptoms and the presence of an acidic milieu as the result of reflux in the proximal esophagus and oral cavity. The other common factors that can produce similar dental erosions are juice consumption and bulimia.

CHAPTER 350

Eosinophilic Esophagitis, Pill Esophagitis, and Infective Esophagitis

Seema Khan

Eosinophilic Esophagitis

Eosinophilic esophagitis (EoE) is a chronic esophageal disorder characterized by esophageal dysfunction and infiltration of the esophageal epithelium by ≥15 eosinophils per high-power field. The diagnostic criteria has recently been updated as a result of the consensus conference on Appraisal of Guidelines for Research and Evaluation (AGREE). The diagnosis of EoE should be considered in the clinical presentation of esophageal dysfunction, associated with esophageal epithelial infiltration of at least 15 eosinophils (eos) per high power field (hpf) or ~60 eos per mm^2 , and after a careful evaluation of non-EoE disorders. Proton pump inhibitors should be considered as another treatment option rather than a diagnostic criterion to differentiate from GERD. EoE is a global disease, with incidence and prevalence rates in children 5 and 29.5 per 100,000. While infants and toddlers present commonly with vomiting, feeding problems, and poor weight gain, older children and adolescents usually experience solid food dysphagia with occasional food impactions (Fig. 350.1) or strictures and may complain of heartburn, chest or epigastric pain. Most patients are male. The mean age at diagnosis is 7 yr (range: 1-17 yr), and the duration of symptoms is 3 yr. Many patients have other atopic diseases (or a positive family history) and associated food allergies; laboratory abnormalities can include peripheral eosinophilia and elevated immunoglobulin E (IgE) levels. The pathogenesis involves mainly T-helper type 2 cytokine-mediated (interleukin 5 and 13) pathways leading to production of a potent eosinophil chemoattractant, eotaxin-3, by esophageal epithelium. The eosinophilic esophagitis endoscopic reference score (**EREFS**), based on commonly observed features of edema (E), rings (R; Fig. 350.2), exudates (E; see Fig. 350.2), furrows (F; Fig. 350.3), strictures (S), has utility in diagnosis and monitoring response to treatment. Esophageal histology reveals profound eosinophilia, with a currently acceptable cutoff for diagnosis chosen at ≥15 to 20/high-power field. Up to 30% children with EoE have grossly normal esophageal mucosa. EoE is differentiated from gastroesophageal reflux disease by concurrent atopic diseases, its general lack of erosive esophagitis, its greater eosinophil density, and its normal esophageal pH-multichannel intraluminal impedance results. A favorable response to proton pump inhibitor therapy should no longer be considered diagnostic of gastroesophageal reflux disease, as approximately two-thirds of children with EoE also demonstrate histologic response and constitute a proton pump inhibitor–responsive EoE (PPI-REF) group. Observations in children and adults with EoE are notable for striking similarities between PPI responders and PPI non-responders with regard to symptoms, histology, molecular signature, and mechanistic features. This response may be because of an acid suppressive action or down regulation of Th-2 allergic cell pathway, an antieosinophil effect of the PPI class that is mediated by inhibition of eotaxin-3 secretion. Evaluation of EoE should include a search for food (aerodigestive) and environmental allergies via skin prick (IgE mediated) and patch (non–IgE mediated) tests to guide decisions regarding dietary elimination and future food challenges.

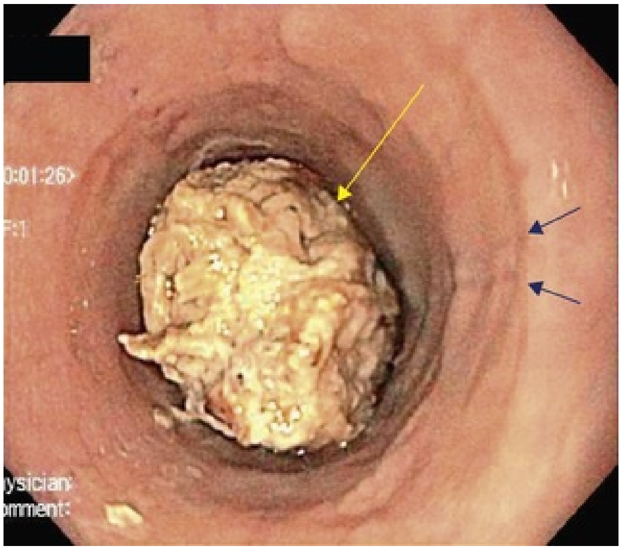

FIG. 350.1 Endoscopic visualization of esophageal food impaction *(yellow arrow)* and mucosal rings *(blue arrows)* .

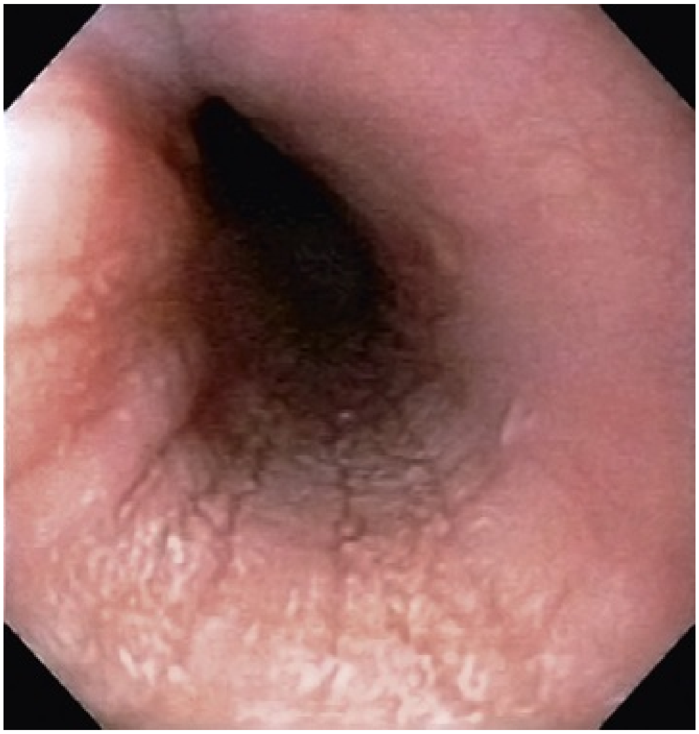

FIG. 350.2 Endoscopic image of eosinophilic esophagitis with characteristic mucosal appearance of furrowing and white specks.

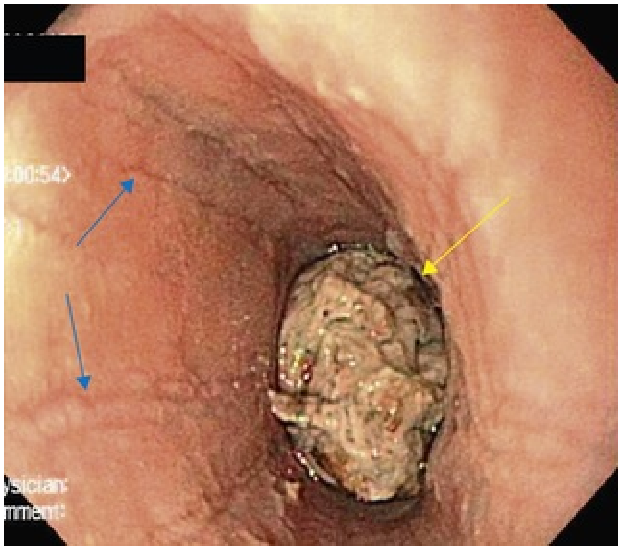

[redacted]

FIG. 350.3 Endoscopy photograph showing mucosal furrowing *(blue arrows)* characteristic of Eosinophilic esophagitis in a patient with food impaction *(yellow arrow)* .

Treatment involves dietary restrictions that take one of 3 forms: elimination diets guided by circumstantial evidence and food allergy test results; “6 food elimination diet” removing the major food allergens (milk, soy, wheat, egg, peanuts and tree nuts, seafood); and elemental diet composed exclusively of an amino acid-based formula. Elimination diets are generally successful, with highest histologic response observed in nearly 91% on elemental diet and in 72% to empiric dietary elimination. Targeted elimination diets guided by multimodal allergy testing are comparable to empiric food elimination and hence lead to the argument against rigorous testing. The major drawbacks of dietary therapy lie in its cost, difficult access, and lower quality of life, any or all of which influence adherence and outcome.

Topically acting swallowed corticosteroids (fluticasone without spacer, viscous budesonide suspension) have been used successfully for those who refuse, fail to adhere, or have a poor response to restricted diets. Histologic remission is observed in 65-77% children and adults treated with fluticasone for 3 mo. Histologic recurrence after discontinuation of fluticasone is common, and emphasizes the need for maintenance therapy, and an approach that would carefully balance the risks of adrenocortical insufficiency as well as, bone demineralization and fungal infections against the risk of EoE evolution from an inflammatory to fibrostenotic disease producing esophageal stenosis and strictures. Therapies under investigation include anti-interleukin-5 antibodies (mepolizumab, reslizumab). Patients require periodic endoscopy and histologic reassessment for the most reliable monitoring of response to treatment, particularly given a significant disconnect between symptoms and histology in the evolution of the disease. Expert clinical guidelines stress long-term studies to develop systematic treatment and best follow-up protocols.

Infective Esophagitis

Uncommon, and most often affecting immunocompromised children, infective esophagitis is caused by fungal agents, such as *Candida* albicans and *Torulopsis glabrata;* viral agents, such as herpes simplex, cytomegalovirus, HIV, and varicella zoster; and, rarely, bacterial infections, including diphtheria and tuberculosis, or parasites. The typical presenting signs and symptoms are odynophagia, dysphagia, and retrosternal or chest pain; there may also be fever, nausea, and vomiting. Candida is the leading cause of infective esophagitis in immunocompetent and immunocompromised children and presents with concurrent oropharyngeal infection in the majority of immunocompromised patients. It may also be an incidental finding in asymptomatic patients, notably in those with EoE receiving topical swallowed corticosteroids. Esophageal viral infections can also manifest in immunocompetent hosts as an acute febrile illness. Infectious esophagitis, like other forms of esophageal inflammation, occasionally progresses to esophageal stricture. Diagnosis of infectious esophagitis is made by endoscopy, usually notable for white plaques in candida, multiple superficial ulcers or *volcano ulcers* in herpes simplex virus, and single deep ulcer in cytomegalovirus. Histopathologic examination solidifies the diagnosis with the detection of yeast and pseudohyphae in Candida; tissue invasion distinguishes esophagitis from mere colonization. Multinucleated giant cells with intranuclear Cowdry type A (eosinophilic) and type B (ground glass appearance) inclusions in HSV, and both intranuclear and intracytoplasmic inclusions producing an *owl's eye* appearance in CMV are typically described. Adding polymerase chain reaction, tissue-viral culture, and immunocytochemistry enhances the diagnostic sensitivity and precision. Treatment is with appropriate antimicrobial agents; azole therapy, particularly oral fluconazole for Candida; oral acyclovir for HSV, and oral valganciclovir for CMV, or alternatively intravenous ganciclovir in severe CMV disease.

Pill Esophagitis

This acute injury is produced by contact with a damaging agent. Medications implicated in pill esophagitis include tetracycline, doxycycline, potassium chloride, ferrous sulfate, nonsteroidal antiinflammatory medications, cloxacillin, and alendronate (Table 350.1). Most often the offending tablet is ingested at bedtime with inadequate water. This practice often produces acute discomfort followed by progressive retrosternal pain, odynophagia, and dysphagia. Endoscopy shows a focal lesion often localized to one of the anatomic narrowed regions of the esophagus or to an unsuspected pathologic narrowing (Fig. 350.4). Treatment is supportive; lacking much evidence, sucralfate, antacids, topical anesthetics, and bland or liquid diets are often used. The offending pill may be restarted after complete resolution of symptoms, if deemed necessary, though with clear emphasis on ingestion with adequate volume of water, usually at least 4 oz.

Table 350.1

Medications Commonly Associated With Esophagitis or Esophageal Injury

ANTIBIOTICS
Clindamycin
Doxycycline
Penicillin
Rifampin
Tetracycline
ANTIVIRAL AGENTS
Nelfinavir
Zalcitabine
Zidovudine
BISPHOSPHONATES
Alendronate
Etidronate
Pamidronate
CHEMOTHERAPEUTIC AGENTS
Bleomycin
Cytarabine
Dactinomycin
Daunorubicin
5-Fluorouracil
Methotrexate
Vincristine
NSAIDs
Aspirin
Ibuprofen
Naproxen
OTHER MEDICATIONS
Ascorbic acid
Ferrous sulfate
Lansoprazole
Multivitamins
Potassium chloride
Quinidine
Theophylline

CHAPTER 351

Esophageal Perforation

Seema Khan

The majority of esophageal perforations in children are from blunt trauma (automobile injury, gunshot wounds, child abuse) or are iatrogenic. Cardiac massage, the Heimlich maneuver, nasogastric tube placement, traumatic laryngoscopy or endotracheal intubation, excessively vigorous postpartum suctioning of the airway during neonatal resuscitation, difficult upper endoscopy, sclerotherapy of esophageal varices, esophageal compression by a cuffed endotracheal tube, and dilation for therapy of achalasia and strictures have all been implicated. Esophageal rupture has followed forceful vomiting in patients with anorexia and has followed esophageal injury due to caustic ingestion, foreign body ingestion, food impactions, pill esophagitis, or eosinophilic esophagitis. Drinking cold, carbonated beverages rapidly is also known to cause esophageal perforation.

Spontaneous esophageal rupture **(Boerhaave syndrome)** is less common and is associated with sudden increases in intraesophageal pressure wrought by situations such as vomiting, coughing, or straining at stool. Children and adults with eosinophilic esophagitis have also been described with Boerhaave syndrome in the setting of forceful emesis in the aftermath of esophageal food impaction. In older children, as in adults, the tear occurs on the distal left lateral esophageal wall, because the smooth muscle layer here is weakest; in neonates (neonatal Boerhaave syndrome), spontaneous rupture is on the right.

Symptoms of esophageal perforation include pain, neck tenderness, dysphagia, subcutaneous crepitus, fever, and tachycardia; several patients with cervical perforations have displayed cold water polydipsia in an attempt to soothe pain in the throat. Imaging studies are important for a rapid and accurate diagnosis. Perforations in the proximal thoracic esophagus tend to create signs (pneumothorax, effusions) in the left chest, whereas the signs of distal tears are more often on the right. Plain radiography (posteroanterior and lateral views) and computed tomography of the neck and chest are often used, with the latter as more sensitive and accurate in diagnosis. Signs of perforation include pneumomediastinum, mediastinal widening, subcutaneous emphysema, pneumothorax, hydrothorax, pleural effusion, and lung collapse. If these x-rays are normal, an esophagogram using water-soluble contrast media should be performed, but esophagograms miss >30% of cervical perforations. Therefore, a negative water-soluble contrast esophagogram should be followed by a barium study; the greater density of barium can better demonstrate a small defect, although with a higher risk of inflammatory mediastinitis. Endoscopy may also be useful but carries a 30% false-negative rate.

Treatment must be individualized. Small tears in contained perforations with minimal mediastinal contamination in hemodynamically stable patients can be treated conservatively with broad-spectrum antibiotics, nothing given orally, gastric drainage, and parenteral nutrition. Endoscopic techniques, considered less invasive and morbid, are now being used more frequently and include clips for defects <2 cm, and placement of stents and suturing for larger defects. Chest exploration and direct surgical repair is infrequently indicated these days. Mortality rates range between 20% and 28%, with poor prognosis correlated with delayed diagnosis and interventions.

CHAPTER 352

Esophageal Varices

Seema Khan

Esophageal varices form in adults with portal hypertension with hepatic venous pressure gradient above 10 mm Hg and pose a risk for bleeding at above 12 mm Hg (see Chapter 394). Spontaneous decompression of this hypertension through portosystemic collateral circulation via the coronary vein, in conjunction with the left gastric veins, gives rise to esophageal varices. Most esophageal varices are *uphill varices* ; less commonly, those that arise in the absence of portal hypertension and with superior vena cava obstruction are *downhill varices* . Their treatment is directed at the underlying cause of the superior vena cava abnormality. Hemorrhage from esophageal varices is the major cause of morbidity and mortality from portal hypertension. Presentation is with significant hematemesis and melena; whereas most patients have liver disease, some children with extrahepatic portal venous obstruction might have been previously asymptomatic. Any child with hematemesis and splenomegaly should be presumed to have esophageal variceal bleeding until proved otherwise. The leading causes of pediatric portal hypertension, biliary atresia, and extrahepatic portal vein obstruction are uniquely distinct from diseases encountered in adults. Hence, children tend to tolerate variceal bleeding better due to generally well compensated liver disease, with studies reporting mortality risk <1% after initial variceal bleed.

Upper endoscopy is the preferred diagnostic test for esophageal varices, as it provides definitive diagnosis and delineation of details that aid in predicting the risk for bleeding, as well as enabling therapy for acute bleeding episodes via either sclerotherapy or band ligation. A report comprising a large series of children with biliary atresia and portal hypertension described endoscopic findings of large varices, red marks, and the presence of gastric varices as predictive of bleeding. Noninvasive methods of evaluating varices include barium contrast studies, ultrasound, computerized tomography, magnetic resonance, and elastography, but they are not recommended for routine diagnostic evaluation because of suboptimal accuracy compared to endoscopy.

Primary prophylaxis with the goal of preventing an initial hemorrhage can decrease the incidence of esophageal bleeding; the various modalities used are nonselective β blockade (e.g., propranolol or nadolol), sclerotherapy, ligation, and portosystemic shunt surgery. A recent expert consensus based on a large review of the available evidence has proposed that MesoRex bypass surgery should be offered to children with EHPVO as both primary and secondary prophylaxis in the appropriate context. Due to insufficient evidence, the same cannot be recommended regarding endoscopic therapies and nonselective beta blockers for primary prophylaxis in children. In contrast, adults do have a reduced risk of first-time variceal bleeding with endoscopic variceal ligation when compared with untreated controls as well as patients treated with β blockade; a decrease in mortality is only noted in comparison to the control group (see Chapter 394). The management of acute variceal bleeding must include attention to hemodynamic stability through blood transfusion, vasoactive drugs (e.g., octreotide), short-term antibiotic use, and endoscopy to perform ligation or sclerotherapy, as needed. Transjugular intrahepatic portosystemic shunt should be considered for variceal bleeding refractory to medical and endoscopic therapy. Secondary prophylaxis to reduce recurrence of bleeding uses nonselective β blockade and obliteration of varices through serial treatment via ligation or sclerotherapy. The only randomized controlled pediatric study has shown superiority of ligation over sclerotherapy in reducing the risk for rebleeding and complications.

CHAPTER 353

Ingestions

353.1

Foreign Bodies in the Esophagus

Seema Khan

The majority (80%) of accidental foreign-body ingestions occur in children, most of whom are 5 yr of age or younger. Older children and adolescents with developmental delays and those with psychiatric disorders are also at increased risk. The presentation of a foreign body lodged in the esophagus constitutes an emergency and is associated with significant morbidity and mortality because of the potential for perforation and sepsis. Coins are by far the most commonly ingested foreign body, followed by small toy items. Food impactions are less common in children than in adults and usually occur in children in association with eosinophilic esophagitis *(diagnosed in 92% of those presenting with food impactions and dysphagia)*, repair of esophageal atresia, and Nissen fundoplication. Most esophageal foreign bodies lodge at the level of the cricopharyngeus (upper esophageal sphincter), the aortic arch, or just superior to the diaphragm at the gastroesophageal junction (lower esophageal sphincter).

At least 30% of children with esophageal foreign bodies may be totally asymptomatic, so any history of foreign body ingestion should be taken seriously and investigated. An initial bout of choking, gagging, and coughing may be followed by excessive salivation, dysphagia, food refusal, emesis, or pain in the neck, throat, or sternal notch regions. Respiratory symptoms such as stridor, wheezing, cyanosis, or dyspnea may be encountered if the esophageal foreign body impinges on the larynx or membranous posterior tracheal wall. Cervical swelling, erythema, or subcutaneous crepitations suggest perforation of the oropharynx or proximal esophagus.

Evaluation of the child with a history of foreign body ingestion starts with plain anteroposterior radiographs of the neck, chest, and abdomen, along with lateral views of the neck and chest. The flat surface of a coin in the esophagus is seen on the anteroposterior view and the edge on the lateral view (Fig. 353.1). The reverse is true for coins lodged in the trachea; here, the edge is seen anteroposteriorly and the flat side is seen laterally. Disk-shaped button batteries can look like coins and be differentiated by the double halo and step-off on anteroposterior and lateral views, respectively (Fig. 353.2). The use of button batteries has been increasingly popular, leading to a sharp rise in accidental ingestions, and critical in the increase in morbidity and mortality. The latter is thought to be due to both an increase in diameter and a change to lithium cells. Children younger than 5 yr of age with ingestion of batteries ≥20 mm are considered to have the highest risk for catastrophic events such as necrosis, tracheoesophageal fistula, perforation, stricture, vocal cord paralysis, mediastinitis, and aortoenteric fistula (Fig. 353.3). Materials such as plastic, wood, glass, aluminum, and bones may be radiolucent; failure to visualize the object with plain films in a symptomatic patient warrants urgent endoscopy. Computed tomography (CT) scan with 3-dimensional reconstruction may increase the sensitivity of imaging a foreign body. Although barium contrast studies may be helpful in the occasional asymptomatic patient with negative plain films, their use is to be discouraged because of the potential of aspiration, as well as making subsequent visualization and object removal more difficult.

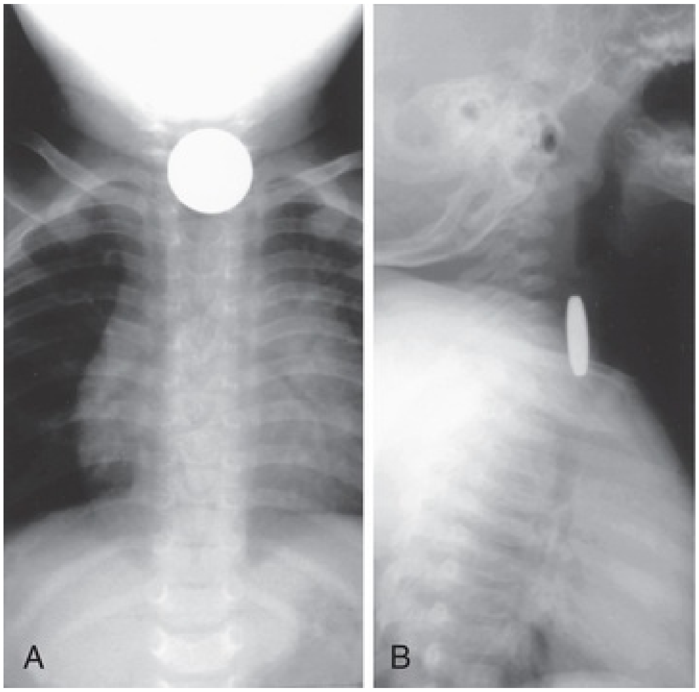

FIG. 353.1 Radiographs of a coin in the esophagus. When foreign bodies lodge in the esophagus, the flat surface of the object is seen in the anteroposterior view (A) and the edge is seen in the lateral view (B) . The reverse is true for objects in the trachea. (Courtesy Beverley Newman, MD.)

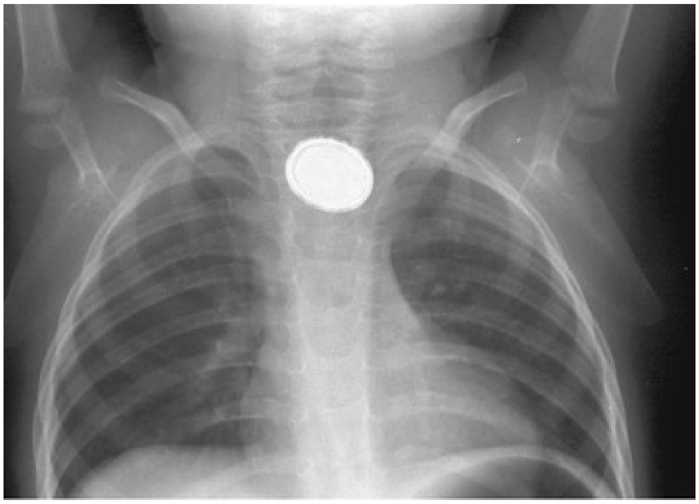

FIG. 353.2 Disk battery impacted in esophagus. Note the double rim. (From Wyllie R, Hyams JS, editors: *Pediatric gastrointestinal and liver disease,* ed 3, Philadelphia, 2006, Saunders.)

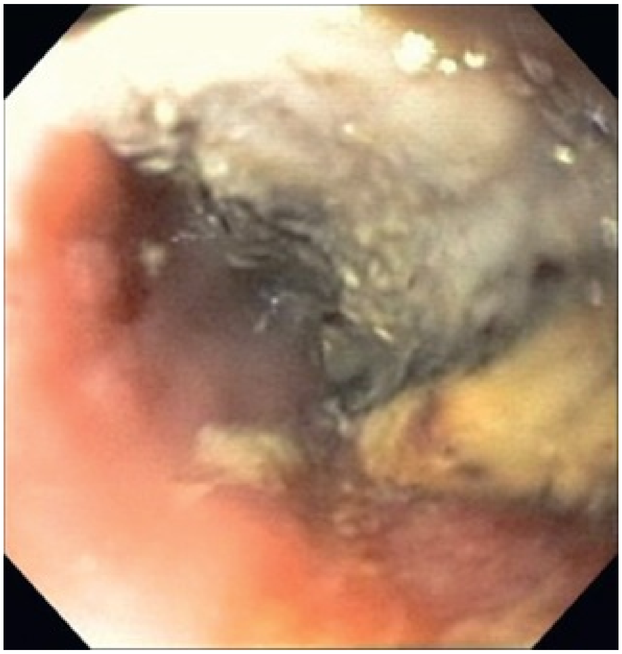

FIG. 353.3 Severe esophageal injury at site of button battery (BB) removal, with necrosis and eschar. (From Leinwand K, Brumbaugh DE, Kramer RE: Button battery ingestion in children—a paradigm for management of severe pediatric foreign body ingestions, *Gastrointest Endoscopy Clin N Am* 26:99–118, 2016, Fig. 1.)

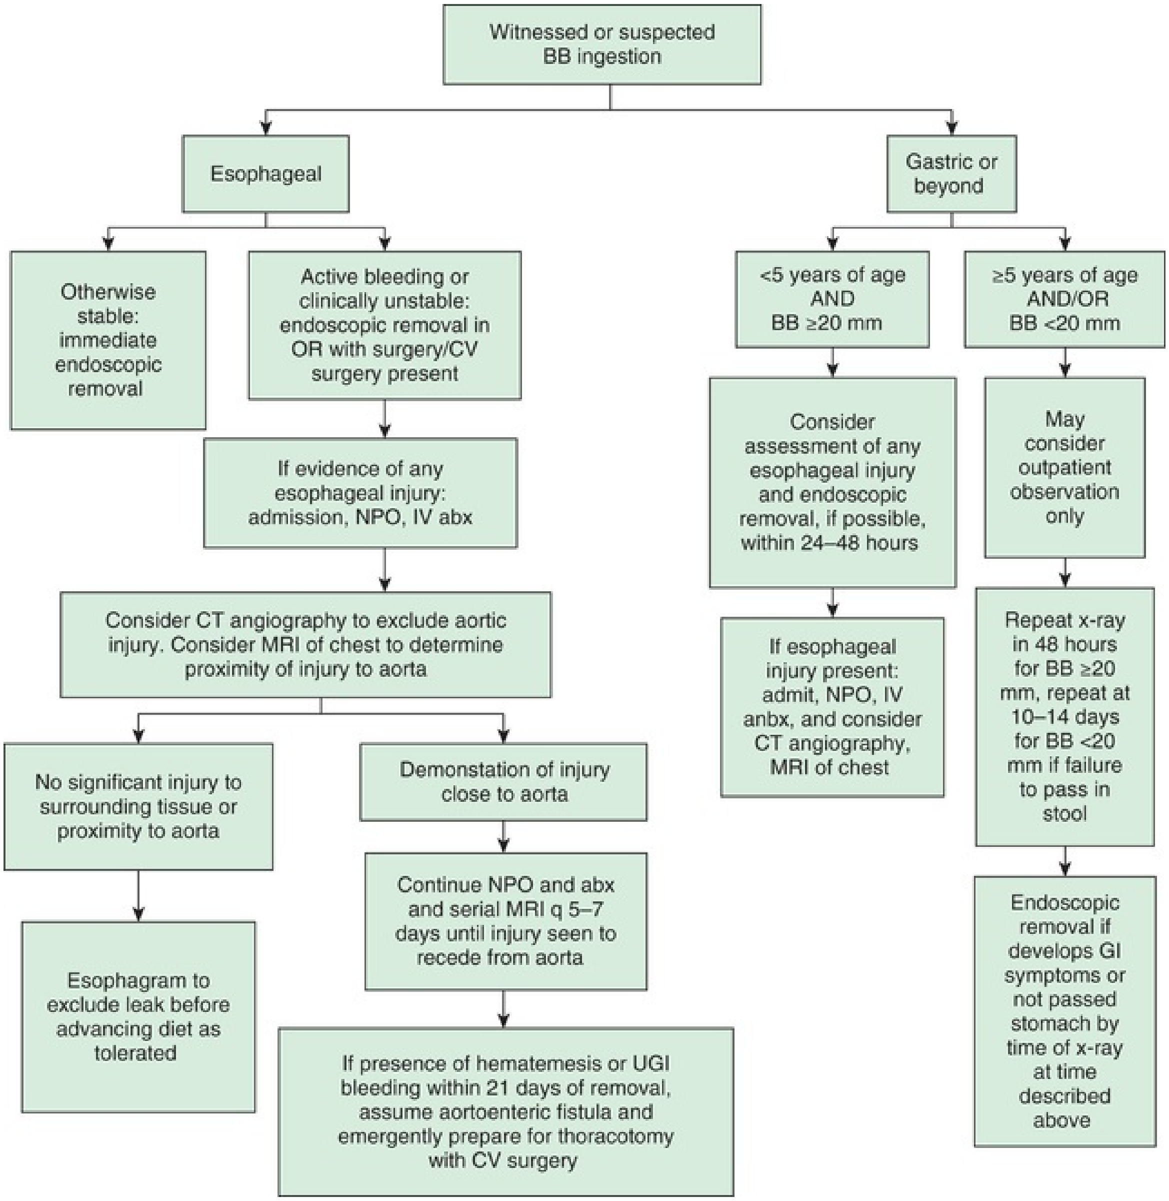
In managing the child with an esophageal foreign body, it is important to assess risk for airway compromise and to obtain a chest CT scan and surgical consultation in cases of suspected airway perforation. Treatment of esophageal foreign bodies usually merits endoscopic visualization of the object and underlying mucosa and removal of the object using an appropriately designed foreign body–retrieving accessory instrument through the endoscope and with an endotracheal tube protecting the airway. Sharp objects in the esophagus, multiple magnets or single magnet with a metallic object, or foreign bodies associated with respiratory symptoms mandate urgent removal within 12 hr of presentation. Button batteries, in particular, must be emergently removed within 2 hr of presentation regardless of the timing of patient's last oral intake because they can induce mucosal injury in as little as 1 hr of contact time and involve all esophageal layers within 4 hr (see Figs. 353.3 and 353.4). Asymptomatic blunt objects and coins lodged in the esophagus can be observed for up to 24 hr in anticipation of passage into the stomach. If there are no problems in handling secretions, meat impactions can be observed for up to 24 hr. In patients without prior esophageal surgeries, glucagon (0.05 mg/kg intravenously [IV]) can sometimes be useful in facilitating passage of distal esophageal food boluses by decreasing the lower esophageal sphincter pressure. The use of meat tenderizers or gas-forming agents can lead to perforation and are not recommended. An alternative technique for removing esophageal coins impacted for <24 hr, performed most safely by experienced radiology personnel, consists of passage of a Foley catheter beyond the coin at fluoroscopy, inflating the balloon, and then pulling the catheter and coin back simultaneously with the patient in a prone oblique position. Concerns about the lack of direct mucosal visualization and, when tracheal intubation is not used, the lack of airway protection prompt caution in the use of this technique. Bougienage of esophageal coins toward the stomach in selected uncomplicated pediatric cases has been suggested to be an effective, safe, and economical modality where endoscopy might not be routinely available.



Witnessed or suspected BB ingestion
Esophageal
Gastric or beyond
Otherwise stable: immediate endoscopic removal
Active bleeding or clinically unstable: endoscopic removal in OR with surgery/CV surgery present
If evidence of any esophageal injury: admission, NPO, IV abx
Consider CT angiography to exclude aortic injury. Consider MRI of chest to determine proximity of injury to aorta
No significant injury to surrounding tissue or proximity to aorta
Esophagram to exclude leak before advancing diet as tolerated
Demonstation of injury close to aorta
Continue NPO and abx and serial MRI q 5–7 days until injury seen to recede from aorta
If presence of hematemesis or UGI bleeding within 21 days of removal, assume aortoenteric fistula and emergently prepare for thoracotomy with CV surgery
<5 years of age AND BB ≥20 mm
Consider assessment of any esophageal injury and endoscopic removal, if possible, within 24–48 hours
If esophageal injury present: admit, NPO, IV anbx, and consider CT angiography, MRI of chest
≥5 years of age AND/OR BB <20 mm
May consider outpatient observation only
Repeat x-ray in 48 hours for BB ≥20 mm, repeat at 10–14 days for BB <20 mm if failure to pass in stool
Endoscopic removal if develops GI symptoms or not passed stomach by time of x-ray at time described above

FIG. 353.4 Proposed management algorithm for ingestion of button battery *(BB)* in children. Abx, antibiotics; BB, button battery; CT, computed tomography; CV, cardiovascular; GI, gastrointestinal; IV, intravenous; MRI, magnetic resonance imaging; NPO, nil per os; OR, operating room; Q, every; UGI, upper gastrointestinal series. (From Kramer RE, Lerner DG, Lin T, et al: Management of ingested foreign bodies in children: a clinical report of the NASPGHAN endoscopy committee, *J Pediatr Gastroenterol Nutr* 60(4):562–574, 2015, Fig. 1.)

353.2

Caustic Ingestions

Seema Khan

Keywords

esophageal foreign body
magnet
button battery
caustic ingestion
endoscopy.

Ingestion of caustic substances is a worldwide public health problem accounting for a significant burden on healthcare resources. According to an inpatient database of U.S. pediatric hospital discharges in 2009, the estimated number of caustic ingestions was 807 (95% confidence interval [CI], 731-882) cases, amounting to $22,900,000 in total hospital charges. The medical sequelae of caustic ingestions are esophagitis, necrosis, perforation, and stricture formation (see Chapter 77). Most cases (70%) are accidental ingestions of liquid alkali substances that produce severe, deep liquefaction necrosis; drain decloggers are most common, and because they are tasteless, more is ingested (Table 353.1). **Acidic agents** (20% of cases) are bitter, so less may be consumed; they produce coagulation necrosis and a somewhat protective thick eschar. They can produce severe gastritis, and volatile acids can result in respiratory symptoms. Children younger than 5 yr of age account for half of the cases of caustic ingestions, and boys are far more often involved than girls.

Table 353.1

Ingestible Caustic Materials Around the House

CATEGORY	MOST DAMAGING AGENTS	OTHER AGENTS
Alkaline drain cleaners, milking machine pipe cleaners	Sodium or potassium hydroxide	Ammonia Sodium hypochlorite Aluminum particles
Acidic drain openers	Hydrochloric acid Sulfuric acid	
Toilet cleaners	Hydrochloric acid Sulfuric acid Phosphoric acid Other acids	Ammonium chloride Sodium hypochlorite
Oven and grill cleaners	Sodium hydroxide Perborate (borax)	
Denture cleaners	Persulfate (sulfur) Hypochlorite (bleach)	
Dishwasher detergent • Liquid • Powdered • Packaged	Sodium hydroxide Sodium hypochlorite Sodium carbonate	
Bleach	Sodium hypochlorite	Ammonia salt
Swimming pool chemicals	Acids, alkalis, chlorine	
Battery acid (liquid)	Sulfuric acid	
Disk batteries	Electric current	Zinc or other metal salts
Rust remover	Hydrofluoric, phosphoric, oxalic, and other acids	
Household delimers	Phosphoric acid Hydroxyacetic acid Hydrochloric acid	
Barbeque cleaners	Sodium and potassium hydroxide	
Glyphosate surfactant (RoundUp) acid	Glyphosate herbicide	Surfactants
Hair relaxer	Sodium hydroxide	
Weed killer	Dichlorophenoxyacetate, ammonium phosphate, propionic acid

Caustic ingestions produce signs and symptoms such as vomiting, drooling, refusal to drink, oral burns, dysphagia, dyspnea, abdominal pain, hematemesis, and stridor. Twenty percent of patients develop esophageal strictures. Absence of oropharyngeal lesions does not exclude the possibility of significant esophagogastric injury, which can lead to perforation or stricture. The absence of symptoms is usually associated with no or minimal lesions; hematemesis, respiratory distress, or presence of at least 3 symptoms predicts severe lesions. An upper endoscopy is recommended as the most efficient means of rapid identification of tissue damage and must be undertaken in all symptomatic children.

Dilution by water or milk is recommended as acute treatment, but neutralization, induced emesis, and gastric lavage are contraindicated. Treatment depends on the severity and extent of damage (Table 353.2 , Fig. 353.5). Stricture risk is increased by circumferential ulcerations, white plaques, and sloughing of the mucosa and is reported to occur in 70–100% of grade IIB and grade III caustic esophagitis. Strictures can require treatment with dilation, and in some severe cases, surgical resection and colon or small bowel interposition are needed. Silicone stents (self-expanding) placed endoscopically after a dilation procedure can be an alternative and conservative approach to the management of strictures. Rare late cases of superimposed esophageal carcinoma are reported. The role of corticosteroids is controversial; they are not recommended in grade 1 burns, but they can reduce the risk of strictures in more-advanced caustic esophagitis. Many centers also use proton pump inhibitors as well as antibiotics in the initial treatment of caustic esophagitis on the premise that reducing superinfection in the necrotic tissue bed will, in turn, lower the risk of stricture formation. Studies examining the role of antibiotics in caustic esophagitis have not reported a clinically significant benefit even in those with grade 2 or greater severity of esophagitis.

Table 353.2

Classification of Caustic Injury

GRADE	VISIBLE APPEARANCE	CLINICAL SIGNIFICANCE
Grade 0	History of ingestion but no visible damage or symptoms	Able to take fluids immediately
Grade 1	Edema, loss of normal vascular pattern, hyperemia, no transmucosal injury	Temporary dysphagia, able to swallow within 0-2 days, no long-term sequelae
Grade 2a	Transmucosal injury with friability, hemorrhage, blistering, exudate, scattered superficial ulceration	Scarring, no circumferential damage (no stenosis), no long-term sequelae
Grade 2b	Grade 2a plus discrete ulceration and/or circumferential	Small risk of perforation, scarring that may

	ulceration	result in later stenosis
Grade 3a	Scattered deep ulceration with necrosis of the tissue	Risk of perforation, high risk of later stenosis
Grade 3b	Extensive necrotic tissue	High risk of perforation and death, high risk of stenosis

From Wylie R, Hyams JS, Kay M, editors: *Pediatric gastrointestinal and liver disease* , ed 4, Philadelphia, 2011, WB Saunders, Table 19.2, p. 199.

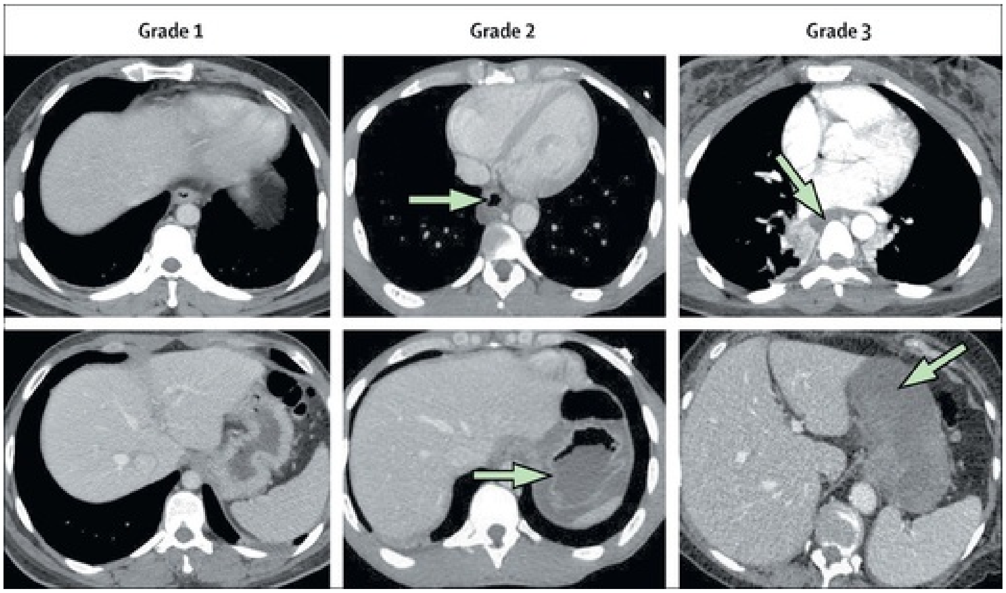

FIG. 353.5 Computed Tomography (CT) Grading of Corrosive Injuries of the Esophagus and the Stomach. Grade 1, normal appearance; grade 2, wall and soft tissue edema, increased wall enhancement *(arrow)* ; grade 3, transmural necrosis with absent wall enhancement *(arrow)* . (From Chirica M, Bonavina L, Kelly MD, et al: Caustic ingestion, *Lancet* 389:2041–2050, 2017, Fig. 1.)

There may be an increase of esophageal (not gastric) carcinoma following a caustic ingestion.

Normal Development, Structure, and Function of the Stomach and Intestines

Asim Maqbool, Chris A. Liacouras

Development

The primitive gut is recognizable by the 4th wk of gestation and is composed of the foregut, midgut, and hindgut. The **foregut** gives rise to the upper gastrointestinal tract, which includes the esophagus, stomach, and duodenum to the level of the insertion of the common bile duct. The **midgut** gives rise to the rest of the small bowel and the large bowel to the level of the midtransverse colon. The **hindgut** forms the remainder of the colon and upper anal canal. The rapid growth of the midgut causes it to protrude out of the abdominal cavity through the umbilical ring during fetal development. The midgut subsequently returns to the peritoneal cavity and rotates counterclockwise until the cecum lies in the right lower quadrant. The process is normally complete by the 8th wk of gestation.

The liver derives from the hepatic diverticulum that evolves into parenchymal cells, bile ducts, vascular structures, and hematopoietic and Kupffer cells. The extrahepatic bile ducts and gallbladder develop first as solid cords that canalize by the 3rd mo of gestation. The dorsal and ventral pancreatic buds grow from the foregut by the 4th wk of gestation. The two buds fuse by the 6th wk. Exocrine secretory capacity is present by the 5th mo.

Cis -regulatory genomic sequences govern gene expression during development. Modules of *cis* sequences are linked and allow a cascade of gene regulation that controls functional development. Extrinsic factors have the capacity to influence gene expression. In the gut, several growth factors, including growth factor-β, insulin-like growth factor, and growth factors found in human colostrum (human growth factor and epidermal growth factor), influence gene expression.

Propulsion of food down the gastrointestinal tract relies on the coordinated action of muscles in the bowel wall. The contractions are regulated by the enteric nervous system under the influence of a variety of peptides and hormones. The enteric nervous system is derived from neural crest cells that migrate in a cranial to caudal fashion. Migration of the neural crest tissue is complete by the 24th wk of gestation. Interruption of the migration results in **Hirschsprung disease** . Newborn bowel motor patterns are different from adults. Normal fasting upper gastrointestinal motility is characterized by a triphasic pattern known as the migrating motor complex. Migrating motor complexes occur less often in neonates, and they have more nonmigrating phasic activity. This leads to ineffective propulsion, particularly in premature infants. Motility in the fed state consists of a series of ring contractions that spread caudad over variable distances.

Digestion and Absorption

The wall of the stomach, small bowel, and colon consists of four layers: the mucosa, submucosa, muscularis, and serosa. Eighty-five percent of the gastric mucosa is lined by oxyntic glands containing cells that secrete hydrochloric acid, pepsinogen, and intrinsic factor, and mucous and endocrine cells that secrete peptides having paracrine and endocrine effects. Pepsinogen is a precursor of the proteolytic enzyme pepsin, and intrinsic factor is required for the absorption of vitamin B_{12} . Pyloric glands are located in the antrum and contain gastrin-secreting cells. Acid production and gastrin levels are inversely related to each other except in pathologic secretory states. Acid secretion is low at birth but increases dramatically by 24 hr. Acid and pepsin secretions peak in the first 10 days and decrease from 10 to 30 days after birth. Intrinsic factor secretion rises slowly in the first 2 wk of life.

The small bowel is approximately 270 cm long at birth in a term neonate and grows to an adult length of 450-550 cm by 4 yr of age. The mucosa of the small intestine is composed of villi, which are finger-like projections of the mucosa into the bowel lumen that significantly expand the absorptive surface area. The mucosal surface is further expanded by a brush border containing digestive enzymes and transport mechanisms for monosaccharides, amino acids, dipeptides and tripeptides, and fats. The cells of the villi originate in adjacent crypts and become functional as they migrate from the crypt up the villus. The small bowel mucosa is completely renewed in 4-5 days, providing a mechanism for rapid repair after injury, but in young infants or malnourished children, the process may be delayed. Crypt cells also secrete fluid and electrolytes. The villi are present by 8 wk of gestation in the duodenum and by 11 wk in the ileum.

Disaccharidase activities are measurable at 12 wk, but lactase activity does not reach maximal levels until 36 wk. Even premature infants usually tolerate lactose-containing formulas because of carbohydrate salvage by colonic bacteria. In children of African and Asian ethnicity, lactase levels may begin to fall at 4 yr of age, leading to intolerance to mammalian milk. Mechanisms to digest and absorb protein, including pancreatic enzymes and mucosal mechanisms to transport amino acids, dipeptides, and tripeptides, are in place by the 20th wk of gestation.

Carbohydrates, protein, and fat are normally absorbed by the upper half of the small intestine; the distal segments represent a vast reserve of absorptive capacity. Most of the sodium, potassium, chloride, and water are absorbed in the small bowel. Bile salts and vitamin B_{12} are selectively absorbed in the distal ileum, and iron is absorbed in the duodenum and proximal jejunum. Intraluminal digestion depends on the exocrine pancreas. Secretin and cholecystokinin stimulate synthesis and secretion of bicarbonate and digestive enzymes, which are released by the upper intestinal mucosa in response to various intraluminal stimuli, among them components of the diet.

Carbohydrate digestion is normally an efficient process that is completed in the distal duodenum. Starches are broken down to glucose, oligosaccharides, and disaccharides by pancreatic amylase. Residual glucose polymers are broken down at the mucosal level by glucoamylase. Lactose is broken down at the brush border by lactase, forming glucose and galactose; sucrose is broken down by sucrase-isomaltase to fructose and glucose. Galactose and glucose are primarily transported into the cell by a sodium- and energy-dependent process, whereas fructose is transported by facilitated diffusion.

Proteins are hydrolyzed by pancreatic enzymes, including trypsin, chymotrypsin, elastase, and carboxypeptidases, into individual amino acids and oligopeptides. The pancreatic enzymes are secreted as proenzymes, which are activated by release of the mucosal enzyme enterokinase. Oligopeptides are further broken down at the brush border by peptidases into dipeptides, tripeptides, and amino acids. Protein can enter the cell by separate noncompetitive carriers that can transport individual amino acids or dipeptides and tripeptides similar to those in the renal tubule. The human gut is capable of absorbing antigenic intact proteins in the first few wk of life because of *leaky* junctions between enterocytes. Entry of potential protein antigens through the mucosal barrier might have a role in later food- and microbe-induced symptoms.

Fat absorption occurs in two phases. Dietary triglycerides are broken down into monoglycerides and free fatty acids by pancreatic lipase and colipase. The free fatty acids are subsequently emulsified by bile acids, forming micelles with phospholipids and other fat-soluble substances, and are transported to the cell membrane, where they are absorbed. The fats are reesterified in the enterocyte, forming chylomicrons that are transported through the intestinal lymphatics to the thoracic duct. Medium-chain fats are absorbed more efficiently and can directly enter the cell. They are subsequently transported to the liver via the portal system. Fat absorption can be affected at any stage of the digestion and absorption process. Decreased pancreatic enzymes occur in cystic fibrosis, cholestatic liver disease leads to poor bile salt production and micelle formation, celiac disease affects mucosal surface area, abnormal chylomicron formation occurs in abetalipoproteinemia, and intestinal lymphangiectasia affects transport of the chylomicrons.

Fat absorption is less efficient in the neonate compared with adults. Premature infants can lose up to 20% of their fat calories compared with up to 6% in the adult. Decreased synthesis of bile acids and pancreatic lipase and decreased efficiency of ileal absorption are contributing factors. Fat digestion in the neonate is facilitated by lingual and gastric lipases. Bile salt–stimulated lipase in human milk augments the action of pancreatic lipase. Infants with malabsorption of fat are usually fed with formulas that have a greater percentage of medium-chain triglycerides, which are absorbed independently of bile salts.

The colon is a 75-100 cm sacculated tube formed by three strips of longitudinal muscle called *taenia coli* that traverse its length and fold the mucosa into haustra. Haustra and taenia appear by the 12th wk of gestation. The most common motor activity in the colon is nonpropulsive rhythmic segmentation that acts to mix the chyme and expose the contents to the colonic mucosa. Mass movement within the colon typically occurs after a meal. The colon extracts additional water and electrolytes from the luminal contents to render the stools partially or completely solid. The colon also acts to scavenge by-products of bacterial degradation of carbohydrates. Stool is stored in the rectum until distention triggers a defecation reflex that, when assisted by voluntary relaxation of the external sphincter, permits evacuation.

CHAPTER 355

Pyloric Stenosis and Other Congenital Anomalies of the Stomach

355.1

Hypertrophic Pyloric Stenosis

Asim Maqbool, Chris A. Liacouras

Hypertrophic pyloric stenosis occurs in 1-3/1,000 infants in the United States. It is more common in whites of northern European ancestry, less common in blacks, and rare in Asians. Males (especially firstborns) are affected approximately 4-6 times as often as females. The offspring of a mother and, to a lesser extent, the father who had pyloric stenosis are at higher risk for pyloric stenosis. Pyloric stenosis develops in approximately 20% of the male and 10% of the female descendants of a mother who had pyloric stenosis. The incidence of pyloric stenosis is increased in infants with B and O blood groups. Pyloric stenosis is occasionally associated with other congenital defects, including tracheoesophageal fistula and hypoplasia or agenesis of the inferior labial frenulum.

Etiology

The cause of pyloric stenosis is unknown, but many factors have been implicated. Pyloric stenosis is usually not present at birth and is more concordant in monozygotic than dizygotic twins. It is unusual in stillbirths and probably develops after birth. Pyloric stenosis has been associated with eosinophilic gastroenteritis, Apert syndrome, Zellweger syndrome, trisomy 18, Smith-Lemli-Opitz syndrome, and Cornelia de Lange syndrome. An association has been found with the use of erythromycin in neonates with highest risk if the medication is given within the first 2 wk of life. There have also been reports of higher incidence of pyloric stenosis among mostly female infants of mothers treated with macrolide antibiotics during pregnancy and breastfeeding. Abnormal muscle innervation, elevated serum levels of prostaglandins, and infant hypergastrinemia have been implicated. Reduced levels of neuronal nitric oxide synthase have been found with altered expression of the neuronal nitric oxide synthase exon 1c regulatory region, which influences the expression of the neuronal nitric oxide synthase gene. Reduced nitric oxide might contribute to the pathogenesis of pyloric stenosis.

Clinical Manifestations

Non-bilious vomiting is the initial symptom of pyloric stenosis. The vomiting may or may not be projectile initially but is usually progressive, occurring immediately after a feeding. Emesis might follow each feeding, or it may be intermittent. The vomiting usually starts after 3 wk of age, but symptoms can develop as early as the first wk of life and as late as the 5th mo. Approximately 20% have intermittent emesis from birth that then progresses to the classic picture. After vomiting, the infant is hungry and wants to feed again. As vomiting continues, a progressive loss of fluid, hydrogen ion, and chloride leads to *hypochloremic metabolic alkalosis* . Awareness of pyloric stenosis has led to earlier identification of patients with fewer instances of chronic malnutrition and severe dehydration and at times a subclinical self-resolving hypertrophy.

Hyperbilirubinemia is the most common clinical association of pyloric stenosis, also known as *icteropyloric syndrome* . Unconjugated hyperbilirubinemia is more common than conjugated and usually resolves with surgical correction of the pyloric stenosis. It may be associated with a decreased level of glucuronyl transferase as seen in approximately 5% of affected infants; mutations in the bilirubin uridine diphosphate glucuronosyltransferase gene *(UGT1A1)* have also been implicated. If conjugated hyperbilirubinemia is a part of the presentation, other etiologies need to be investigated. Other coexistent clinical diagnoses have been described, including eosinophilic gastroenteritis, hiatal hernia, peptic ulcer, congenital nephrotic syndrome, congenital heart disease, and congenital hypothyroidism.

The diagnosis has traditionally been established by palpating the pyloric mass. The mass is firm, movable, approximately 2 cm in length, olive shaped, hard, best palpated from the left side, and located above and to the right of the umbilicus in the mid epigastrium beneath the liver's edge. The olive is easiest palpated after an episode of vomiting. After feeding, there may be a visible gastric peristaltic wave that progresses across the abdomen (Fig. 355.1).

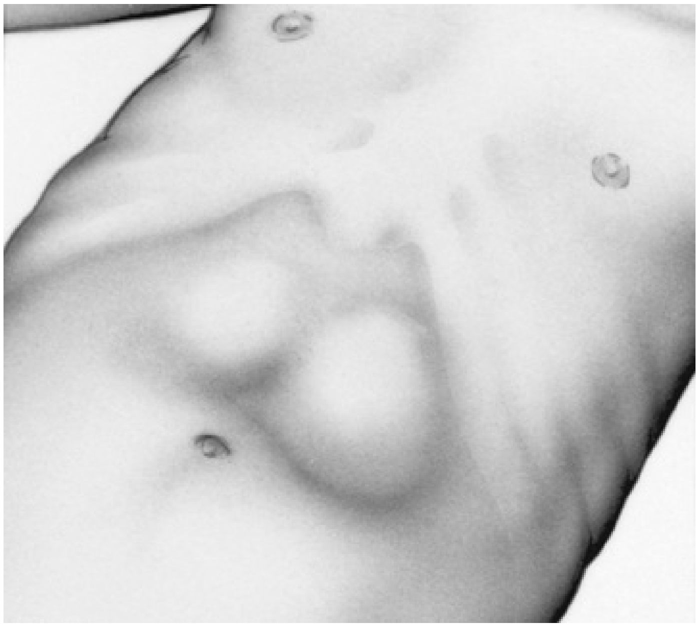

FIG. 355.1 **Gastric peristaltic wave in an infant with pyloric stenosis.**

Two imaging studies are commonly used to establish the diagnosis. Ultrasound examination confirms the diagnosis in the majority of cases. Criteria for diagnosis include pyloric thickness 3-4 mm, an overall pyloric length 15-19 mm, and pyloric diameter of 10-14 mm (Fig. 355.2). Ultrasonography has a sensitivity of approximately 95%. When contrast studies are performed, they demonstrate an elongated pyloric channel (string sign), a bulge of the pyloric muscle into the antrum (shoulder sign), and parallel streaks of barium seen in the narrowed channel, producing a “double tract sign” (Fig. 355.3).

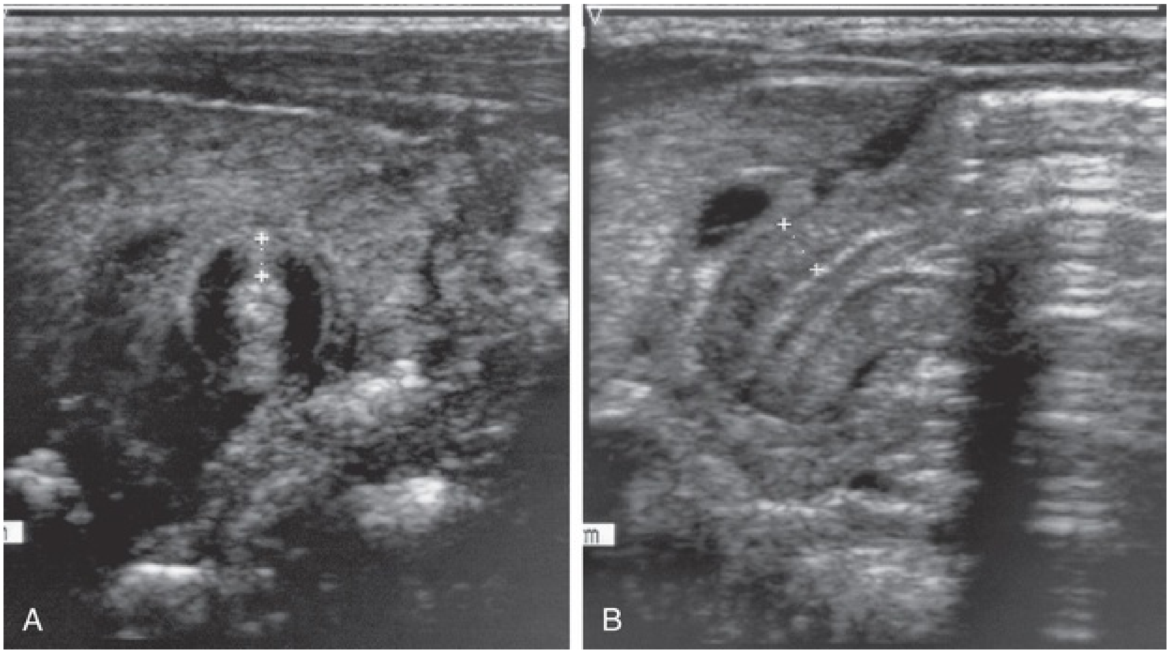

FIG. 355.2 **A,** Transverse sonogram demonstrating a pyloric muscle wall thickness of >4 mm (distance between *crosses*). **B,** Horizontal image demonstrating a pyloric channel length >14 mm (wall thickness outlined between *crosses*) in an infant with pyloric stenosis.

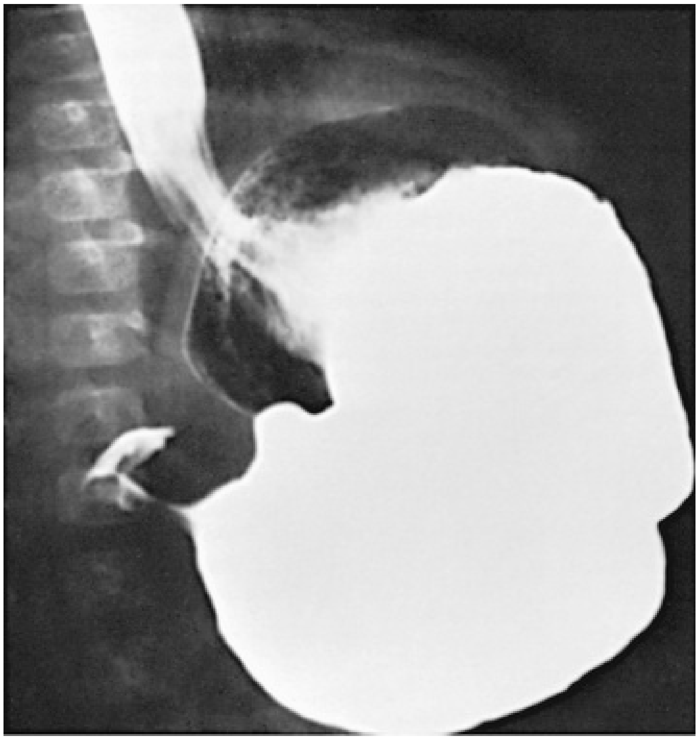

FIG. 355.3 **Barium in the stomach of an infant with projectile vomiting. The attenuated**

pyloric canal is typical of congenital hypertrophic pyloric stenosis.

Differential Diagnosis

Gastric waves are occasionally visible in small, emaciated infants who do not have pyloric stenosis. Infrequently, gastroesophageal reflux, with or without a hiatal hernia, may be confused with pyloric stenosis. Gastroesophageal reflux disease can be differentiated from pyloric stenosis by radiographic studies. Adrenal insufficiency from the adrenogenital syndrome can simulate pyloric stenosis, but the absence of a metabolic acidosis and elevated serum potassium and urinary sodium concentrations of adrenal insufficiency aid in differentiation (see Chapter 594). Inborn errors of metabolism can produce recurrent emesis with alkalosis (urea cycle) or acidosis (organic acidemia) and lethargy, coma, or seizures. Vomiting with diarrhea suggests gastroenteritis, but patients with pyloric stenosis occasionally have diarrhea. Rarely, a pyloric membrane or pyloric duplication results in projectile vomiting, visible peristalsis, and, in the case of a duplication, a palpable mass (Table 355.1). Duodenal stenosis proximal to the ampulla of Vater results in the clinical features of pyloric stenosis but can be differentiated by the presence of a pyloric mass on physical examination or ultrasonography.

Table 355.1

Anomalies of the Stomach

ANOMALY	INCIDENCE	AGE AT PRESENTATION	SYMPTOMS AND SIGNS	TREATMENT
Stomach				
Gastric, antral, or pyloric atresia	3/100,000, when combined with webs	Infancy	Nonbilious emesis	Gastroduodenostomy, gastrojejunostomy
Pyloric or antral membrane (web)	As above	Any age	Failure to thrive, emesis	Incision or excision, pyloroplasty
Microgastria	Rare	Infancy	Emesis, malnutrition	Continuous-drip feedings or jejunal reservoir pouch
Gastric diverticulum	Rare	Any age	Usually asymptomatic	Usually unnecessary
Gastric duplication	Rare; male:female, 1 : 2	Any age	Abdominal mass, emesis, hematemesis; peritonitis if ruptured	Excision or partial gastrectomy

Gastric teratoma	Rare	Any age	Upper abdominal mass	Resection
Gastric volvulus	Rare	Any age	Emesis, refusal to feed	Reduction of volvulus, anterior gastropexy
Pyloric stenosis (infantile hypertrophic and adult forms)	United States, 3/1,000 (range, 1-8/1,000 in various regions); male:female, 4 : 1	Infancy	Non-bilious emesis	Pyloromyotomy
Congenital absence of the pylorus	Rare	Childhood, adulthood	Dyspepsia, if symptomatic	Usually unnecessary

Modified from Semrin MG, Russo MA: Anatomy, histology, and developmental anomalies of the stomach and duodenum. In Feldman M, Friedman LS, Brandt LJ, editors: *Sleisenger and Fordtran's gastrointestinal and liver disease* , ed 10, Philadelphia, Saunders, 2015, Table 48.1.

Treatment

The preoperative treatment is directed toward correcting the fluid, acid–base, and electrolyte losses. Correction of the alkalosis is essential to prevent postoperative apnea, which may be associated with anesthesia. Most infants can be successfully rehydrated within 24 hr. Vomiting usually stops when the stomach is empty, and only an occasional infant requires nasogastric suction.

The surgical procedure of choice is pyloromyotomy. The traditional Ramstedt procedure is performed through a short transverse skin incision. The underlying pyloric mass is cut longitudinally to the layer of the submucosa, and the incision is closed. Laparoscopic technique is equally successful and in one study resulted in a shorter time to full feedings and discharge from the hospital as well as greater parental satisfaction. The success of laparoscopy depends on the skill of the surgeon. Postoperative vomiting occurs in half the infants and is thought to be secondary to edema of the pylorus at the incision site. In most infants, feedings can be initiated within 12-24 hr after surgery and advanced to maintenance oral feedings within 36-48 hr after surgery. Persistent vomiting suggests an incomplete pyloromyotomy, gastritis, gastroesophageal reflux disease, or another cause of the obstruction. The surgical treatment of pyloric stenosis is curative, with an operative mortality of 0–0.5%. Endoscopic balloon dilation has been successful in infants with persistent vomiting secondary to incomplete pyloromyotomy.

Conservative management with nasoduodenal feedings is advisable in patients who are not good surgical candidates. Oral and intravenous atropine sulfate (pyloric muscle relaxant) has also been described when surgical expertise is not available with 80% success rate described in some studies. In conservative protocols, atropine is administered intravenously at a dose of 0.01 mg/kg 6 times a day 5 min before feeding. During atropine infusion, the heart rate needs to be continuously monitored by electrocardiography. Oral feeding is started at a volume of 10 mL formula, 6 times a day. The volume is increased day by day until patients tolerate 150 mL/kg/day unless vomiting occurs more than twice a day. When patients are able to tolerate the full volume of formula without vomiting more than twice a day, 0.02 mg/kg atropine is administered orally 6 times a day before feeding. As the conservative management takes longer and oral feedings may not be tolerated at first, worsening of the nutrition status may occur and total parenteral nutrition may be required. It was also postulated that surgical management is more time and cost effective.

355.2

Congenital Gastric Outlet Obstruction

Asim Maqbool, Chris A. Liacouras

Gastric outlet obstruction resulting from pyloric atresia and antral webs is uncommon and accounts for <1% of all the atresias and diaphragms of the alimentary tract (see Table 355.1). The cause of the defects is unknown. Pyloric atresia has been associated with **epidermolysis bullosa** and usually presents in early infancy. The gender distribution is equal.

Clinical Manifestations

Infants with pyloric atresia present with nonbilious vomiting, feeding difficulties, and abdominal distention during the first day of life. **Polyhydramnios** occurs in most cases, and low birth weight is common. The gastric aspirate at birth is large (>20 mL fluid) and should be removed to prevent aspiration. Rupture of the stomach may occur as early as the first 12 hr of life. Infants with antral web may present with less dramatic symptoms, depending on the degree of obstruction. Older children with antral webs present with nausea, vomiting, abdominal pain, and weight loss.

Diagnosis

The diagnosis of congenital gastric outlet obstruction is suggested by the finding of a large, dilated stomach on abdominal plain radiographs or in utero ultrasonography. Upper gastrointestinal (GI) contrast series is usually diagnostic and demonstrates a pyloric dimple. When contrast studies are performed, care must be taken to avoid possible aspiration. An antral web may appear as a thin septum near the pyloric channel. In older children, endoscopy has been helpful in identifying antral webs.

Treatment

The treatment of all causes of gastric outlet obstruction in neonates starts with the correction of dehydration and hypochloremic alkalosis. Persistent vomiting should be relieved with nasogastric decompression. Surgical or endoscopic repair should be undertaken when a patient is stable.

355.3

Gastric Duplication

Asim Maqbool, Chris A. Liacouras

Gastric duplications are uncommon cystic or tubular structures that usually occur within the wall of the stomach (see Table 355.1). They account for 2–7% of all GI duplications. They are most commonly located on the greater curvature. Most are <12 cm in diameter and do not usually communicate with the stomach lumen; however, they do have common blood supply. Associated anomalies occur in as many as 35% of patients. Several hypotheses for the etiology of the duplication cysts have been developed including the splitting notochord theory, diverticulation, canalization defects, and caudal twinning.

The most common clinical manifestations are associated with partial or complete gastric outlet obstruction. In 33% of patients, the cyst may be palpable. Communicating duplications can cause gastric ulceration and be associated with hematemesis or melena.

Radiographic studies usually show a paragastric mass displacing stomach. Ultrasound can show the inner hyperechoic mucosal and outer hypoechoic muscle layers that are typical of GI duplications. Surgical excision is the treatment for symptomatic gastric duplications.

355.4

Gastric Volvulus

Asim Maqbool, Chris A. Liacouras

The stomach is tethered longitudinally by the gastrohepatic, gastrosplenic, and gastrocolic ligaments. In the transverse axis, it is tethered by the gastrophrenic ligament and the retroperitoneal attachment of the duodenum. A volvulus occurs when one of these attachments is absent or elongated, allowing the stomach to rotate around itself. In some children, other associated defects are present, including intestinal malrotation, diaphragmatic defects, hiatal hernia, or adjacent organ abnormalities such as asplenia. Volvulus can occur along the longitudinal axis, producing organoaxial volvulus, or along the transverse axis, producing mesenteroaxial volvulus. Combined volvulus occurs if the stomach rotates around both organoaxial and mesenteroaxial axes.

The clinical presentation of gastric volvulus is nonspecific and suggests high intestinal obstruction. Gastric volvulus in infancy is usually associated with nonbilious vomiting and epigastric distention. It has also been associated with episodes of dyspnea and apnea in this age group. Acute volvulus can advance rapidly to strangulation and perforation. Chronic gastric volvulus is more common in older children; the children present with a history of emesis, abdominal pain and distention, early satiety, and failure to thrive.

The diagnosis is suggested in plain abdominal radiographs by the presence of a dilated stomach. Erect abdominal films demonstrate a double fluid level with a characteristic “beak” near the lower esophageal junction in mesenteroaxial volvulus. The stomach tends to lie in a vertical plane. In organoaxial volvulus, a single air–fluid level is seen without the characteristic beak with stomach lying in a horizontal plane. Upper GI series has also been used to aid the diagnosis.

Treatment of acute gastric volvulus is emergent surgery once a patient is stabilized. Laparoscopic gastropexy is the most common surgical approach. In selected cases of chronic volvulus in older patients, endoscopic correction has been successful.

355.5

Hypertrophic Gastropathy

Asim Maqbool, Chris A. Liacouras

Hypertrophic gastropathy in children is uncommon and, in contrast to that in adults (Ménétrier disease), is usually a transient, benign, and self-limited condition.

Pathogenesis

The condition is most often secondary to cytomegalovirus (CMV) infection, but other agents, including herpes simplex virus, *Giardia*, and *Helicobacter pylori*, are also implicated. The pathophysiologic mechanisms underlying the clinical picture are not completely understood but might involve widening of gap junctions between gastric epithelial cells with resultant fluid and protein losses. There is an association with increased expression of transforming growth factor-α in gastric mucosal tissue shown in CMV-induced gastropathy. *H. pylori* infection can cause the elevation of serum glucagon-like peptide-2 levels, a mucosal growth-inducing gut hormone.

Clinical Manifestations

Clinical manifestations include vomiting, anorexia, upper abdominal pain, diarrhea, edema (hypoproteinemic protein-losing enteropathy), ascites, and, rarely, hematemesis if ulceration occurs.

Diagnosis and Differential Diagnosis

The mean age at diagnosis is 5 yr (range: 2 days to 17 yr); the illness usually lasts 2-14 wk. Endoscopy with biopsy and tissue CMV polymerase chain reaction is diagnostic. Endoscopy shows characteristic enlarged gastric folds. The upper GI series might show thickened gastric folds. The differential diagnosis includes eosinophilic gastroenteritis, gastric lymphoma or carcinoma, Crohn disease, and inflammatory pseudotumor.

Treatment

Therapy is supportive and should include adequate hydration, antisecretory agents (H_2 receptor blockade, acid suppression with proton pump inhibitors), and albumin replacement if the hypoalbuminemia is symptomatic. When *H. pylori* are detected, appropriate treatment is recommended. Ganciclovir in CMV-positive gastropathy is indicated only in severe cases. There are no official guidelines as far as the length of treatment. In practice, IV therapy is initiated for the 1st 24-48 hr. Treatment is continued with oral valganciclovir for a total of 3 wk. Complete recovery is the rule. Hypertrophic gastropathy should be considered in a previously healthy child with new onset edema and no other causes of protein losses. This is not a chronic condition in children, and the disease tends to have much more severe course in adult patients.

CHAPTER 356

Intestinal Atresia, Stenosis, and Malrotation

Asim Maqbool, Christina Bales, Chris A. Liacouras

Approximately 1 in 1,500 children is born with intestinal obstruction. Obstruction may be partial or complete, and it may be characterized as simple or strangulating. Luminal contents fails to progress in an aboral direction in simple obstruction, whereas blood flow to the intestine is also impaired in strangulating obstruction. If strangulating obstruction is not promptly relieved, it can lead to bowel infarction and perforation.

Intestinal obstruction can be further classified as either intrinsic or extrinsic based on underlying etiology. Intrinsic causes include inherent abnormalities of intestinal innervation, mucus production, or tubular anatomy. Among these, congenital disruption of the tubular structure is most common and can manifest as obliteration (**atresia**) or narrowing (**stenosis**) of the intestinal lumen. More than 90% of intestinal stenosis and atresia occurs in the duodenum, jejunum, and ileum. Rare cases occur in the colon, and these may be associated with more proximal atresias.

Extrinsic causes of congenital intestinal obstruction involve compression of the bowel by vessels (e.g., preduodenal portal vein), organs (e.g., annular pancreas), and cysts (e.g., duplication, mesenteric). Abnormalities in intestinal rotation during fetal development also represent a unique extrinsic cause of congenital intestinal obstruction. Malrotation is associated with inadequate mesenteric attachment of the intestine to the posterior abdominal wall, which leaves the bowel vulnerable to auto obstruction as a result of intestinal twisting or volvulus. Malrotation is commonly accompanied by congenital adhesions that can compress and obstruct the duodenum as they extend from the cecum to the right upper quadrant.

Obstruction is typically associated with bowel distention, which is caused by an accumulation of ingested food, gas, and intestinal secretions proximal to the point of obstruction. As the bowel dilates, absorption of intestinal fluid is decreased and secretion of fluid and electrolytes is increased. This shift results in isotonic intravascular depletion, which is usually associated with hypokalemia. Bowel distention also results in a decrease in blood flow to the obstructed bowel. As blood flow is shifted away from the intestinal mucosa, there is loss of mucosal integrity. Bacteria proliferate in the stagnant bowel, with a predominance of coliforms and anaerobes. This rapid proliferation of bacteria, coupled with the loss of mucosal integrity, allows bacteria to translocate across the bowel wall and potentially lead to endotoxemia, bacteremia, and sepsis.

The clinical presentation of intestinal obstruction varies with the cause, level of obstruction, and time between the obstructing event and the patient's evaluation. Classic symptoms of obstruction in the neonate include vomiting, abdominal distention, and obstipation. Obstruction high in the intestinal tract results in large-volume, frequent, bilious emesis with little or no abdominal distention. Pain is intermittent and is usually relieved by vomiting. Obstruction in the distal small bowel leads to moderate or marked abdominal distention with emesis that is progressively feculent. Both proximal and distal obstructions are eventually associated with obstipation. However, meconium stools can be passed initially if the obstruction is in the upper part of the intestinal tract or if the obstruction developed late in intrauterine life.

The diagnosis of congenital bowel obstruction relies on a combination of history, physical examination, and radiologic findings. In certain cases, the diagnosis is suggested in the prenatal period. Routine prenatal ultrasound can detect polyhydramnios, which often accompanies high intestinal obstruction. The presence of polyhydramnios should prompt aspiration of the infant's stomach immediately after birth. Aspiration of more than 15-20 mL of fluid, particularly if it is bile stained, is highly indicative of proximal intestinal obstruction.

In the postnatal period, a plain radiograph is the initial diagnostic study and can provide valuable information about potential associated complications. With completely obstructing lesions, plain radiographs reveal bowel distention proximal to the point of obstruction. Upright or crosstable lateral views typically demonstrate a series of air–fluid levels in the distended loops. Caution must be exercised in using plain films to determine the location of intestinal obstruction. Because colonic haustra are not fully developed in the neonate, small and large bowel obstructions may be difficult to distinguish with plain films. In these cases, contrast studies of the bowel or computed tomography images may be indicated. Oral or nasogastric contrast medium may be used to identify obstructing lesions in the proximal bowel, and contrast enemas may be used to diagnose more-distal entities. Indeed, enemas may also play a therapeutic role in relieving distal obstruction caused by meconium ileus or meconium plug syndrome.

Initial treatment of infants and children with bowel obstruction must be directed at fluid resuscitation and stabilizing the patient. Nasogastric decompression usually relieves pain and vomiting. After appropriate cultures, broad-spectrum antibiotics are usually started in ill-appearing neonates with bowel obstruction and those with suspected strangulating infarction. Patients with strangulation must have immediate surgical relief before the bowel infarcts, resulting in gangrene and intestinal perforation. Extensive intestinal necrosis results in short bowel syndrome (see Chapter 364.7). Nonoperative conservative management is usually limited to children with suspected adhesions or inflammatory strictures that might resolve with nasogastric decompression or antiinflammatory medications. If clinical signs of improvement are not evident within 12-24 hr, then operative intervention is usually indicated.

356.1

Duodenal Obstruction

Asim Maqbool, Chris A. Liacouras

Congenital duodenal obstruction occurs in 2.5-10/100,000 live births. In most cases, it is caused by atresia, an intrinsic defect of bowel formation. It can also result from extrinsic compression by abnormal neighboring structures (e.g., annular pancreas, preduodenal portal vein), duplication cysts, or congenital bands associated with malrotation. Although intrinsic and extrinsic causes of duodenal obstruction occur independently, they can also coexist. Thus a high index of suspicion for more than one underlying etiology may be critical to avoiding unnecessary reoperations in these infants.

Duodenal atresia complicates 1/10,000 live births and accounts for 25–40% of all intestinal atresias. In contrast to more-distal atresias, which likely arise from prenatal vascular accidents, duodenal atresia results from failed recanalization of the intestinal lumen during gestation. Throughout the 4th and 5th wk of normal fetal development, the duodenal mucosa exhibits rapid proliferation of epithelial cells. Persistence of these cells, which should degenerate after the 7th wk of gestation, leads to occlusion of the lumen (atresia) in approximately two-thirds of cases and narrowing (stenosis) in the remaining one-third. Duodenal atresia can take several forms, including a thin membrane that occludes the lumen, a short fibrous cord that connects two blind duodenal pouches, or a gap that spans two nonconnecting ends of the duodenum. The membranous form is most common, and it almost invariably occurs near the ampulla of Vater. In rare cases, the membrane is distensible and is referred to as a *windsock web* . This unusual form of duodenal atresia causes obstruction several centimeters distal to the origin of the membrane.

Approximately 50% of infants with duodenal atresia are premature. Concomitant congenital anomalies are common and include congenital heart disease (30%), malrotation (20–30%), annular pancreas (30%), renal anomalies (5–15%), esophageal atresia with or without tracheoesophageal fistula (5–10%), skeletal malformations (5%), and anorectal anomalies (5%). Of these anomalies, only complex congenital heart disease is associated with increased mortality. Annular pancreas is associated with increased late complications, including gastroesophageal reflux disease, peptic ulcer disease, pancreatitis, gastric outlet and recurrent duodenal obstruction, and gastric cancer. Thus long-term follow-up of these patients into adulthood is warranted. Nearly half of patients with duodenal atresia have chromosome abnormalities; trisomy 21 is identified in up to one-third of patients.

Clinical Manifestations and Diagnosis

The hallmark of duodenal obstruction is bilious vomiting without abdominal distention, which is usually noted on the first day of life. Peristaltic waves may be visualized early in the disease process. A history of polyhydramnios is present in half the pregnancies and is caused by inadequate absorption of amniotic fluid in the distal intestine. This fluid may be bile stained because of intrauterine vomiting. Jaundice is present in one-third of the infants.

The diagnosis is suggested by the presence of a *double-bubble* sign on a plain abdominal radiograph (Fig. 356.1). The appearance is caused by a distended and gas-filled stomach and proximal duodenum, which are invariably connected. Contrast studies are occasionally needed to exclude malrotation and volvulus because intestinal infarction can occur within 6-12 hr if the volvulus is not relieved. Contrast studies are generally not necessary and may be associated with aspiration. Prenatal diagnosis of duodenal atresia is readily made by fetal ultrasonography, which reveals a sonographic double-bubble. Prenatal identification of duodenal atresia is associated with decreased morbidity and fewer hospitalization days.

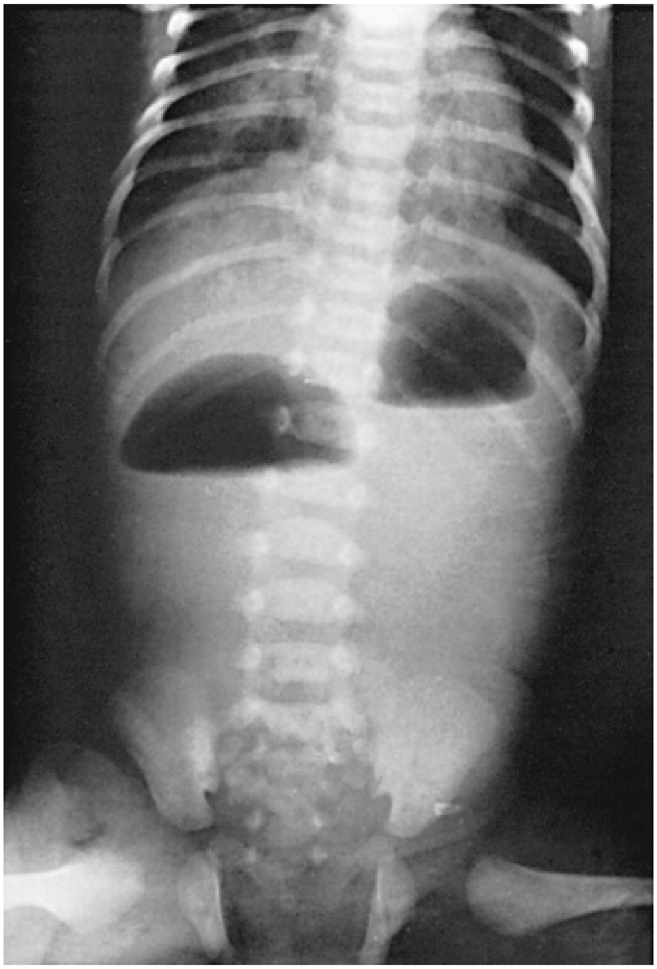

FIG. 356.1 Abdominal radiograph of a newborn infant held upright. Note the "double-bubble" gas shadow above and the absence of gas in the distal bowel in this case of congenital duodenal atresia.

Treatment

The initial treatment of infants with duodenal atresia includes nasogastric or orogastric decompression and intravenous fluid replacement. Echocardiography, renal ultrasound, and radiology of the chest and spine should be performed to evaluate for associated anomalies. Definitive correction of the atresia is usually postponed until life-threatening anomalies are evaluated and treated.

The typical surgical repair for duodenal atresia is duodenoduodenostomy. This procedure is also preferred in cases of concomitant or isolated annular pancreas. In these instances, the duodenoduodenostomy is performed without dividing the pancreas. The dilated proximal bowel might have to be tapered to improve peristalsis. Postoperatively, a gastrostomy tube can be placed to drain the stomach and protect the airway. Intravenous nutritional support or a transanastomotic jejunal tube is needed until an infant starts to feed orally. Long-term prognosis is excellent, approaching 90% survival in most series.

356.2

Jejunal and Ileal Atresia and Obstruction

Asim Maqbool, Chris A. Liacouras

The primary etiologies of congenital small bowel obstruction involve intrinsic abnormalities in anatomic development (jejunoileal stenosis and atresia), mucus secretion (meconium ileus), and bowel wall innervation (long-segment Hirschsprung disease).

Jejunoileal atresias are generally attributed to intrauterine vascular accidents, which result in segmental infarction and resorption of the fetal intestine. Underlying events that potentiate vascular compromise include intestinal volvulus, intussusception, meconium ileus, and strangulating herniation through an abdominal wall defect associated with gastroschisis or omphalocele. Maternal behaviors that promote vasoconstriction, such as cigarette smoking and cocaine use, might also have a role. Only a few cases of familial inheritance have been reported. In these families, multiple intestinal atresias have occurred in an autosomal recessive pattern. Jejunoileal atresias have been linked with multiple births, low birthweight, and prematurity. Unlike atresia in the duodenum, they are not commonly associated with extraintestinal anomalies.

Five types of jejunal and ileal atresias are encountered (Fig. 356.2). In type I, a mucosal web occludes the lumen, but continuity is maintained between the proximal and distal bowel. Type II involves a small-diameter solid cord that connects the proximal and distal bowel. Type III is divided into two subtypes. Type IIIa occurs when both ends of the bowel end in blind loops, accompanied by a small mesenteric defect. Type IIIb is similar, but it is associated with an extensive mesenteric defect and a loss of the normal blood supply to the distal bowel. The distal ileum coils around the ileocolic artery, from which it derives its entire blood supply, producing an “apple-peel” appearance. This anomaly is associated with prematurity, an unusually short distal ileum, and significant foreshortening of the bowel. Type IV involves multiple atresias. Types II and IIIa are the most common, each accounting for 30-35% of cases. Type I occurs in approximately 20% of patients. Types IIIb and IV account for the remaining 10–20% of cases, with IIIb being the least-common configuration.

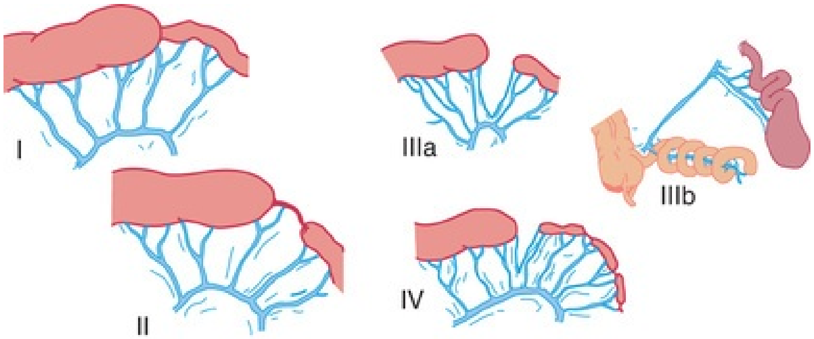

FIG. 356.2 Classification of intestinal atresia. *Type I:* Mucosal obstruction caused by an intraluminal membrane with intact bowel wall and mesentery. *Type II:* Blind ends are separated by a fibrous cord. *Type IIIa:* Blind ends are separated by a V-shaped mesenteric defect. *Type IIIb:* "Apple-peel" appearance. *Type IV:* Multiple atresias. (From Grosfeld J: Jejunoileal atresia and stenosis. In Welch KJ, Randolph JG, Ravitch MM, editors: *Pediatric surgery,* ed 4, Chicago, 1986, Year Book Medical Publishers.)

Meconium ileus occurs primarily in newborn infants with cystic fibrosis, an exocrine gland defect of chloride transport that results in abnormally viscous secretions (Chapter 432). Approximately 80–90% of infants with meconium ileus have cystic fibrosis, but only 10–15% of infants with cystic fibrosis present with meconium ileus. In simple cases, the distal 20-30 cm of ileum is collapsed and filled with pellets of pale stool. The proximal bowel is dilated and filled with thick meconium that resembles sticky syrup or glue. Peristalsis fails to propel this viscid material forward, and it becomes impacted in the ileum. In complicated cases, a volvulus of the dilated proximal bowel can occur, resulting in intestinal ischemia, atresia, and/or perforation. Perforation in utero results in meconium peritonitis, which can lead to potentially obstructing adhesions and calcifications.

Both intestinal atresia and meconium ileus must be distinguished from long-segment Hirschsprung disease. This condition involves congenital absence of ganglion cells in the myenteric and submucosal plexuses of the bowel wall. In a small subset (5%) of patients, the aganglionic segment includes the terminal ileum in addition to the entire length of the colon. Infants with long-segment Hirschsprung disease present with a dilated small intestine that is ganglionated but has hypertrophied walls, a funnel-shaped transitional hypoganglionic zone, and a collapsed distal aganglionic bowel.

Clinical Manifestation and Diagnosis

Distal intestinal obstruction is less likely than proximal obstruction to be detected in utero. Polyhydramnios is identified in 20–35% of jejunoileal atresias, and it may be the first sign of intestinal obstruction. Abdominal distention is rarely present at birth, but it develops rapidly after initiation of feeds in the first 12-24 hr. Distention is often accompanied by vomiting, which is often bilious. Up to 80% of infants fail to pass meconium in the first 24 hr of life. Jaundice, associated with unconjugated hyperbilirubinemia, is reported in 20–30% of patients.

In patients with obstruction caused by jejunoileal atresia or long-segment Hirschsprung disease, plain radiographs typically demonstrate multiple air–fluid levels proximal to the obstruction in the upright or lateral decubitus positions (Fig. 356.3). These levels may be absent in patients with meconium ileus because the viscosity of the secretions in the proximal bowel prevents layering. Instead, a typical hazy or ground-glass appearance may be appreciated in the right lower quadrant. This haziness is caused by small bubbles of gas that become trapped in inspissated meconium in the terminal ileal region. If there is meconium peritonitis, patchy calcification may also be noted, particularly in the flanks. Plain films can reveal evidence of pneumoperitoneum due to intestinal perforation. Air may be seen in the subphrenic regions on the upright view and over the liver in the left lateral decubitus position.

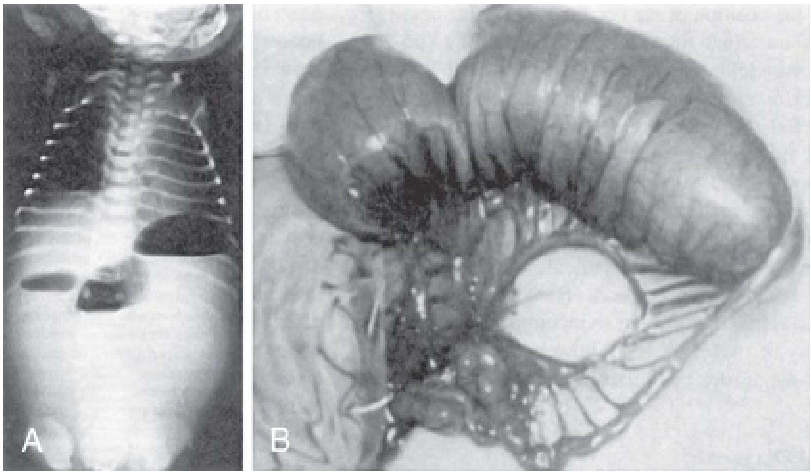

FIG. 356.3 **A,** Abdominal radiograph in a neonate with bilious vomiting shows a few loops of dilated intestine with air–fluid levels. **B,** At laparotomy, a type I (mucosal) jejunal atresia was observed. (From O'Neill JA Jr, Grosfeld JL, Fonkalsrud EW, et al, editors: *Principles of pediatric surgery,* ed 2, St. Louis, 2003, Mosby, p. 493.)

Because plain radiographs do not reliably distinguish between small and large bowel in neonates, contrast studies are often required to localize the obstruction. Water-soluble enemas (Gastrografin, Hypaque) are particularly useful in differentiating atresia from meconium ileus and Hirschsprung disease. A small *microcolon* suggests disuse and the presence of obstruction proximal to the ileocecal valve. Abdominal ultrasound may be an important adjunctive study, which can distinguish meconium ileus from ileal atresia and also identify concomitant intestinal malrotation.

Treatment

Patients with small bowel obstruction should be stable and in adequate fluid and electrolyte balance before operation or radiographic attempts at disimpaction unless volvulus is suspected. Documented infections should be treated with appropriate antibiotics. Prophylactic antibiotics are usually given before surgery.

Ileal or jejunal atresia requires resection of the dilated proximal portion of the bowel followed by end-to-end anastomosis. If a simple mucosal diaphragm is present, jejunoplasty or ileoplasty with partial excision of the web is an acceptable alternative to resection. In uncomplicated meconium ileus, Gastrografin enemas diagnose the obstruction and wash out the inspissated material. Gastrografin is hypertonic, and care must be taken to avoid dehydration, shock, and bowel perforation. The enema may have to be repeated after 8-12 hr. Resection after reduction is not needed if there have been no ischemic complications.

Approximately 50% of patients with simple meconium ileus do not adequately respond to water-soluble enemas and need laparotomy. Operative management is indicated when the obstruction cannot be relieved by repeated attempts at nonoperative management and for infants with complicated meconium ileus. The extent of surgical intervention depends on the degree of pathology. In simple meconium ileus, the plug can be relieved by manipulation or direct enteral irrigation with *N* -acetylcysteine following an enterotomy. In complicated cases, bowel resection, peritoneal lavage, abdominal drainage, and stoma formation may be necessary. Total parenteral nutrition is generally required.

356.3

Malrotation

Asim Maqbool, Chris A. Liacouras

Malrotation is incomplete rotation of the intestine during fetal development and involves the intestinal nonrotation or incomplete rotation around the superior mesenteric artery. The gut starts as a straight tube from stomach to rectum. Intestinal rotation and attachment begin in the 5th wk of gestation when the midbowel (distal duodenum to midtransverse colon) begins to elongate and progressively protrudes into the umbilical cord until it lies totally outside the confines of the abdominal cavity. As the developing bowel rotates in and out of the abdominal cavity, the superior mesenteric artery, which supplies blood to this section of gut, acts as an axis. The duodenum, on reentering the abdominal cavity, moves to the region of the ligament of Treitz, and the colon that follows is directed to the left upper quadrant. The cecum subsequently rotates counterclockwise within the abdominal cavity and comes to lie in the right lower quadrant. The duodenum becomes fixed to the posterior abdominal wall before the colon is completely rotated. After rotation, the right and left colon and the mesenteric root become fixed to the posterior abdomen. These attachments provide a broad base of support to the mesentery and the superior mesenteric artery, thus preventing twisting of the mesenteric root and kinking of the vascular supply. Abdominal rotation and attachment are completed by the 12th wk of gestation.

Nonrotation occurs when the bowel fails to rotate after it returns to the abdominal cavity. The first and second portions of the duodenum are in their normal position, but the remainder of the duodenum, jejunum, and ileum occupy the right side of the abdomen and the colon is located on the left. The most common type of malrotation involves failure of the cecum to move into the right lower quadrant (Fig. 356.4). The usual location of the cecum is in the subhepatic area. Failure of the cecum to rotate properly is associated with failure to form the normal broad-based adherence to the posterior abdominal wall. The mesentery, including the superior mesenteric artery, is tethered by a narrow stalk, which can twist around itself and produce a midgut volvulus. Bands of tissue **(Ladd bands)** can extend from the cecum to the right upper quadrant, crossing, and possibly obstructing, the duodenum.

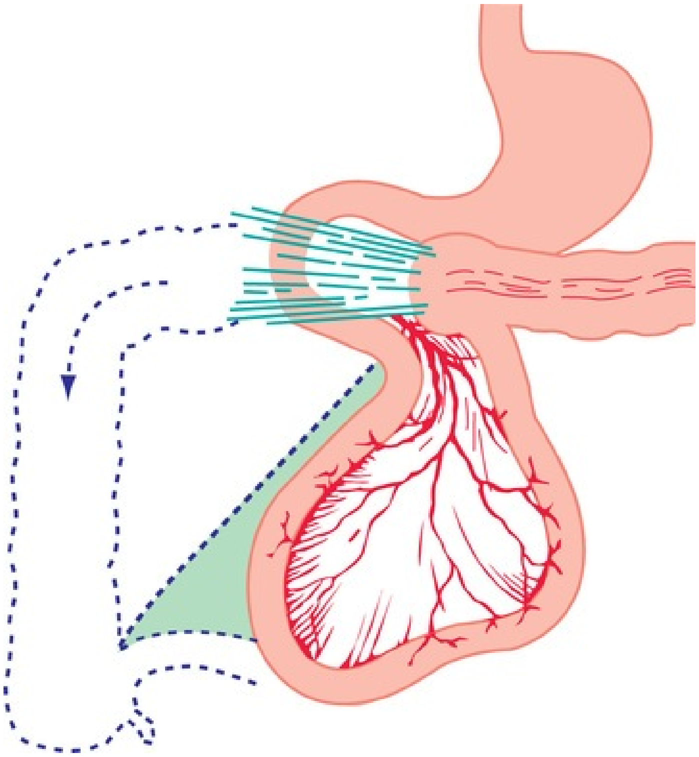

FIG. 356.4 **The mechanism of intestinal obstruction with incomplete rotation of the midgut (malrotation). The *dotted lines* show the course the cecum should have taken. Failure to rotate has left obstructing bands across the duodenum and a narrow pedicle for the midgut loop, making it susceptible to volvulus. (From Nixon HH, O'Donnell B: *The essentials of pediatric surgery,* Philadelphia, 1961, JB Lippincott.)**

Malrotation and nonrotation are often associated with other anomalies of the abdominal wall such as diaphragmatic hernia, gastroschisis, and omphalocele. Malrotation is also associated with the **heterotaxy syndrome** , which is a complex of congenital anomalies including congenital heart malformations, malrotation, biliary atresia, and either asplenia or polysplenia (see Chapter 458.11).

Clinical Manifestations

The reported incidence of malrotation is approximately 1 in 500 infants. The majority, about 75–85% of patients, present in the first yr of life, and more than 50% present within the first mo of life, with symptoms of acute or chronic obstruction. Vomiting is the most common symptom in this age group. Infants often present in the first wk of life with **bilious emesis** and acute bowel obstruction. Older infants present with episodes of recurrent abdominal pain that can mimic colic and suggest intermittent volvulus. Malrotation in older children can manifest with recurrent episodes of vomiting and/or abdominal pain. Patients occasionally present with **malabsorption** or **protein-losing enteropathy** associated with bacterial overgrowth. Symptoms are caused by intermittent volvulus or duodenal compression by Ladd bands or other adhesive bands affecting the small and large bowel. Approximately 25–50% of adolescents with malrotation are asymptomatic. Adolescents who become symptomatic present with acute intestinal obstruction or history of recurrent episodes of abdominal pain or postprandial bloating and occasional vomiting. Patients of any age with a rotational anomaly can develop acute bowel-threatening volvulus without preexisting symptoms.

An acute presentation of small bowel obstruction in a patient without previous bowel surgery can be the result of **volvulus** associated with malrotation. This is a life-threatening complication of malrotation, which resembles an acute abdomen or sepsis and is the main reason that symptoms suggesting malrotation should always be investigated. Volvulus occurs when the small bowel twists around the superior mesenteric artery leading to vascular compromise of the bowel. The diagnosis may be suggested by ultrasound but is confirmed by contrast radiographic studies. The abdominal plain film is usually nonspecific but might demonstrate a gasless abdomen or evidence of duodenal obstruction with a double-bubble sign. Upper gastrointestinal series is the imaging test of choice and the gold standard in the evaluation and diagnosis of malrotation and volvulus. Normal rotation is indicated by the duodenal C-loop crossing the midline and a duodenojejunal junction located to the left of the spine. Upper gastrointestinal series is the best exam to visualize the malposition of the ligament of Treitz and can also reveal a corkscrew appearance of the small bowel or a duodenal obstruction with a *bird's beak* appearance of the duodenum. Barium enema usually demonstrates malposition of the cecum but is normal in up to 20% of patients. Ultrasonography can demonstrate the inversion of the superior mesenteric artery and vein. A superior mesenteric vein located to the left of the superior mesenteric artery suggests malrotation. Malrotation with volvulus is suggested by duodenal obstruction, thickened bowel loops to the right of the spine, the superior mesenteric vein coiling around the superior mesenteric artery, and free peritoneal fluid.

Treatment

Surgical intervention is recommended for any patient with a significant rotational abnormality, regardless of age. If a volvulus is present, surgery is done immediately as an acute emergency, the volvulus is reduced, and the duodenum and upper jejunum are freed of any bands and remain in the right abdominal cavity. The colon is freed of adhesions and placed in the right abdomen with the cecum in the left lower quadrant, usually accompanied by incidental appendectomy. The Ladd procedure may be done laparoscopically for malrotation without volvulus and if gut ischemia is not present, but it is generally done as an open procedure if volvulus is present. The purpose of surgical intervention is to minimize the risk of subsequent volvulus rather than to return the bowel to a normal anatomic configuration. Extensive intestinal ischemia from volvulus can result in short bowel syndrome (see Chapter 364.7).

Intestinal Duplication

Asim Maqbool, Chris A. Liacouras

Duplications of the intestinal tract are rare anomalies that consist of well-formed tubular or spherical structures firmly attached to the intestine with a common blood supply. The lining of the duplications resembles that of the gastrointestinal (GI) tract. Duplications are located on the mesenteric border and can communicate with the intestinal lumen. Duplications can be classified into three categories: localized duplications, duplications associated with spinal cord defects and vertebral malformations, and duplications of the colon. Occasionally (10–15% of cases), multiple duplications are found.

Localized duplications can occur in any area of the GI tract but are most common in the ileum and jejunum. They are usually cystic or tubular structures within the wall of the bowel. The cause is unknown, but their development has been attributed to defects in recanalization of the intestinal lumen after the solid stage of embryologic development. Duplication of the intestine occurring in association with **vertebral and spinal cord anomalies** (hemivertebra, anterior spina bifida, band connection between lesion and cervical or thoracic spine) is thought to arise from splitting of the notochord in the developing embryo.

Duplication of the colon is usually associated with anomalies of the urinary tract and genitals. Duplication of the entire colon, rectum, anus, and terminal ileum can occur. The defects are thought to be secondary to caudal twinning, with duplication of the hindgut, genital, and lower urinary tracts.

Clinical Manifestations

Symptoms depend on the size, location, and mucosal lining. Duplications can cause bowel obstruction by compressing the adjacent intestinal lumen, or they can act as the lead point of an intussusception or a site for a volvulus. If they are lined by acid-secreting mucosa, they can cause ulceration, perforation, and hemorrhage of or into the adjacent bowel. Patients can present with abdominal pain, vomiting, palpable mass, or acute GI hemorrhage. Intestinal duplications in the thorax **(neuroenteric cysts)** can manifest as respiratory distress. Duplications of the lower bowel can cause constipation or diarrhea or be associated with recurrent prolapse of the rectum.

The diagnosis is suspected on the basis of the history and physical examination. Radiologic studies such as barium studies, ultrasonography, CT, and MRI are helpful but usually nonspecific, demonstrating cystic structures or mass effects. Radioisotope technetium scanning can localize ectopic gastric mucosa. The treatment of duplications is surgical resection and management of associated defects.

357.2

Meckel Diverticulum and Other Remnants of the Omphalomesenteric Duct

Melissa A. Kennedy, Asim Maqbool, Chris A. Liacouras

Meckel diverticulum is the most common congenital anomaly of the GI tract and is caused by the incomplete obliteration of the omphalomesenteric duct during the 7th wk of gestation. The omphalomesenteric duct connects the yolk sac to the gut in a developing embryo and provides nutrition until the placenta is established. Between the 5th and 7th wk of gestation, the duct attenuates and separates from the intestine. Just before this involution, the epithelium of the yolk sac develops a lining similar to that of the stomach. Partial or complete failure of involution of the omphalomesenteric duct results in various residual structures. Meckel diverticulum is the most common of these structures and is the most common congenital GI anomaly, occurring in 2–3% of all infants. A typical Meckel diverticulum is a 3-6 cm outpouching of the ileum along the antimesenteric border 50-75 cm (approximately 2 feet) from the ileocecal valve (Fig. 357.1). The distance from the ileocecal valve depends on the age of the patient. Meckel diverticulum has been conveniently referred to by the “rule of 2s,” which explains the classic presentation of this congenital anomaly. Meckel diverticulum are found in approximately 2% of the general population, are usually located 2 feet proximal to the ileocecal valve and are approximately 2 inches in length, can contain 2 types of ectopic tissue (pancreatic or gastric), generally present before the age of 2 yr, and are found twice as commonly in females. Although intraabdominal in location, a rare presentation of a Meckel diverticulum is entrapment in an inguinal, umbilical, or femoral hernia (Littre hernia). Other omphalomesenteric duct remnants occur infrequently, including a persistently patent duct, a solid cord, or a cord with a central cyst or a diverticulum associated with a persistent cord between the diverticulum and the umbilicus.

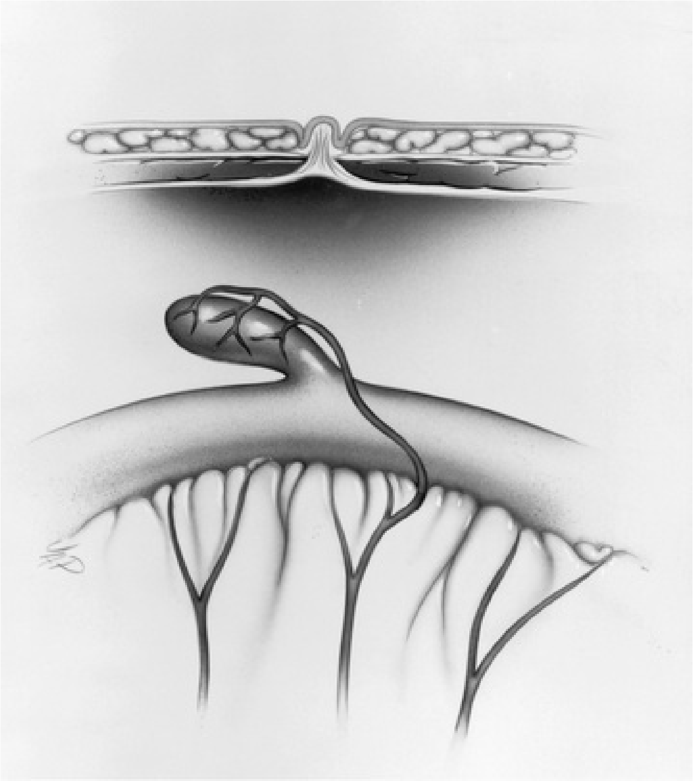

FIG. 357.1 Typical Meckel diverticulum located on the antimesenteric border.

Clinical Manifestations

Symptoms of a Meckel diverticulum usually arise in the first or second yr of life (average: 2.5 yr), but initial symptoms can occur in the first decade. The majority of symptomatic Meckel diverticula are lined by an ectopic mucosa, including an acid-secreting mucosa that causes intermittent painless rectal bleeding by ulceration of the adjacent normal ileal mucosa. This ectopic mucosa is most commonly of gastric origin, but it can also be pancreatic, jejunal, or a combination of these tissues. Unlike the upper duodenal mucosa, the acid is not neutralized by pancreatic bicarbonate.

The stool is typically described as brick colored or currant jelly colored. Bleeding can cause significant anemia but is usually self-limited because of contraction of the splanchnic vessels, as patients become hypovolemic. Bleeding from a Meckel diverticulum can also be less dramatic, with melanotic stools.

Less often, a Meckel diverticulum is associated with partial or complete bowel obstruction. The most common mechanism of obstruction occurs when the diverticulum acts as the lead point of an intussusception. The mean age of onset of obstruction is younger than that for patients presenting with bleeding. Obstruction can also result from intraperitoneal bands connecting residual omphalomesenteric duct remnants to the ileum and umbilicus. These bands cause obstruction by internal herniation or volvulus of the small bowel around the band. A Meckel diverticulum occasionally becomes inflamed **(diverticulitis)** and manifests similarly to acute appendicitis. These children are older, with a mean of 8 yr of age. Diverticulitis can lead to perforation and peritonitis.

Diagnosis

The diagnosis of omphalomesenteric duct remnants depends on the clinical presentation. If an infant or child presents with significant painless rectal bleeding, the presence of a Meckel diverticulum should be suspected because Meckel diverticulum accounts for 50% of all lower GI bleeds in children younger than 2 yr of age.

Confirmation of a Meckel diverticulum can be difficult. Plain abdominal radiographs are of no value, and routine barium studies rarely fill the diverticulum. The most sensitive study is a Meckel radionuclide scan, which is performed after intravenous infusion of technetium-99m pertechnetate. The mucus-secreting cells of the ectopic gastric mucosa take up pertechnetate, permitting visualization of the Meckel diverticulum (Fig. 357.2). The uptake can be enhanced with various agents, including cimetidine, ranitidine, glucagon, and pentagastrin. The sensitivity of the enhanced scan is approximately 85%, with a specificity of approximately 95%. A false-negative scan may be seen in anemic patients; although false-positive results are uncommon, they have been reported with intussusception, appendicitis, duplication cysts, arteriovenous malformations, and tumors. Other methods of detection include radiolabeled tagged red blood cell scan (the patient must be actively bleeding), abdominal ultrasound, superior mesenteric angiography, abdominal CT scan, or exploratory laparoscopy. In patients who present with intestinal obstruction or a picture of appendicitis with omphalomesenteric duct remnants, the diagnosis is rarely made before surgery.

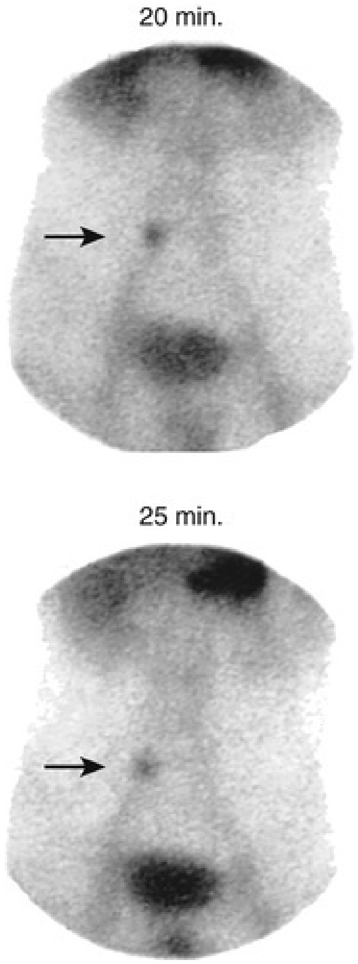

FIG. 357.2 Meckel scan demonstrating accumulation of technetium in the stomach superior bladder (inferior) and in the acid-secreting mucosa of a Meckel diverticulum.

The treatment of a symptomatic Meckel diverticulum is surgical excision. A diverticulectomy can be performed safely as either a laparoscopic or open procedure, although most continue to be performed as open procedures. There is significant debate regarding the proper management of an asymptomatic Meckel diverticulum and whether excision vs observation is appropriate. However, the risk of serious complications does seem to exceed the operative risk in children younger than 8 yr old.

CHAPTER 358

Motility Disorders and Hirschsprung Disease

358.1

Chronic Intestinal Pseudoobstruction

Asim Maqbool, Kristin N. Fiorino, Chris A. Liacouras

Chronic intestinal pseudoobstruction (CIPO) comprises a group of primary and secondary disorders characterized as a motility disorder with the dominant defect of impaired peristalsis; symptoms are consistent with intestinal obstruction in the absence of mechanical obstruction (Table 358.1). The natural history of primary pseudoobstruction is that of a progressive disorder, although there are occasional cases of secondary pseudoobstruction caused by conditions that can transiently or permanently alter bowel motility. The most common cause of acute pseudoobstruction is Ogilvie syndrome (acute pseudoobstruction of the colon). Pseudoobstruction represents a wide spectrum of pathologic disorders from abnormal myoelectric activity to abnormalities of the nerves (intestinal neuropathy) or musculature (intestinal myopathy) of the gut. The organs involved can include the entire gastrointestinal tract or be limited to certain components, although almost always include the small bowel. The distinctive pathologic abnormalities are considered together because of their clinical similarities. For these reasons, CIPO may be thought of more as a clinical syndrome at times.

Table 358.1

Causes of Secondary Chronic Intestinal Pseudoobstruction in Children

- Autoimmune
- Autoimmune myositis
- Autoimmune ganglionitis
- Scleroderma
- Endocrine
- Diabetes mellitus
- Hypoparathyroidism

  - Polymyositis
  - Systemic lupus erythematous

From Bitton S, Markowitz JF: Ulcerative colitis in children and adolescents. In Wyllie R, Hyams JS, Kay M, editors: *Pediatric gastrointestinal and liver disease,* 5th ed, Elsevier, 2016, Philadelphia, Box. 44.3, p. 548.

Most congenital forms of primary pseudoobstruction occur sporadically, although autosomal dominant *(SOX10),* autosomal recessive *(RAD2I, SGOL1, TYMP, POLG),* X-linked *(FLNA, L1CAM),* and familial patterns of inheritance have been identified. Patients with autosomal dominant forms of pseudoobstruction have variable expressions of the disease. Patients with mutations in *TYMP* and *POLG* genes present with mitochondrial neurogastrointestinal encephalomyopathy syndrome (MNGIE); MELAS syndrome is another mitochondrial disorder associated with CIPO. MNGIE is characterized by intestinal dysmotility, abdominal pain and distention, emesis, cachexia, ptosis, leukoencephalopathy, peripheral neuropathy (paresthesia, pain), and myopathy. Sixty percent have symptoms (often subtle) before age 20 yr (see Chapter 358.2). *Acquired* pseudoobstruction can follow episodes of acute gastroenteritis, presumably resulting in injury to the myenteric plexus.

In *congenital* pseudoobstruction, abnormalities of the muscle or nerves can be demonstrated in most cases. In myopathies, the smooth muscle is involved, in which the outer longitudinal muscle layer is replaced by fibrous material. These manifestations of visceral myopathies may be primary or secondary phenomenon. The enteric nervous system is usually altered in neuropathies and may involve disorganized ganglia, hypoganglionosis, or hyperganglionosis. Abnormalities in the interstitial cells of Cajal, the intestinal pacemaker, are classified as mesenchymopathies. In others, mitochondrial defects have been identified.

Clinical Manifestations

More than half the children with congenital pseudoobstruction experience symptoms in the first few mo of life (Table 358.2). Two-thirds of the infants presenting in the first few days of life are born prematurely, and approximately 40% have malrotation of the intestine. In 75% of all affected children, symptoms occur in the first year of life, while the remainder are usually symptomatic within the next several years. Females present with CIPO more than males do during the first year of life, with equal sex distribution in older children. The most common symptoms are abdominal distention (85–95% of patients) and vomiting (55–90%). Constipation, growth failure, and abdominal pain occur in approximately 60% of patients and diarrhea in 25–30%. The symptoms wax and wane in most patients; poor nutrition, psychologic stress, and intercurrent illness tend to exacerbate symptoms. Urinary tract and bladder involvement occurs in 80% of children with myopathic pseudoobstruction and in 20% of those with neuropathic disease. Symptoms can manifest as recurrent urinary tract infection, megacystis, or obstructive symptoms. Megacystis-microcolon–intestinal hypoperistalsis syndrome is a prenatal or neonatal manifestation of CIPO.

Table 358.2

Main Similarities and Differences in Chronic Intestinal Pseudoobstruction in Children, Adolescents, and Young Adults

	CHILDREN	ADOLESCENTS—YOUNG ADULTS
Etiology	Mainly idiopathic	Half of cases are secondary to acquired diseases
Histopathology	Myopathies and neuropathies	Mainly neuropathies
Symptom onset	In utero, from birth or early infancy with 65–80% of patients symptomatic by 12 mo of age	Median age of onset at 17 yr
Clinical features	Occlusive symptoms at birth and/or chronic symptoms without free intervals Urologic involvement is commonly encountered ranging from 36% to 100% pediatric case series High risk of colonic and small bowel volvulus secondary to severe gut dilation, dysmotility, congenital bridles, or concurrent malrotation	Chronic abdominal pain and distension with superimposed acute episodes of pseudoobstruction Urinary bladder involvement not so often reported
Natural history	Myopathic CIPO, urinary involvement and concurrent intestinal malrotation are poor prognostic factors	The ability to restore oral feeding and the presence of symptoms <20 yr of age is associated with a low mortality; while, systemic sclerosis and severe/diffuse esophageal and intestinal dysmotility are associated with a high mortality
Diagnostic approach	Specialized tests (e.g., intestinal manometry) often difficult to perform; noninvasive, radiation-free imaging tests are warranted	Various methodologic approaches usually starting from endoscopy and radiological tests up to more sophisticated functional exams
Nutritional therapy	To ensure normal growth extensively hydrolyzed and elemental formulas are often empirically used to facilitate intestinal absorption	To improve nutritional status and prevent malnutrition
Pharmacologic therapy	Small number/sample size-controlled trials	Small number/sample-size controlled trials; few conclusions can be drawn for most drugs
Surgical therapy	Venting ostomies (although characterized by high complication rates) possibly helpful; surgery as a “bridge” to transplantation may be indicated in highly selected cases	Venting ostomies can be helpful; resective surgery may be indicated in accurately selected patients (i.e., cases with proven segmental gut dysfunction)

From Di Nardo G, Di Lorenzo C, Lauro A, et al: Chronic intestinal pseudo-obstruction in children and adults: diagnosis and therapeutic options, *Neurogastroenterol Motil* 29:e12945, 2017, Table 2.

Diagnosis

The diagnosis of pseudoobstruction is based on the presence of compatible symptoms in the absence of mechanical obstruction (Fig. 358.1). Plain abdominal radiographs demonstrate air-fluid levels in the intestine. Neonates with evidence of obstruction at birth may have a microcolon. Contrast studies demonstrate slow passage of barium; water-soluble agents should be considered. Esophageal motility is abnormal in about half the patients. Antroduodenal (small intestinal) motility and gastric emptying studies have abnormal results if the upper gut is involved (Table 358.3). The clinical manifestations depend in large part to the areas of the gastrointestinal tract that are involved, with milder forms more common in older children. Although counterintuitive, older children with CIPO may present with both abdominal distention and diarrhea, related to *small bowel bacterial overgrowth* because of altered motility. Other presentations may include constipation and bilious emesis, as well as failure to thrive, as a consequence of decreased enteral feeding tolerance.

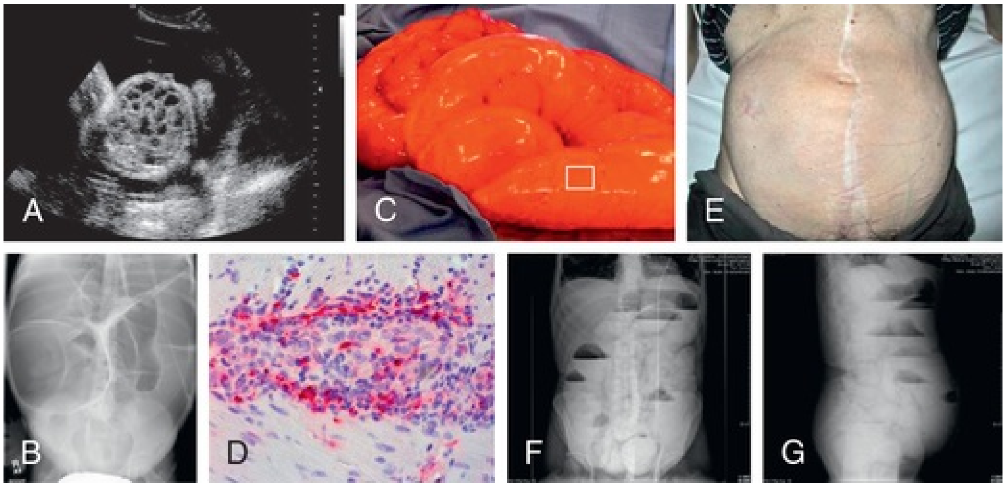

FIG. 358.1 Synoptic view of the chronic intestinal pseudoobstruction (CIPO) spectrum. A and B, The most severe pediatric cases with antenatal (in utero) evidence of multivisceral dilation—often gut (B) and urinary system—commonly associated with an extremely poor prognosis. C and D, CIPO phenotype with rapid progression to intestinal dilation (± ureter/bladder) and failure, often occurring as a result of an anamnestically reported gastroenteritis. Massive bowel dilation (C) and associated histopathology (D ; corresponds to white squared area in C) revealed an intense inflammatory (mainly lymphocytic) neuropathy (hence, myenteric ganglionitis). Alkaline phosphatase antialkaline phosphatase immunohistochemical technique using specific anti-CD8 monoclonal antibodies was used to identify a subset of T lymphocytes. E and G, Examples of another phenotype of the syndrome that may be seen in patients who have more insidious mild and nonspecific symptoms progressing to a classic CIPO over time. E, Markedly distended abdomen of a 32 yr old man who presented with subocclusive episodes after years of unspecific (dyspeptic-/irritable bowel syndrome–

like) symptoms. Note the evident air-fluid levels detectable in upright position in anteroposterior (F) and laterolateral (G) plain abdominal radiographs. (A, From Shen O, Schimmel MS, Eitan R, et al: Prenatal diagnosis of intestinal pseudo-obstruction, *Ultrasound Obstet Gynecol* 29:229–231, 2007. B–G, From Di Nardo G, Di Lorenzo C, Lauro A, et al: Chronic intestinal pseudo-obstruction in children and adults: diagnosis and therapeutic options, *Neurogastroenterol Motil* 29:e12945, 2017.)

Table 358.3

Findings in Pseudoobstruction

GI SEGMENT	FINDINGS*
Esophageal motility	Abnormalities in approximately half of CIPO, although in some series up to 85% demonstrate abnormalities
	Decreased LES pressure
	Failure of LES relaxation
	Esophageal body: low-amplitude waves, poor propagation, tertiary waves, retrograde peristalsis, occasionally aperistalsis
Gastric emptying	May be delayed
EGG	Tachygastria or bradygastria may be seen
ADM	Postprandial antral hypomotility is seen and correlates with delayed gastric emptying
	Myopathic subtype: low-amplitude contractions, <10-20 mm Hg
	Neuropathic subtype: contractions are uncoordinated, disorganized
	Absence of fed response
	Fasting MMC is absent, or MMC is abnormally propagated
Colonic	Absence of gastrocolic reflex because there is no increased motility in response to a meal
ARM	Normal rectoanal inhibitory reflex

[*] Findings can vary according to the segment(s) of the GI tract that are involved.

ADM, antroduodenal manometry; ARM, anorectal manometry; CIPO, chronic intestinal pseudoobstruction; EGG, electrogastrography; GI, gastrointestinal; LES, lower esophageal sphincter; MMC, migrating motor complex.

From Steffen R: Gastrointestinal motility. In Wyllie R, Hyams JS, Kay M, editors: *Pediatric gastrointestinal and liver disease,* ed 3, Philadelphia, 2006, WB Saunders, p. 66.

The initial focus is to rule out anatomic obstruction and to assess for bladder involvement, because that is a frequent and significant extraintestinal manifestation of concern. Manometric evidence of a normal migrating motor complex and postprandial activity should redirect the diagnostic evaluation. CIPO due to an intestinal myopathy may demonstrate manometry evidence of low-amplitude contractions, whereas CIPO due to enteric neuropathy demonstrates normal amplitude but poorly organized contractions (nonperistaltic or tonic). Anorectal motility is normal and differentiates pseudoobstruction from Hirschsprung disease. Full-thickness intestinal biopsy might show involvement of the muscle layers or abnormalities of the intrinsic intestinal nervous system.

The differential diagnosis is broad and includes such etiologies as Hirschsprung disease, mitochondrial neurogastrointestinal encephalomyopathy, mechanical obstruction, psychogenic constipation, neurogenic bladder, and superior mesenteric artery syndrome. Secondary causes of ileus or pseudoobstruction that should be considered include medication side effects, infectious etiologies, metabolic disturbances, immunologic disorders, oncologic processes, vasculitides, neuropathies, and myopathies (see Table 358.1). Examples include use of opiates hypokalemia, hypothyroidism, hypokalemia, diabetic neuropathy, porphyria, amyloidosis, Chagas disease, scleroderma, hereditary angioedema, mitochondrial disorders, and radiation, and these must be excluded. Other causes of abdominal distention such as small bowel bacterial overgrowth and aerophagia may present similarly and should be considered. *Small bowel bacterial overgrowth is a complication of CIPO.*

Treatment

Nutritional support is the mainstay of treatment for pseudoobstruction. Thirty to 50% of patients require partial or complete parenteral nutrition. Some patients can be treated with intermittent enteral supplementation, whereas others can maintain themselves on selective oral diets. Prokinetic drugs are generally used, although studies have not shown definitive evidence of their efficacy. Isolated gastroparesis can follow episodes of viral gastroenteritis and spontaneously resolves, usually in 6-24 mo. Erythromycin, a motilin receptor agonist, and cisapride, a serotonin 5-HT_4 receptor agonist, may enhance gastric emptying and proximal small bowel motility and may be useful in this select group of patients. Metoclopramide, a prokinetic and antinausea agent, is effective in gastroparesis, although side effects, such as tardive dyskinesia, limit its use. Domperidone, an antidopaminergic agent, is a prokinetic agent that can be considered. Pain management is difficult and requires a multidisciplinary approach.

Symptomatic small bowel bacterial overgrowth is usually treated with rotated nonabsorbable oral antibiotics and/or probiotics. Bacterial overgrowth can be associated with steatorrhea and malabsorption. Octreotide, a long-acting somatostatin analog, has been used in low doses to treat small bowel bacterial overgrowth. Patients with acid peptic symptoms are generally treated with acid suppression. Many patients with CIPO benefit from a gastrostomy, and some benefit from decompressive enterostomies (Fig. 358.2). Colectomy with ileorectal anastomosis is beneficial if the large bowel is the primary site of the motility abnormality. Bowel transplantation may benefit selected patients with CIPO. The prognosis is better for patients without urinary tract involvement and for those with neuropathic etiologies over myopathic disorders.

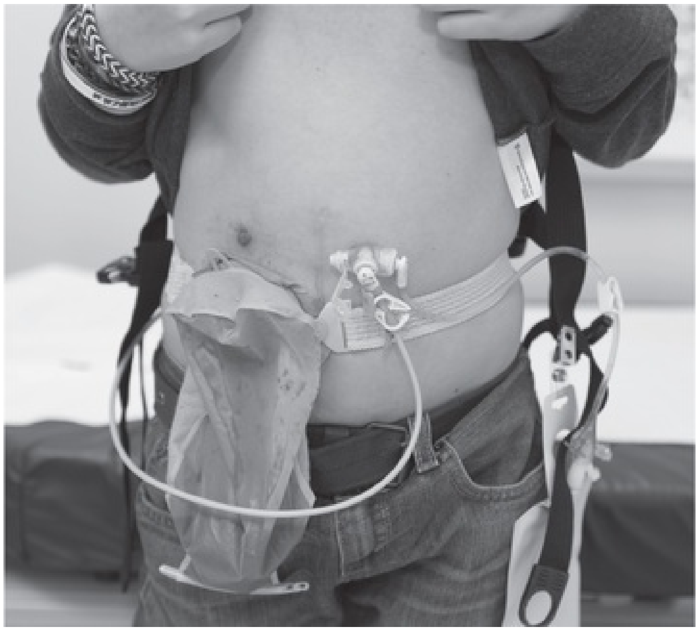

FIG. 358.2 Photograph of a child with chronic intestinal pseudoobstruction who improved clinically after ileostomy creation. He receives enteral feeding through his jejunal feeding tube, whereas his gastrostomy tube remains to straight drain. (From Bitton S, Markowitz JF: Ulcerative colitis in children and adolescents. In Wyllie R, Hyams JS, Kay M, editors: *Pediatric gastrointestinal and liver disease* , ed 5, Philadelphia, 2016, Elsevier, Fig. 44.3).

358.2

Mitochondrial Neurogastrointestinal Encephalomyopathy

Asim Maqbool, Chris A. Liacouras

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is a multisystem autosomal recessive disease that initially presents with severe gastrointestinal disturbances; the neurologic manifestations usually occur later in the illness and may initially be subtle or asymptomatic.

MNGIE is caused by a mutation in the nuclear DNA *TYMP* gene encoding thymidine phosphorylase that results in abnormalities in intergenomic communication with resulting instability of mitochondrial DNA (some patients have mutations on *POLG1*). There are at least 50 individual mutations with a poor genotype-phenotype correlation and varying manifestations within each family. Consanguinity is present in 30% of families.

MNGIE affects both males and females and is usually diagnosed in the 2nd and 3rd decade (average age: 18 yr; range: 5 mo-35 yr). Onset is usually around age 12 yr, but there is often a 5- to 10-yr delay in the diagnosis.

MNGIE *initially* presents with gastrointestinal symptoms. Severe intestinal dysmotility and gastroparesis are associated with early satiety, postprandial emesis, episodic pseudoobstruction, diarrhea, constipation, and abdominal pain and cramping, which leads to significant cachexia. Because of the age of onset, emesis, early satiety, and cachexia patients are often misdiagnosed with an eating disorder.

Most often, following the onset of gastrointestinal manifestations, ptosis, progressive external ophthalmoplegia, hearing loss, myopathy, and peripheral neuropathy may develop. The neuropathy is either demyelinating or a mixed axonal demyelinating type and manifests as weakness, decreased or absent deep tendon reflexes, and paresthesias. Leukoencephalopathy is initially asymptomatic and noted on MRI as patchy lesions predominantly in the cortex but also in the basal ganglia and brainstem. Eventually the central nervous system lesions become diffuse and confluent. A small number of patients develop cognitive impairment or dementia.

The diagnosis is suggested by the constellation of gastrointestinal and neurologic symptoms, lactic acidosis, ragged red fibers, and cytochrome C oxidase–deficient fibers seen in most patients on muscle biopsy. Reduced activity of thymidine phosphorylase enzyme and elevated plasma levels of thymidine and deoxyuridine are often diagnostic; genetic testing for the mutation or other genes *(POLG1)* is recommended.

Treatment is focused on providing sufficient nutritional support and avoidance of infectious complications and of nutritional deficiencies. Domperidone has been used for nausea and emesis, antibiotics for small bowel bacterial overgrowth, amitriptyline or gabapentin for neuropathic pain, and parenteral alimentation for nutritional support. Opiates and any medications that affect intestinal motility or mitochondrial function must be avoided. Stem cell transplantation has been successful in a small number of patients.

Overall the prognosis is poor, with few surviving into the 4th or 5th decade.

358.3

Encopresis and Functional Constipation

Asim Maqbool, Chris A. Liacouras

Constipation is defined as a delay or difficulty in defecation present for >1 month and significant enough to cause distress to the patient. Another approach to the definition is the Rome criteria, outlined in Tables 358.4 and 358.5 . Functional constipation, also known as idiopathic constipation or fecal withholding, can usually be differentiated from constipation secondary to organic causes based on a history and physical examination. Unlike anorectal malformations and Hirschsprung disease, functional constipation typically starts after the neonatal period. Usually, there is an intentional or subconscious withholding of stool. An acute episode usually precedes the chronic course. This acute event could include a social stressor such as initiation of toilet training, birth of a sibling, starting daycare, or abuse. The acute episode may be a dietary change from human milk to cow's milk, secondary to the change in the protein and carbohydrate ratio or an allergy to cow's milk. Although iron has been suspected of causing issues with cow's milk–related constipation, this has not been consistently demonstrated or substantiated. The stool becomes firm, smaller, and difficult to pass, resulting in anal irritation and often an anal fissure. In toddlers, coercive or inappropriately early toilet training is a factor that can initiate a pattern of stool retention. In older children, retentive constipation can develop after entering a situation that makes stooling inconvenient such as school. Because the passage of bowel movements is painful, voluntary withholding of feces to avoid the painful stimulus develops.

Table 358.4

Rome IV Diagnostic Criteria for Defecatory Disorders in Neonates and Toddlers

FGID	AGE RANGE	CRITERIA REQUIREMENTS	CRITERIA ELEMENTS
Functional constipation	All pediatric age groups	Must include 1 month of ≥2 of the following in infants up to 4 months of age: In toilet trained children, the following additional criteria may be used:	• 2 or fewer defections weekly • History of excessive stool retention • History of hard/painful bowel movements • History of large-diameter stools • Presence of a large fecal mass in the rectum • At least 1 weekly episode of incontinence after being toilet trained • History of large-diameter stools that may clog the toilet

FGID, Functional gastrointestinal disorders.

Modified from Benninga MA, Faure C, Hyman PE, et al. Childhood functional gastrointestinal disorders: neonate/toddler, *Gastroenterology* 150:1443–1455, 2016.

Table 358.5

Rome IV Diagnostic Criteria for Defecatory Disorders in Children and Adolescents

	AGE RANGE	CRITERIA REQUIREMENTS	CRITERIA ELEMENTS
Functional Constipation	Developmental age ≥4 yr	Must include ≥2 of the following ≥1/wk for 1 ≥1 mo with insufficient criteria to diagnose irritable bowel syndrome	• ≤ 2 defecations in the toilet per week • ≥1 episode of fecal incontinence per week • History of retentive posturing or excessive volitional stool retention • History of painful or hard bowel movements • Presence of a large fecal mass in the rectum • History of large diameter stools that can obstruct the toilet • After appropriate evaluation, symptoms cannot be fully explained by another medical condition
Nonretentive Fecal Incontinence	developmental age ≥4 yr	≥1-mo history of the following symptoms:	• Defecation into places inappropriate to the sociocultural context • No evidence of fecal retention • After appropriate evaluation, symptoms cannot be fully explained by another medical condition

Modified from Hyams JS, Di Lorenzo C, Saps M, et al. Childhood functional gastrointestinal disorders: child/adolescent, *Gastroenterology* 150:1456–1468, 2016.

Clinical Manifestations

When children have the urge to defecate, typical behaviors include contracting the gluteal muscles by stiffening the legs while lying down, holding onto furniture while standing, or squatting quietly in corners, waiting for the call to stool to pass. The urge to defecate passes as the rectum accommodates to its contents. A vicious cycle of retention develops, as increasingly larger volumes of stool need to be expelled. Caregivers may misinterpret these activities as straining, but it is withholding behavior. There is often a history of blood in the stool noted with the passage of a large bowel movement. Findings suggestive of underlying pathology include failure to thrive, weight loss, abdominal pain, vomiting, or persistent anal fissure or fistula.

In functional constipation, daytime encopresis is common. **Encopresis** is defined as voluntary or involuntary passage of feces into inappropriate places at least once a mo for 3 consecutive months once a chronologic or developmental age of 4 yr has been reached. Encopresis is not diagnosed when the behavior is exclusively the result of the direct effects of a substance (e.g., laxatives) or a general medical condition (except through a mechanism involving constipation). Subtypes include retentive encopresis (with constipation and overflow incontinence), representing 65–95% of cases, and nonretentive encopresis (without constipation and overflow incontinence). **Nonretentive fecal incontinence** is defined as no evidence of fecal retention (impaction), ≥1 episodes per week in the previous 1 mo, or defecation in places inappropriate to the social context in a child who has been previously toilet trained and without evidence of anatomic, inflammatory, metabolic, endocrine, or neoplastic process that could explain the symptoms. Encopresis can persist from infancy onward (primary) or can appear after successful toilet training (secondary). The updated Rome criteria (IV) differentiate between infants/toddlers and older children who have been toilet trained versus not toilet trained, for practical assessment purposes.

Diagnosis

The physical examination often demonstrates a large volume of stool palpated in the suprapubic area; rectal examination demonstrates a dilated rectal vault filled with guaiac-negative stool. Children with encopresis often present with reports of underwear soiling, and many parents initially presume that diarrhea, rather than constipation, is the cause. In **retentive encopresis** , associated complaints of difficulty with defecation, abdominal or rectal pain, impaired appetite with poor growth, and urinary (day and/or night) incontinence are common. Children often have large bowel movements that obstruct the toilet. There may also be retentive posturing or recurrent urinary tract infections. **Nonretentive encopresis** is more likely to occur as a solitary symptom and have an associated primary underlying psychological etiology. Children with encopresis can present with poor school performance and attendance that is triggered by the scorn and derision from schoolmates because of the child's offensive odor.

The location of the anus relative to perineal anatomic landmarks by sex also needs to be considered. This is expressed as the **anogenital index** , and it can be calculated when necessary. This is determined by the distance in centimeters from the vagina or scrotum to the anus, divided by the distance from the vagina or scrotum to the coccyx. The normal anogenital index in females is 0.39 ± 0.09, whereas 0.56 ± 0.2 is normal for males. The presence of a hair tuft over the spine or spinal dimple, or failure to elicit a cremasteric reflex or anal wink suggests spinal pathology. A tethered cord is suggested by decreased or absent lower leg reflexes. **Spinal cord lesions** can occur with overlying skin anomalies. Urinary tract symptoms include recurrent urinary tract infection and enuresis. Children with no evidence of abnormalities on physical examination rarely require radiologic evaluation.

In refractory patients (intractable constipation), specialized testing should be considered to rule out conditions such as hypothyroidism, hypocalcemia, lead toxicity, celiac disease, and disorders of neuromuscular gastrointestinal pathology (Table 358.6). Colonic transit studies using radiopaque markers or scintigraphy techniques may be useful. Selected children can benefit from MRI of the spine to identify an intraspinal process, motility studies to identify underlying myopathic or neuropathic bowel abnormalities, or a contrast enema to identify structural abnormalities. In patients with severe functional constipation, water-soluble contrast enema reveals the presence of a mega rectosigmoid (Fig. 358.3). Anorectal motility studies can demonstrate a pattern of paradoxical contraction of the external anal sphincter during defecation, which can be treated by behavior modification and biofeedback. Colonic motility can guide therapy in refractory cases, demonstrating segmental problems that might require surgical intervention.

Table 358.6

London Classification of Gastrointestinal Neuromuscular Pathology

- 1. Neuropathies
  - 1.1 Absent neurons
    - 1.1.1 Aganglionosis[*]
  - 1.2 Decreased numbers of neurons
    - 1.2.1 Hypoganglionosis
  - 1.3 Increased numbers of neurons
    - 1.3.1 Ganglioneuromatosis[†]
    - 1.3.2 IND, type B[‡]
  - 1.4 Degenerative neuropathy[§]
  - 1.5 Inflammatory neuropathies
    - 1.5.1 Lymphocytic ganglionitis[¶]
    - 1.5.2 Eosinophilic ganglionitis
  - 1.6 Abnormal content in neurons
    - 1.6.1 Intraneuronal nuclear inclusions
    - 1.6.2 Megamitochondria
  - 1.7 Abnormal neurochemical coding[**]
  - 1.8 Relative immaturity of neurons
  - 1.9 Abnormal enteric glia
    - 1.9.1 Increased numbers of enteric glia

- 2. Myopathies
  - 2.1 Muscularis propria malformations [††]
  - 2.2 Muscle cell degeneration
    - 2.2.1 Degenerative leiomyopathy/ [‡‡]
    - 2.2.2 Inflammatory leiomyopathy
      - 2.2.2.1 Lymphocytic leiomyositis
      - 2.2.2.2 Eosinophilic leiomyositis
  - 2.3 Muscle hyperplasia/hypertrophy
    - 2.3.1 Muscularis mucosae hyperplasia
  - 2.4 Abnormal content in myocytes
    - 2.4.1 Filament protein abnormalities
      - 2.4.1.1 Alpha-actin myopathy [§§]
      - 2.4.1.2 Desmin myopathy
    - 2.4.2 Inclusion bodies
      - 2.4.2.1 Polyglucosan bodies
      - 2.4.2.2 Amphophilic
      - 2.4.2.3 Megamitochondria [¶¶]
  - 2.5 Abnormal supportive tissue
    - 2.5.1 Atrophic desmosis[***]
- 3. ICC abnormalities (enteric mesenchymopathy)
  - 3.1 Abnormal ICC networks [†††]

[*] Can include rare cases of non-Hirschsprung disease severe hypoplastic hypoganglionosis with long interganglionic intervals (zonal aganglionosis).

[†] Although neurons have not been formally quantified, gross increases of disorganized neurons are evident.

[‡] Can include retarded neuronal maturation.

[§] May occur with or without neuronal loss but is best regarded as a separate entity.

[¶] May occur with neuronal degeneration and/or loss; lymphocytic epithelioganglionitis is a variant.

[**] Includes neurotransmitter loss (e.g., reduced or absent expression) or loss of a neurochemically defined functional subset of nerves (see text).

[††] Includes absence, fusion, or additional muscle coats.

[‡‡] Hollow visceral myopathy may be diagnosed in familial cases with other characteristic phenotypic features; myopathy with autophagic activity and pink blush myopathy with nuclear crowding are rare variants in which degenerative findings are less overt.

[§§] Smooth muscle alpha-actin deficiency is best described, although deficiencies of other proteins related to the contractile apparatus of myocytes have been reported.

[¶¶] Mitochondrial neurogastrointestinal encephalomyopathy causes a degenerative appearance predominantly in the longitudinal muscle.

[***] Absent connective tissue scaffold has been almost exclusively described in the colon.

[†††] Generally reduced or absent ICC, although abnormal morphology also reported.

ICC, interstitial cells of Cajal; IND, intestinal neuronal dysplasia.

59:882–887, 2010, Table 1, p. 883.

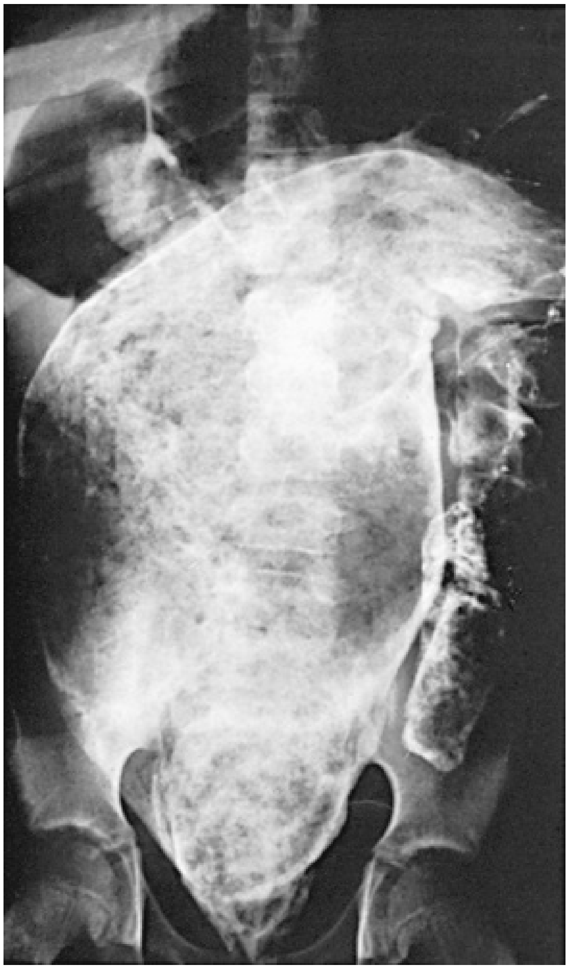

FIG. 358.3 Barium enema in a 14 yr old boy with severe constipation. The enormous dilation of the rectum and distal colon is typical of acquired functional megacolon.

Complications of retentive encopresis include day and night urinary incontinence, urinary retention, urinary tract infection, megacystis, and rarely toxic megacolon.

Treatment

Therapy for functional constipation and encopresis includes patient education, relief of impaction, and softening of the stool. Caregivers must understand that soiling associated with overflow incontinence is associated with loss of normal sensation and not a willful act. There needs to be a focus on adherence with regular postprandial toilet sitting and adoption of a balanced diet. In addition, caregivers should be instructed not to respond to soiling with retaliatory or punitive measures, because children are likely to become angry, ashamed, and resistant to intervention. From the outset, parents should be actively encouraged to reward the child for adherence to a healthy bowel regimen and to avoid power struggles.

If an impaction is present on the initial physical examination, an enema is usually required to clear the impaction while stool softeners are started as maintenance medications. Typical regimens include the use of polyethylene glycol preparations, lactulose, or mineral oil (Tables 358.7 and 358.8). Prolonged use of stimulants such as senna or bisacodyl should be avoided.

Table 358.7

Suggested Medications and Dosages for Disimpaction

MEDICATION	AGE	DOSAGE
RAPID RECTAL DISIMPACTION		
Glycerin suppositories	Infants and toddlers	
Phosphate enema	<1 yr	60 mL
	>1 yr	6 mL/kg body weight, up to 135 mL twice
SLOW ORAL DISIMPACTION IN OLDER CHILDREN		
Over 2-3 Days		
Polyethylene glycol with electrolytes		25 mL/kg body weight/hr, up to 1,000 mL/hr until clear fluid comes from the anus
Over 5-7 Days		
Polyethylene without electrolytes		1.5 g/kg body weight/day for 3 days
Milk of magnesia		2 mL/kg body weight twice/day for 7 days
Mineral oil		3 mL/kg body weight twice/day for 7 days
Lactulose or sorbitol		2 mL/kg body weight twice/day for 7 days

From Loening-Baucke V: Functional constipation with encopresis. In Wyllie R, Hyams JS, Kay M, editors: *Pediatric gastrointestinal and liver disease* , ed 3, Philadelphia, 2006, WB Saunders, p. 183.

Table 358.8

Suggested Medications and Dosages for Maintenance Therapy of Constipation

MEDICATION	AGE	DOSE
TYPICAL DOSES FOR LONG-TERM TREATMENT (YEARS)		

Milk of magnesia	>1 mo	1-3 mL/kg body weight/day, divided into 1-2 doses
Mineral oil	>12 mo	1-3 mL/kg body weight/day, divided into 1-2 doses
Lactulose or sorbitol	>1 mo	1-3 mL/kg body weight/day, divided into 1-2 doses
Polyethylene glycol 3350 (MiraLAX)	>1 yr	0.7 g/kg body weight/day (max 17.5 g/day)
FOR SHORT-TERM TREATMENT (MONTHS)		
Senna (Senokot) syrup, tablets	1-5 yr	5 mL (1 tablet) with breakfast, max 15 mL daily
	5-15 yr	2 tablets with breakfast, maximum 3 tablets daily
Glycerin enemas	>10 yr	20-30 mL/day (½ glycerin and ½ normal saline)
Bisacodyl suppositories	>10 yr	10 mg daily

From Loening-Baucke V: Functional constipation with encopresis. In Wyllie R, Hyams JS, Kay M, editors: *Pediatric gastrointestinal and liver disease* , ed 3, Philadelphia, 2006, WB Saunders, p. 185.

Compliance can wane, and failure of this standard treatment approach sometimes requires more intensive intervention. In cases where behavioral or psychiatric problems are evident, involvement of a psychologist or behavioral management (e.g., behavior programs and/or biofeedback) is recommended. Maintenance therapy is generally continued until a regular bowel pattern has been established and the association of pain with the passage of stool is abolished.

For children with chronic diarrhea and/or irritable bowel syndrome where stress and anxiety play a major role, stress reduction and learning effective coping strategies can play an important role in responding to the encopresis. Relaxation training, stress inoculation, assertiveness training, and/or general stress management procedures can be helpful, and the participation of behavioral health specialists is valuable.

Neurostimulation (transcutaneous or sacral implantation) and pelvic physiotherapy are novel approaches used in patients with medication refractory constipation. Children with spinal problems can be successfully managed with low volumes of fluid through a cecostomy or sigmoid tube.

358.4

Congenital Aganglionic Megacolon (Hirschsprung Disease)

Asim Maqbool, Chris A. Liacouras

Hirschsprung disease, or congenital aganglionic megacolon, is a developmental disorder (neurocristopathy) of the enteric nervous system, characterized by the absence of ganglion cells in the submucosal and myenteric plexus. It is the most common cause of lower intestinal obstruction in neonates, with an overall incidence of 1 in 5,000 live births. The male:female ratio for Hirschsprung disease is 4 : 1 for short-segment disease and approximately 2 : 1 with total colonic aganglionosis. Prematurity is uncommon.

There is an increased familial incidence in long-segment disease. Hirschsprung disease may be associated with other congenital defects, including trisomy 21, Joubert syndrome, Goldberg-Shprintzen syndrome, Smith-Lemli-Opitz syndrome, Shah-Waardenburg syndrome, cartilage-hair hypoplasia, multiple endocrine neoplasm 2 syndrome, neurofibromatosis, neuroblastoma, congenital hypoventilation (Ondine's curse), and urogenital or cardiovascular abnormalities. Hirschsprung disease has been seen in association with microcephaly, mental retardation, abnormal facies, autism, cleft palate, hydrocephalus, and micrognathia.

Pathology

Hirschsprung disease is the result of an absence of ganglion cells in the bowel wall, extending proximally and continuously from the anus for a variable distance. The absence of neural innervation is a consequence of an arrest of neuroblast migration from the proximal to distal bowel. Without the myenteric and submucosal plexus, there is inadequate relaxation of the bowel wall and bowel wall hypertonicity, which can lead to intestinal obstruction.

Hirschsprung disease is usually sporadic, although dominant and recessive patterns of inheritance have been demonstrated in family groups. Genetic defects have been identified in multiple genes that encode proteins of the RET signaling pathway (*RET, GDNF,* and *NTN*) and involved in the endothelin (EDN) type B receptor pathway (*EDNRB, EDN3,* and *EVE-1*). Syndromic forms of Hirschsprung disease have been associated with the *L1CAM, SOX10,* and *ZFHX1B* (formerly *SIP1*) genes.

The aganglionic segment is limited to the rectosigmoid in 80% of patients. Approximately 10–15% of patients have long-segment disease, defined as disease proximal to the sigmoid colon. Total bowel aganglionosis is rare and accounts for approximately 5% of cases. Observed histologically is an absence of Meissner's and Auerbach's plexuses and hypertrophied nerve bundles with high concentrations of acetylcholinesterase between the muscular layers and in the submucosa.

Clinical Manifestations

Hirschsprung disease is usually diagnosed in the neonatal period secondary to a distended abdomen, failure to pass meconium, and/or bilious emesis or aspirates with feeding intolerance. In 99% of healthy full-term infants, meconium is passed within 48 hr of birth. Hirschsprung disease should be suspected in any full-term infant (the disease is unusual in preterm infants) with delayed passage of stool. Some neonates pass meconium normally but subsequently present with a history of chronic constipation. Failure to thrive with hypoproteinemia from protein-losing enteropathy is a less common presentation because Hirschsprung disease is usually recognized early in the course of the illness but has been known to occur. Breastfed infants might not present as severely as formula-fed infants.

Failure to pass stool leads to dilation of the proximal bowel and abdominal distention. As the bowel dilates, intraluminal pressure increases, resulting in decreased blood flow and deterioration of the mucosal barrier. Stasis allows proliferation of bacteria, which can lead to enterocolitis (*Clostridium difficile, Staphylococcus aureus,* anaerobes, coliforms) with associated diarrhea, abdominal tenderness, sepsis, and signs of bowel obstruction. *Red flags* in the neonatal period then include neonatal intestinal obstruction, bowel perforation, delayed passage of meconium, abdominal distention relieved by digital rectal stimulation or enemas, chronic severe constipation, and enterocolitis. Early recognition of Hirschsprung disease before the onset of enterocolitis is essential in reducing morbidity and mortality.

Hirschsprung disease in older patients must be distinguished from other causes of abdominal distention and chronic constipation (see Tables 358.6 and 358.9 and Figs. 358.4 and 358.5). The history often reveals constipation starting in infancy that has responded poorly to medical management. Failure to thrive is not uncommon. Fecal incontinence, fecal urgency, and stool-withholding behaviors are usually not present. Significant abdominal distention is unusual in non-Hirschsprung related constipation, as is emesis. The abdomen is tympanitic and distended, with a large fecal mass palpable in the left lower abdomen. Rectal examination demonstrates a normally placed anus that easily allows entry of the finger but feels snug. The rectum is usually empty of feces, and when the finger is removed, there may be an explosive discharge of foul-smelling feces and gas. The stools, when passed, can consist of small pellets, be ribbon-like, or have a fluid consistency, unlike the large stools seen in patients with functional constipation. Intermittent attacks of intestinal obstruction from retained feces may be associated with pain and fever. Urinary retention with enlarged bladder or hydronephrosis can occur secondary to urinary compression.

Table 358.9

Distinguishing Features of Hirschsprung Disease and

Functional Constipation

VARIABLE	FUNCTIONAL	HIRSCHSPRUNG DISEASE
HISTORY		
Onset of constipation	After 2 yr of age	At birth
Encopresis	Common	Very rare
Failure to thrive	Uncommon	Possible
Enterocolitis	None	Possible
Forced bowel training	Usual	None
EXAMINATION		
Abdominal distention	Uncommon	Common
Poor weight gain	Rare	Common
Rectum	Filled with stool	Empty
Rectal examination	Stool in rectum	Explosive passage of stool
Malnutrition	None	Possible
INVESTIGATIONS		
Anorectal manometry	Relaxation of internal anal sphincter	Failure of internal anal sphincter relaxation
Rectal biopsy	Normal	No ganglion cells, increased acetylcholinesterase staining
Barium enema	Massive amounts of stool, no transition zone	Transition zone, delayed evacuation (>24 hr)

From Imseis E, Gariepy C: Hirschsprung disease. In Walker WA, Goulet OJ, Kleinman RE, et al, editors: *Pediatric gastrointestinal disease* , ed 4, Hamilton, ON, 2004, BC Decker, p. 1035.

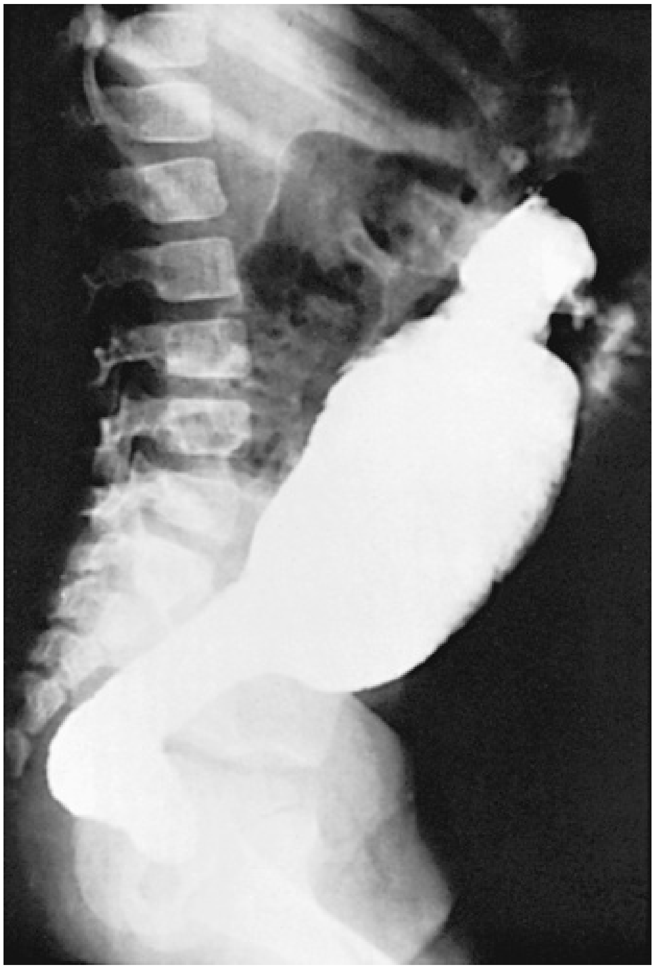

FIG. 358.4 Lateral view of a barium enema in a 3 yr old girl with Hirschsprung disease. The aganglionic distal segment is narrow, with distended normal ganglionic bowel above it.

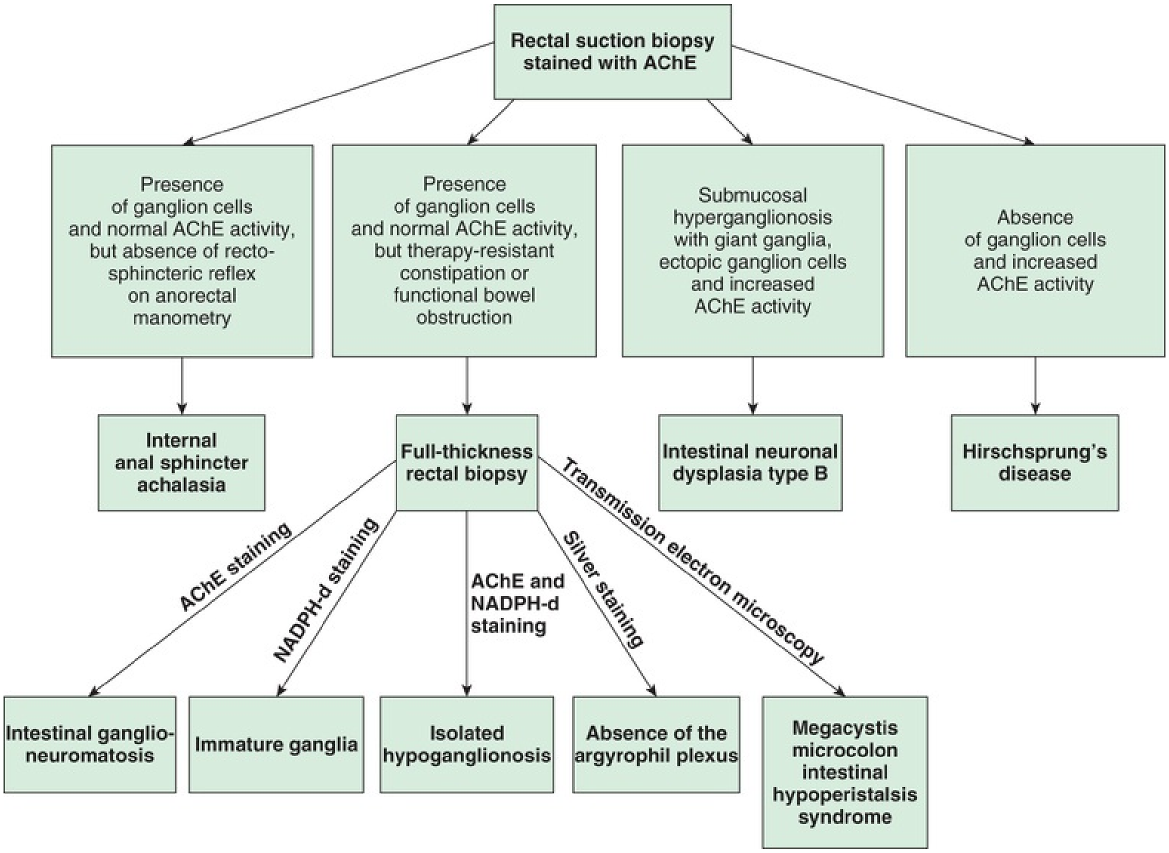

Rectal suction biopsy stained with AChE
Presence of ganglion cells and normal AChE activity, but absence of recto-sphincteric reflex on anorectal manometry
Presence of ganglion cells and normal AChE activity, but therapy-resistant constipation or functional bowel obstruction
Submucosal hyperganglionosis with giant ganglia, ectopic ganglion cells and increased AChE activity
Absence of ganglion cells and increased AChE activity
Internal anal sphincter achalasia
Full-thickness rectal biopsy
Intestinal neuronal dysplasia type B
Hirschsprung's disease
AChE staining
NADPH-d staining
AChE and NADPH-d staining
Silver staining
Transmission electron microscopy
Intestinal ganglio-neuromatosis
Immature ganglia
Isolated hypoganglionosis
Absence of the argyrophil plexus
Megacystis microcolon intestinal hypoperistalsis syndrome

FIG. 358.5 Diagnostic algorithm for investigating chronic constipation and functional bowel obstruction in newborn infants and young children. *AChE,* Acetylcholinesterase; *NADPH-d,* nicotinamide adenine dinucleotide phosphate diaphorase. (From Friedmacher F, Puri P: Classification and diagnostic criteria of variants of Hirschsprung's disease, *Pediatr Surg Int* 29:855–872, 2013, Fig. 1.)

In neonates, Hirschsprung disease must be differentiated from meconium plug syndrome, meconium ileus, and intestinal atresia. In older patients, the **Currarino triad** must be considered, which includes anorectal malformations (ectopic anus, anal stenosis, imperforate anus), sacral bone anomalies (hypoplasia, poor segmentation), and presacral anomaly (anterior meningoceles, teratoma, cyst).

Diagnosis

Rectal suction biopsy is the "gold standard" for diagnosing Hirschsprung disease (see Fig. 358.5). The biopsy material should contain an adequate amount of submucosa to evaluate for the presence of ganglion cells. To avoid obtaining biopsies in the normal area of hypoganglionosis, which ranges from 3 to 17 mm in length, the suction rectal biopsy should be obtained no closer than 2 cm above the dentate line. The biopsy specimen should be stained for acetylcholinesterase to facilitate interpretation. Patients with aganglionosis demonstrate a large number of hypertrophied nerve bundles that stain positively for acetylcholinesterase with an absence of ganglion cells. Calretinin staining may provide a diagnosis of Hirschsprung disease when acetylcholinesterase staining may not be sufficient.

Anorectal manometry evaluates the internal anal sphincter while a balloon is distended in the rectum. In healthy individuals, rectal distention initiates relaxation of the internal anal sphincter in response to rectal distention (known as the rectoanal inhibitory reflux [RAIR]). In patients with Hirschsprung disease, the internal anal sphincter fails to relax in response to rectal distention, and there is absence of the RAIR. Although the sensitivity and specificity can vary widely, in experienced hands, the test can be quite sensitive. However, the test can be technically difficult to perform in young infants. A normal response in the course of manometric evaluation precludes a diagnosis of Hirschsprung disease; an equivocal or paradoxical response requires a repeat motility or rectal biopsy. The sensitivity and specificity of anorectal manometry are both >90%.

An unprepared contrast enema is most likely to aid in the diagnosis in children older than 1 mo of age because the proximal ganglionic segment might not be significantly dilated in the first few wk of life. Classic findings are based on the presence of an abrupt narrow transition zone between the normal dilated proximal colon and a smaller-caliber obstructed distal aganglionic segment. In the absence of this finding, it is imperative to compare the diameter of the rectum to that of the sigmoid colon, because a rectal diameter that is the same as or smaller than the sigmoid colon suggests Hirschsprung disease. Radiologic evaluation should be performed without prior preparation (i.e., *unprepped contrast enema study*) to prevent transient dilation of the aganglionic segment. As many as 10% of newborns with Hirschsprung disease have a normal contrast study. This diagnostic test is most valuable in the disease that involves the distal colon, and specifically, the rectosigmoid. A transition zone may not be readily identifiable in total bowel aganglionosis. Twenty-four-hour delayed films are helpful in showing retained contrast (see Fig. 358.4). If significant barium is still present in the colon, it increases the suspicion of Hirschsprung disease even if a transition zone is not identified. Barium enema examination is useful in determining the extent of aganglionosis before surgery and in evaluating other diseases that manifest as lower bowel obstruction in a neonate. The sensitivity (~70%) and specificity (50–80%) of barium enema studies diagnosing

Hirschsprung disease is lower than other methodologies. Full-thickness rectal biopsies can be performed at the time of surgery to confirm the diagnosis, level of involvement and to differentiate other disorders (see Fig. 358.5).

Treatment

Once the diagnosis is established, the definitive treatment is operative intervention. Previously, a temporary ostomy was placed, and definitive surgery was delayed until the child was older. Currently, many infants undergo a primary pull-through procedure unless there is associated enterocolitis or other complications, when a decompressing ostomy is usually required.

There are essentially three surgical options. The first successful surgical procedure, described by Swenson, was to excise the aganglionic segment and anastomose the normal proximal bowel to the rectum 1-2 cm above the dentate line. The operation is technically difficult and led to the development of two other procedures. Duhamel described a procedure to create a neorectum, bringing down normally innervated bowel behind the aganglionic rectum. The neorectum created in this procedure has an anterior aganglionic segment with normal sensation and a posterior ganglionic segment with normal propulsion. The endorectal pull-through procedure described by Soave involves stripping the mucosa from the aganglionic rectum and bringing normally innervated colon through the residual muscular cuff, thus bypassing the abnormal bowel from within. Advances in techniques have led to successful laparoscopic single-stage endorectal pull-through procedures, which are the treatment of choice.

In **ultrashort-segment Hirschsprung disease** , also known as **anal achalasia** , the aganglionic segment is limited to the internal sphincter. The clinical symptoms are similar to those of children with functional constipation. Ganglion cells are present on rectal suction biopsy, but the anorectal manometry is abnormal, with failure of relaxation of the internal anal sphincter in response to rectal distention. Current treatment, although controversial, includes anal botulism injection to relax the anal sphincter and anorectal myectomy if indicated.

Long-segment Hirschsprung disease involving the entire colon and, at times, part of the small bowel presents a difficult problem. Anorectal manometry and rectal suction biopsy demonstrate findings of Hirschsprung disease, but radiologic studies are difficult to interpret because a colonic transition zone cannot be identified. The extent of aganglionosis can be determined accurately by biopsy at the time of laparotomy. When the entire colon is aganglionic, often together with a length of terminal ileum, ileal-anal anastomosis is the treatment of choice, preserving part of the aganglionic colon to facilitate water absorption, which helps the stools to become firm.

The prognosis of surgically treated Hirschsprung disease is generally satisfactory; the great majority of patients achieve fecal continence. Long-term postoperative problems include constipation, recurrent enterocolitis, stricture, prolapse, perianal abscesses, and fecal soiling. Some children require myectomy or a redo pull-through procedure.

Hirschsprung disease–associated **enterocolitis** can occur at any time prior to or following surgery and is the leading cause of death in these patients. Dysmotility related to partial obstruction, underlying disease, impaired immune function, and the intestinal microbiome may all contribute to this pathophysiologic process. Explosive, foul-smelling and/or bloody diarrhea, abdominal distention, explosive discharge of rectal contents on digital examination, diminished peripheral perfusion, lethargy, and fever are all ominous signs. Management principles include hydration, decompression from above and below (nasogastric Salem Sump, rectal tube, rectal irrigation), and the use of broad-spectrum antibiotics.

Intestinal Neuronal Dysplasia

Asim Maqbool, Chris A. Liacouras

Intestinal neuronal dysplasia (IND) describes different quantitative (hypoganglionosis or hyperganglionosis) and qualitative (immature or heterotropic ganglion cells) abnormalities of the myenteric and/or submucosal plexus. The typical histology is that of hyperganglionosis and giant ganglia. Type A occurs very rarely and is characterized by congenital aplasia or hypoplasia of the sympathetic innervation. Patients present early in the neonatal period with episodes of intestinal obstruction, diarrhea, and bloody stools. This type B, which accounts for more than 95% of cases, is characterized by malformation of the parasympathetic submucous and myenteric plexus with giant ganglia and thickened nerve fibers, increased acetylcholinesterase staining, and isolated ganglion cells in the lamina propria. IND type B mimics Hirschsprung disease, and patients present with chronic constipation (see Table

358.6 and Fig. 358.5). Clinical manifestations include abdominal distention, constipation, and enterocolitis. Various lengths of bowel may be affected from segmental to the entire intestinal tract. IND has been observed in an isolated form and proximal to an aganglionic segment. Other intraintestinal and extraintestinal manifestations are present in patients with IND. It has been reported in all age groups, most commonly in infancy, but is also seen in adults who have had constipation not dating back to childhood.

Associated diseases and conditions include Hirschsprung disease, prematurity, small left colon syndrome, and meconium plug syndrome. Studies have identified a deficiency in substance P in patients with IND. Type A IND may be inherited in a familial, autosomal recessive pattern. Most cases of IND type B are sporadic, with few familial clusters, suggesting autosomal dominant inheritance.

Management includes that for functional constipation, and, if unsuccessful, surgery is indicated.

358.6

Superior Mesenteric Artery Syndrome (Wilkie Syndrome, Cast Syndrome, Arteriomesenteric Duodenal Compression Syndrome)

Asim Maqbool, Chris A. Liacouras

Superior mesenteric artery syndrome results from compression of the third duodenal segment by the artery against the aorta. Malnutrition or catabolic states may cause mesenteric fat depletion, which collapses the duodenum within a narrowed aortomesenteric angle. Other etiologies include extraabdominal compression (e.g., body cast) and mesenteric tension, as can occur from ileoanal pouch anastomosis. Rapid weight loss and immobilization are risk factors.

Symptoms include intermittent epigastric pain, anorexia, nausea, and vomiting. Risk factors include thin body habitus, prolonged bed rest, abdominal surgery, and exaggerated lumbar lordosis. Onset can be within weeks of a trigger, but some patients have chronic symptoms that evade diagnosis. A classic example is an underweight adolescent who begins vomiting 1-2 wk following scoliosis surgery or spinal fusion. Recognition may be delayed in the context of an eating disorder.

The diagnosis is established radiologically by demonstrating a duodenal cutoff just right of midline along with proximal duodenal dilation, with or without gastric dilation. Although the upper gastrointestinal series remains a mainstay, modalities including CT, MR angiography, or ultrasound may be more appropriate if there is concern for other etiologies such as malignancy. Upper endoscopy should be considered to rule out intraluminal pathology.

Treatment focuses on obstructive relief, nutritional rehabilitation, and correction of associated fluid and electrolyte abnormalities. Lateral or prone positioning can shift the duodenum away from obstructing structures and allow resumption of oral intake. If repositioning is unsuccessful, patients require nasojejunal enteral nutrition past the obstruction or parenteral nutrition if this is not tolerated. This management is successful in the vast majority of cases, with eventual withdrawal of tube feeding once weight has been regained and enteral feeding tolerance orally has been gradually and fully restored. Patients with refractory courses may require surgery to bypass the obstruction.

CHAPTER 359

Ileus, Adhesions, Intussusception, and Closed-Loop Obstructions

359.1

Ileus

Asim Maqbool, Chris A Liacouras

Ileus is the failure of intestinal peristalsis caused by loss of coordinated gut motility without evidence of mechanical obstruction. In children, it is most often associated with abdominal surgery or infection (gastroenteritis, pneumonia, peritonitis). Ileus also accompanies metabolic abnormalities (e.g., uremia, hypokalemia, hypercalcemia, hypermagnesemia, acidosis) or administration of certain drugs, such as opiates, vincristine, and antimotility agents such as loperamide when used during gastroenteritis.

Ileus manifests with nausea, vomiting, feeding intolerance, abdominal distention with associated pain, and delayed passage of stool and bowel gas. Bowel sounds are minimal or absent, in contrast to early mechanical obstruction, when they are hyperactive. Abdominal radiographs demonstrate multiple air-fluid levels throughout the abdomen. Serial radiographs usually do not show progressive distention as they do in mechanical obstruction. Contrast radiographs, if performed, demonstrate slow movement of barium through a patent lumen. Ileus after abdominal surgery generally resolves in within 72 hr.

Treatment involves correcting the underlying abnormality, supportive care of comorbidities, and mitigation of iatrogenic contributions. Electrolyte abnormalities should be identified and corrected, and narcotic agents, when used, should be weaned as tolerated. Nasogastric decompression can relieve recurrent vomiting or abdominal distention associated with pain; resultant fluid losses should be corrected with isotonic crystalloid solution. Prokinetic agents such as erythromycin are not routinely recommended. Selective peripheral opioid antagonists such as methylnaltrexone hold promise in decreasing postoperative ileus, but pediatric data are lacking.

359.2

Adhesions

Asim Maqbool, Chris A Liacouras

Adhesions are fibrous tissue bands that result from peritoneal injury. They can constrict hollow organs and are a major cause of postoperative small bowel obstruction. Most remain asymptomatic, but problems can arise any time after the 2nd postoperative wk to yr after surgery, regardless of surgical extent. In one study, the 5-yr readmission risk because of adhesions varied by operative region (2.1% for colon to 9.2% for ileum) and procedure (0.3% for appendectomy to 25% for ileostomy formation/closure). The overall risk was 5.3% excluding appendectomy and 1.1% when appendectomy was included.

The diagnosis is suspected in patients with abdominal pain, constipation, emesis, and a history of intraperitoneal surgery. Nausea and vomiting quickly follow onset of pain. Initially, bowel sounds are hyperactive, and the abdomen is flat. Subsequently, bowel sounds disappear, and bowel dilation can cause abdominal distention. Fever and leukocytosis suggest bowel necrosis and peritonitis. Plain radiographs demonstrate obstructive features, and a CT scan or contrast studies may be needed to define the etiology.

Management includes nasogastric decompression, intravenous fluid resuscitation, and broad-spectrum antibiotics in preparation for surgery. Nonoperative intervention is contraindicated unless a patient is stable with obvious clinical improvement. In children with repeated obstruction, fibrin-glued plication of adjacent small bowel loops can reduce the risk of recurrent problems. Long-term complications include female infertility, failure to thrive, and chronic abdominal and/or pelvic pain.

359.3

Intussusception

Asim Maqbool, Chris A Liacouras

Intussusception occurs when a portion of the alimentary tract is telescoped into an adjacent segment. It is the most common cause of intestinal obstruction between 5 mo and 3 yr of age and the most common abdominal emergency in children younger than 2 yr of age. Sixty percent of patients are younger than 1 yr of age and 80% of the cases occur before age 24 mo; it is rare in neonates. The incidence varies from 1 to 4 per 1,000 live births. The male:female ratio is 3 : 1.

Many small bowel–small bowel and a few small bowel–colonic intussusceptions reduce spontaneously; if left untreated, ileal-colonic intussusception may lead to intestinal infarction, perforation, peritonitis, and death.

Etiology and Epidemiology

Approximately 90% of cases of intussusception in children are idiopathic. The seasonal incidence has peaks in fall and winter. Correlation with prior or concurrent respiratory adenovirus (type C) infection has been noted, and the condition can complicate otitis media, gastroenteritis, Henoch-Schönlein purpura, or other upper respiratory tract infections. A slight increase in intussusception has been noted to occur within 3 wk of the rotavirus vaccine (especially after the first dose), but this is a very rare side effect.

It is postulated that gastrointestinal infection or the introduction of new food proteins results in swollen Peyer patches in the terminal ileum. Lymphoid nodular hyperplasia is another related risk factor. Prominent mounds of lymph tissue lead to mucosal prolapse of the ileum into the colon, thus causing an intussusception. In 2–8% of patients, **recognizable lead points** for the intussusception are found, such as a Meckel diverticulum, intestinal polyp, neurofibroma, intestinal duplication cysts, inverted appendix stump, leiomyomas, hamartomas, ectopic pancreatic tissue, anastomotic suture line, enterostomy tube, posttransplant lymphoproliferative disease, hemangioma, or malignant conditions such as lymphoma or Kaposi sarcoma. Gastrojejunal and jejunostomy tubes can also serve as lead points for intussusception. Lead points are more common in children older than 2 yr of age; the older the child, the higher the risk of a lead point. In adults, lead points are present in 90%. Intussusception can complicate mucosal hemorrhage, as in Henoch-Schönlein purpura, idiopathic thrombocytopenic purpura, or hemophilia. Cystic fibrosis, celiac disease, and Crohn disease are other risk factors. Postoperative intussusception is ileoileal and usually occurs within several days of an abdominal operation. Anterograde intussusception may occur rarely following bariatric surgery with a Roux-en-Y gastric bypass and is noteworthy that there does not seem to be a *lead point* in these cases. Intrauterine intussusception may be associated with the development of intestinal atresia. Intussusception in premature infants is rare.

Ileal-ileal intussusception may be more common than previously believed, is often idiopathic or associated with Henoch-Schönlein purpura, and usually resolves spontaneously.

Pathology

Intussusceptions are most often ileocolic, less commonly cecocolic, and occasionally ileal. Very rarely, the appendix forms the apex of an intussusception. The upper portion of bowel, the **intussusceptum,** invaginates into the lower, the **intussuscipiens,** pulling its mesentery along with it into the enveloping loop. Constriction of the mesentery obstructs venous return; engorgement of the intussusceptum follows, with edema, and bleeding from the mucosa leads to a bloody stool, sometimes containing mucus. The apex of the intussusception can extend into the transverse, descending, or sigmoid colon, even to and through the anus in neglected cases. This presentation must be distinguished from rectal prolapse. Most intussusceptions do not strangulate the bowel within the first 24 hr but can eventuate in intestinal gangrene and shock.

Clinical Manifestations

In typical cases, there is sudden onset, in a previously well child, of severe paroxysmal colicky pain that recurs at frequent intervals and is accompanied by straining efforts with legs and knees flexed and loud cries. The infant may initially be comfortable and play normally between the paroxysms of pain, but if the intussusception is not reduced, the infant becomes progressively weaker and lethargic. At times, the **lethargy** is often disproportionate to the abdominal signs. With progression, a shock-like state, with fever and peritonitis, can develop. The pulse becomes weak and thready, the respirations become shallow and grunting, and the pain may be manifested only by moaning sounds. Vomiting occurs in most cases and is usually more frequent in the early phase. In the later phase, the vomitus becomes bile stained. Stools of normal appearance may be evacuated in the first few hr of symptoms. After this time, fecal excretions are small or more often do not occur, and little or no flatus is passed. Blood is generally passed in the first 12 hr but at times not for 1-2 days and infrequently not at all; 60% of infants pass a stool containing red blood and mucus, the currant jelly stool. Some patients have only irritability and alternating or progressive lethargy. The classic triad of pain, a palpable sausage-shaped abdominal mass, and bloody or currant jelly stool is seen in <30% of patients with intussusception. The combination of paroxysmal pain, vomiting, and a palpable abdominal mass has a positive predictive value of >90%; the presence of rectal bleeding increases this to approximately 100%.

Palpation of the abdomen usually reveals a slightly tender sausage-shaped mass, sometimes ill defined, which might increase in size and firmness during a paroxysm of pain and is most often in the right upper abdomen, with its long axis cephalocaudal. If it is felt in the epigastrium, the long axis is transverse. Approximately 30% of patients do not have a palpable mass. The presence of bloody mucus on rectal examination supports the diagnosis of intussusception. Abdominal distention and tenderness develop as intestinal obstruction becomes more acute. On rare occasions, the advancing intestine prolapses through the anus. *This prolapse can be distinguished from prolapse of the rectum by the separation between the protruding intestine and the rectal wall, which does not exist in prolapse of the rectum.*

Ileoileal intussusception in children younger than 2 yr can have a less-typical clinical picture, the symptoms and signs being chiefly those of small intestinal obstruction; these often resolve without treatment. **Recurrent intussusception** is noted in 5–8% and is more common after hydrostatic than surgical reduction. Chronic intussusception, in which the symptoms exist in milder form at recurrent intervals, is more likely to occur with or after acute enteritis and can arise in older children as well as in infants.

Diagnosis

When the clinical history and physical findings suggest intussusception, an ultrasound is typically performed. A plain abdominal radiograph might show a density in the area of the intussusception. Screening ultrasounds for suspected intussusception increases the yield of diagnostic or therapeutic enemas and reduces unnecessary radiation exposure in children with negative ultrasound examinations. The diagnostic findings of intussusception on ultrasound include a tubular mass in longitudinal views and a doughnut or target appearance in transverse images (Fig. 359.1). Ultrasound has a sensitivity of approximately 98–100% and a specificity of approximately 98% in diagnosing intussusception. Air, hydrostatic (saline), and, less often, water-soluble contrast enemas have replaced barium examinations. Contrast enemas demonstrate a filling defect or cupping in the head of the contrast media where its advance is obstructed by the intussusceptum (Fig. 359.2). A central linear column of contrast media may be visible in the compressed lumen of the intussusceptum, and a thin rim of contrast may be seen trapped around the invaginating intestine in the folds of mucosa within the intussuscipiens (coiled-spring sign), especially after evacuation. Retrogression of the intussusceptum under pressure and visualized on x-ray or ultrasound documents successful reduction. Air reduction is associated with fewer complications and lower radiation exposure than traditional contrast hydrostatic techniques.

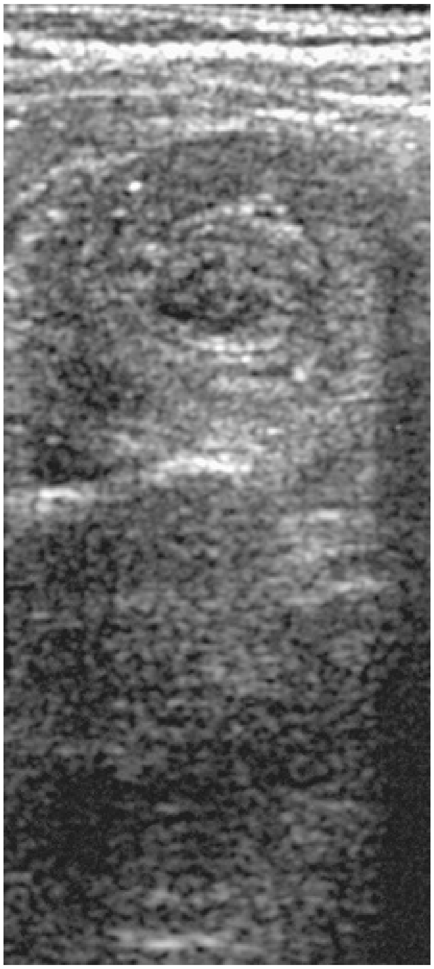

FIG. 359.1 Transverse image of an ileocolic intussusception. Note the loops within the loops of bowel.

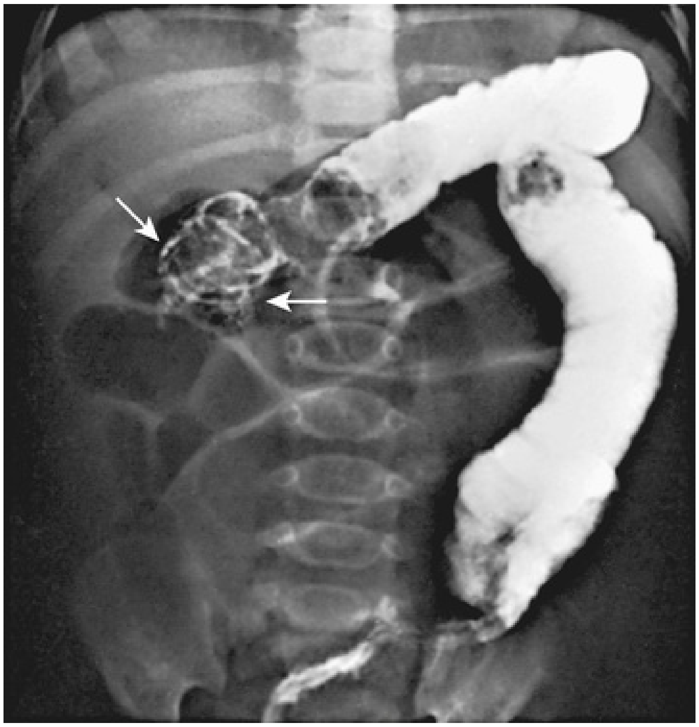

FIG. 359.2 Intussusception in an infant. The obstruction is evident in the proximal transverse colon. Contrast material between the intussusceptum and the intussuscipiens (arrows) is responsible for the coiled-spring appearance.

Differential Diagnosis

It may be particularly difficult to diagnose intussusception in a child who already has gastroenteritis; a change in the pattern of illness, in the character of pain, or in the nature of vomiting or the onset of rectal bleeding should alert the physician. The bloody stools and abdominal cramps that accompany enterocolitis can usually be differentiated from intussusception because in enterocolitis the pain is less severe and less regular, there is diarrhea, and the infant is recognizably ill between pains. Bleeding from a Meckel diverticulum is usually painless. Joint symptoms, purpura, or hematuria usually but not invariably accompany the intestinal hemorrhage of Henoch-Schönlein purpura. Because intussusception can be a complication of this disorder, ultrasonography may be needed to distinguish the conditions.

It is important in patients with cystic fibrosis to distinguish intussusception from distal intestinal obstruction syndrome. Distal intestinal obstruction syndrome requires antegrade treatment, which would be harmful if there was an intussusception.

Treatment

Reduction of an acute intussusception is an emergency procedure and should be performed immediately after diagnosis in preparation for possible surgery. In patients with prolonged intussusception and signs of shock, peritoneal irritation, intestinal perforation, or pneumatosis intestinalis, hydrostatic reduction should not be attempted.

The success rate of radiologic hydrostatic reduction under fluoroscopic or ultrasonic guidance is approximately 80–95% in patients with ileocolic intussusception. Spontaneous reduction of intussusception occurs in approximately 4–10% of patients. Bowel perforations occur in 0.5–2.5% of attempted barium and hydrostatic (saline) reductions. The perforation rate with air reduction is 0.1–0.2%. Surgical reduction is indicated in the presence of refractory shock, suspected bowel necrosis or perforation, peritonitis, and multiple recurrences (suspected lead point).

An **ileoileal intussusception** is best demonstrated by abdominal ultrasonography. Reduction by instillation of contrast agents, saline, or air might not be possible. Such intussusceptions can develop insidiously after bowel surgery and require reoperation if they do not spontaneously reduce. Ileoileal disease is common with Henoch-Schönlein purpura and other unidentifiable disorders and usually resolves without the need for any specific treatment. If manual operative reduction is impossible or the bowel is not viable, resection of the intussusception is necessary, with end-to-end anastomosis.

Prognosis

Untreated ileal-colonic intussusception in infants is usually fatal; the chances of recovery are directly related to the duration of intussusception before reduction. Most infants recover if the intussusception is reduced in the first 24 hr, but the mortality rate rises rapidly after this time, especially after the 2nd day. Spontaneous reduction during preparation for operation is not uncommon.

The **recurrence rate** after reduction of intussusceptions is approximately 10%, and after surgical reduction it is 2–5%; none has recurred after surgical resection. Most recurrences occur within 72 hr of reduction. Corticosteroids may reduce the frequency of recurrent intussusception but are rarely used for this purpose. Repeated reducible episodes caused by lymphonodular hyperplasia may respond to treatment of identifiable food allergies if present. A single recurrence of intussusception can usually be reduced radiologically. In patients with multiple ileal-colonic recurrences, a lead point should be suspected and laparoscopic surgery considered. It is unlikely that an intussusception caused by a lesion such as lymphosarcoma, polyp, or Meckel diverticulum will be successfully reduced by radiologic intervention. With adequate surgical management, laparoscopic reduction carries a very low mortality.

359.4

Closed-Loop Obstructions

Asim Maqbool, Chris A Liacouras

Closed-loop obstructions (i.e., **internal hernia**) result from bowel loops that enter windows created by mesenteric defects or adhesions and become trapped. Vascular engorgement of the strangulated bowel results in intestinal ischemia and necrosis unless promptly relieved. Prior abdominal surgery is an important risk factor. Symptoms include abdominal pain, distention, and bilious emesis. Symptoms can be intermittent if the herniated bowel slides in and out of the defect. Peritoneal signs suggest ischemic bowel. Plain radiographs demonstrate signs of small bowel obstruction or free air if the bowel has perforated. CT scan can identify and delineate internal hernias. Supportive management includes intravenous fluids, antibiotics, and nasogastric decompression. Prompt surgical relief of the obstruction is indicated to prevent bowel necrosis.

Foreign Bodies in the Stomach and Intestine

Asim Maqbool, Chris A. Liacouras

Once in the stomach, 95% of all ingested objects pass without difficulty through the remainder of the gastrointestinal tract. Perforation after ingestion of a foreign body is estimated to be <1% of all objects ingested. Perforation tends to occur in areas of physiologic sphincters (pylorus, ileocecal valve), acute angulation (duodenal sweep), congenital gut malformations (webs, diaphragms, diverticula), or areas of previous bowel surgery.

Most patients who ingest foreign bodies are between the ages of 6 mo and 6 yr. Coins are the most commonly ingested foreign body in children, and meat or food impactions are the most common accidental foreign body in adolescents and adults. Patients with nonfood foreign bodies often describe a history of ingestion. Young children might have a witness to ingestion. Immediate concerns are what the foreign body is, the location of the foreign body, the size of the foreign body, and the time that the ingestion occurred. Approximately 90% of foreign bodies are opaque. Radiologic examination is routinely performed to determine the type, number, and location of the suspected objects. Contrast radiographs may be necessary to demonstrate some objects, such as plastic parts or toys.

Conservative management is indicated for most foreign bodies that have passed through the esophagus and entered the stomach. Most objects pass though the intestine in 4-6 days, although some take as long as 3-4 wk. While waiting for the object to pass, parents are instructed to continue a regular diet and to observe the stools for the appearance of the ingested object. Cathartics should be avoided. Exceptionally long or sharp objects are usually monitored radiologically. Parents or patients should be instructed to report abdominal pain, vomiting, persistent fever, and hematemesis or melena immediately to their physicians. Failure of the object to progress within 3-4 wk seldom implies an impeding perforation but may be associated with a congenital malformation or acquired bowel abnormality.

Certain objects pose more risk than others. In cases of sharp foreign bodies, such as straight pins, weekly assessments are required. Surgical removal is necessary if the patient develops symptoms or signs of obstruction or perforation or if the foreign body fails to progress for several weeks. Small magnets used to secure earrings or parts of toys are associated with bowel perforation. Whereas a single magnet in the stomach may not require intervention in an asymptomatic child, a magnet in the esophagus requires immediate removal. When the *multiple* magnets disperse after ingestion, they may be attracted to each other across bowel walls, leading to pressure necrosis and perforation (Fig. 360.1). Inexpensive toy medallions containing lead can lead to **lead toxicity.** Newer coins can also decompose when subjected to prolonged acid exposure. Unless multiple coins are ingested, the metals released are unlikely to pose a clinical risk.

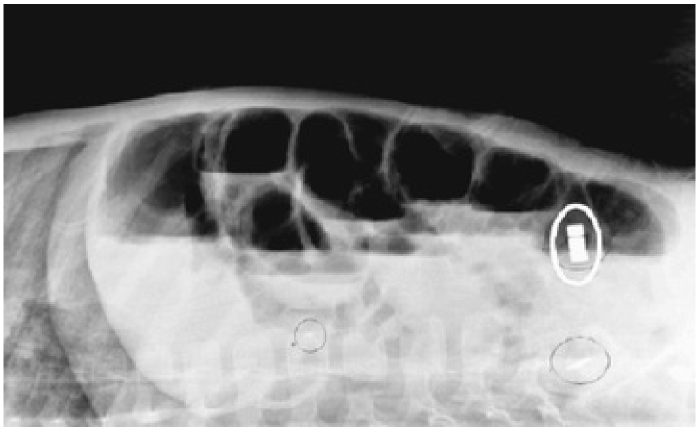

FIG. 360.1 Abdominal radiograph of a boy aged 3 yr, noting three attached magnets that resulted in volvulus (i.e., twisting of the bowel) and multiple

bowel perforations. (Courtesy U.S. Consumer Product Safety Commission. From Centers for Disease Control and Prevention: Gastrointestinal injuries from magnet ingestion in children—United States, 2003–2006. *MMWR Morb Mortal Wkly Rep* 55:1296–1300, 2006.)

Ingestion of batteries rarely leads to problems, but symptoms can arise from leakage of alkali or heavy metal (mercury) from battery degradation in the gastrointestinal tract. Batteries can also generate electrical current and thereby cause low-voltage electrical burns to the intestine. If patients experience symptoms such as vomiting or abdominal pain, if a large-diameter battery (>20 mm in diameter) remains in the stomach for longer than 48 hr, or if a lithium battery is ingested, the battery should be removed. Batteries larger than 15 mm that do not pass the pylorus within 48 hr are less likely to pass spontaneously and generally require removal. In children younger than 6 yr of age, batteries larger than 15 mm are not likely to pass spontaneously and should be removed endoscopically. If the patient develops peritoneal signs, surgical removal is required. Batteries beyond the duodenum pass per rectum in 85% within 72 hr. The battery should be identified by size and imprint code or by evaluation of a duplicate measurement of the battery compartment. The National Button Battery Ingestion Hotline (202-625-3333) can be called for help in identification. The Poison Control Center (800-222-1222) can be called as well for ingestion of batteries and caustic materials. Lithium batteries result in more severe injury than a button alkali battery, with damage occurring in minutes. Button batteries in a symptomatic child should be removed, or if there are multiple batteries, they should be removed.

In older children and adults, oval objects larger than 5 cm in diameter or 2 cm in thickness tend to lodge in the stomach and should be endoscopically retrieved. Thin long objects >6 cm in length fail to negotiate the pylorus or duodenal sweep and should also be removed. In infants and toddlers, objects >3 cm in length or >20 mm in diameter do not usually pass through the pylorus and should be removed. An open safety pin presents a major problem and requires urgent endoscopic removal if within reach. Razor blades can be managed with a rigid endoscope by pulling the blade into instrument. The endoscopist can alternatively use a rubber hood on the head of the endoscope to protect the esophagus. Other sharp objects (needles, bones, pins) usually pass the stomach, but complications may be as high as 35%; if possible, they should be removed by endoscope if in the stomach or proximal duodenum. If sharp objects are not able to be removed but no progress is observed in location during 3 days, surgical removal is indicated. Drugs (aggregated iron pills, cocaine) may have to be surgically removed; initial management can include oral polyethylene glycol lavage. Drug body packing (heroin, cocaine) is usually seen on kidneys-ureters-bladder or CT imaging and often passes without incident. Endoscopic procedures may rupture the material, causing severe toxicity. Surgery is indicated if toxicity develops, if the packages fail to progress, or if there are signs of obstruction.

Ingestion of magnets poses a danger to children. The number of magnets is thought to be critical. If a single magnet is ingested, there is the least likelihood of complications. If 2 or more magnets are ingested, the magnetic poles are attracted to each other and create the risk of obstruction, fistula development, and perforation. Endoscopic retrieval is emergent after films are taken when multiple magnets are ingested. Abdominal pain or peritoneal signs require urgent surgical intervention. If all magnets are located in the stomach, immediate endoscopic removal is indicated. If the ingestion occurred greater than 12 hr prior to evaluation, or if the magnets are beyond the stomach and the patient is symptomatic, general surgery should be consulted. If the patient is asymptomatic, endoscopic or colonoscopic removal may be considered, along with a surgical evaluation.

Lead-based foreign bodies can cause symptoms from lead intoxication. Early endoscopic removal is indicated of an object suspected to contain lead. A lead level should be obtained.

Water-absorbing polymer balls (beads) can expand to approximately 400 times their starting size and if ingested may produce intestinal obstruction. Initially of a small diameter, they pass the pylorus only to rapidly enlarge in the small intestine. Surgical removal is indicated.

Children occasionally place objects in their rectum. Small blunt objects usually pass spontaneously, but large or sharp objects typically need to be retrieved. Adequate sedation is essential to relax the anal sphincter before attempting endoscopic or speculum removal. If the object is proximal to the rectum, observation for 12-24 hr usually allows the object to descend into the rectum.

360.2

Bezoars

Asim Maqbool, Chris A. Liacouras

A bezoar is an accumulation of exogenous matter in the stomach or intestine. They are predominantly composed of food or fiber. Most bezoars have been found in females with underlying personality problems or in neurologically impaired persons. Patients who have undergone abdominal surgery are at higher risk for the development of bezoars. The peak age at onset of symptoms is the 2nd decade of life.

Bezoars are classified on the basis of their composition. **Trichobezoars** are composed of the patient's own hair. It is most frequently a complication of the psychiatric disorder trichotillomania, and the most severe form is known as Rapunzel syndrome (hair bezoar extending beyond the stomach to the small intestine). **Phytobezoars** are composed of a combination of plant and animal material, and gastric phytobezoars are the most common in patients with poor motility. **Lactobezoars** were previously found most often in premature infants and can be attributed to the high casein or calcium content of some premature formulas. Swallowed chewing gum can occasionally lead to a bezoar.

Trichobezoars can become large and form casts of the stomach; they can enter into the proximal duodenum. They manifest as symptoms of gastric outlet or partial intestinal obstruction, including vomiting, anorexia, and weight loss. Patients might complain of abdominal pain, distention, and severe halitosis. Physical examination can demonstrate patchy baldness and a firm mass in the left upper quadrant. Patients occasionally have iron-deficiency anemia, hypoproteinemia, or steatorrhea caused by an associated chronic gastritis. Phytobezoars manifest in a similar manner. Detached segments of the bezoar or trichobezoar can migrate to the small intestine as a “satellite masses” and result in small bowel obstruction.

An abdominal plain film can suggest the presence of a bezoar, which can be confirmed on ultrasound or CT examination. On CT a bezoar appears a nonhomogeneous, nonenhancing mass within the lumen of the stomach or intestine. Oral contrast circumscribes the mass.

Bezoars in the stomach can usually be removed endoscopically. If endoscopy is unsuccessful, surgical intervention may be needed. Lactobezoars usually resolve when feedings are withheld for 24-48 hr. Coca-Cola has been used as a dissolution therapy for gastric phytobezoar and has been shown to be effective when used with endoscopy. Trichobezoars almost always require surgical removal.

Sunflower seed bezoars are reported to cause rectal pain and constipation as a result of the seed shells being associated with fecal impaction. Endoscopic removal is indicated, as these bezoars are refractory to enema or lavage management.

CHAPTER 361

Peptic Ulcer Disease in Children

Samra S. Blanchard, Steven J. Czinn

Peptic ulcer disease, resulting from inflammation caused by an imbalance between cytoprotective and cytotoxic factors in the stomach and duodenum, manifests with varying degrees of gastritis or frank ulceration. The pathogenesis of peptic ulcer disease is multifactorial, but the final common pathway for the development of ulcers is the action of acid and pepsin-laden contents of the stomach on the gastric and duodenal mucosa and the inability of mucosal defense mechanisms to allay those effects. Abnormalities in the gastric and duodenal mucosa can be visualized on endoscopy, with or without histologic changes. Deep mucosal lesions that disrupt the muscularis mucosa of the gastric or duodenal wall define **peptic ulcers.** Gastric ulcers are generally located on the lesser curvature of the stomach, and 90% of duodenal ulcers are found in the duodenal bulb. While there are no large population-based pediatric studies, rates of peptic ulcer disease in childhood appear to be low. Large pediatric centers anecdotally report an incidence of 5-7 children with gastric or duodenal ulcers per 2,500 hospital admissions each year.

Ulcers in children can be classified as **primary** peptic ulcers, which are chronic and more often duodenal, or **secondary,** which are usually more acute in onset and are more often gastric (Table 361.1). Primary ulcers are most often associated with *Helicobacter pylori* infection; idiopathic primary peptic ulcers account for up to 20% of duodenal ulcers in children. Secondary peptic ulcers can result from stress caused by sepsis, shock, or an intracranial lesion (Cushing ulcer), or in response to a severe burn injury (Curling ulcer). Secondary ulcers are often the result of using aspirin or nonsteroidal antiinflammatory drugs (NSAIDs); hypersecretory states like Zollinger-Ellison syndrome (see Chapter 361.1), short bowel syndrome, and systemic mastocytosis are rare causes of peptic ulceration.

Table 361.1

Etiologic Classification of Peptic Ulcers

- Positive for *Helicobacter pylori* infection
- Drug (NSAID)-induced
- *Helicobacter pylori* and NSAID-positive
- *H. pylori* and NSAID-negative*
- Acid hypersecretory state (Zollinger-Ellison syndrome)
- Anastomosis ulcer after subtotal gastric resection
- Tumors (cancer, lymphoma)
- Rare specific causes
- Crohn disease of the stomach or duodenum
- Eosinophilic gastroduodenitis
- Systemic mastocytosis
- Radiation damage
- Viral infections (cytomegalovirus or herpes simplex infection, particularly in immunocompromised patients)
- Colonization of stomach with *Helicobacter heilmannii*
- Severe systemic disease
- Cameron ulcer (gastric ulcer where a hiatal hernia passes through the diaphragmatic hiatus)
- True idiopathic ulcer

* Requires search for other specific causes. *NSAID,* nonsteroidal antiinflammatory drug. (From Vakil N, Megraud F: Eradication therapy for *Helicobacter pylori, Gastroenterology* 133:985–1001, 2007.)

Pathogenesis

Acid Secretion

By 3-4 yr of age, gastric acid secretion approximates adult values. Acid initially secreted by the oxyntic cells of the stomach has a pH of approximately 0.8, whereas the pH of the stomach contents is 1-2. Excessive acid secretion is associated with a large parietal cell mass, hypersecretion by antral G cells, and increased vagal tone, resulting in increased or sustained acid secretion in response to meals and increased secretion during the night. The secretagogues that promote gastric acid production include acetylcholine released by the vagus nerve, histamine secreted by enterochromaffin cells, and gastrin released by the G cells of the antrum. Mediators that decrease gastric acid secretion and enhance protective mucin production include prostaglandins.

Mucosal Defense

A continuous layer of mucous gel that serves as a diffusion barrier to hydrogen ions and other chemicals covers the gastrointestinal (GI) mucosa. Mucus production and secretion are stimulated by prostaglandin E_2 . Underlying the mucous coat, the epithelium forms a second-line barrier, the characteristics of which are determined by the biology of the epithelial cells and their tight junctions. Another important function of epithelial cells is to secrete chemokines when threatened by microbial attack. Secretion of bicarbonate into the mucous coat, which is regulated by prostaglandins, is important for neutralization of hydrogen ions. If mucosal injury occurs, active proliferation and migration of mucosal cells occurs rapidly, driven by epithelial growth factor, transforming growth factor-α, insulin-like growth factor, gastrin, and bombesin, and covers the area of epithelial damage.

Clinical Manifestations

The presenting symptoms of peptic ulcer disease vary with the age of the patient. Hematemesis or melena is reported in up to half of the patients with peptic ulcer disease. School-age children and adolescents more commonly present with epigastric pain and nausea, similar to the presentation generally seen in adults. Dyspepsia, epigastric abdominal pain, and fullness are also seen in older children. Infants and younger children usually present with feeding difficulty, vomiting, crying episodes, hematemesis, or melena. In the neonatal period, gastric perforation can be the initial presentation.

The classic symptom of peptic ulceration, epigastric pain alleviated by the ingestion of food, is present only in a minority of children. Many pediatric patients present with poorly localized abdominal pain, which may be periumbilical. The vast majority of patients with periumbilical or epigastric pain or discomfort do not have a peptic ulcer, but rather a functional GI disorder, such as irritable bowel syndrome or nonulcer (functional) dyspepsia. Patients with peptic ulceration rarely present with acute abdominal pain from perforation or symptoms and signs of pancreatitis from a posterior penetrating ulcer. Occasionally, bright red blood per rectum may be seen if the rate of bleeding is brisk and the intestinal transit time is short. Vomiting can be a sign of gastric outlet obstruction.

The pain is often described as dull or aching, rather than sharp or burning, as in adults. It can last from minutes to hours; patients have frequent exacerbations and remissions lasting from weeks to months. Nocturnal pain waking the child is common in older children. A history of typical ulcer pain with prompt relief after taking antacids is found in <33% of children. Rarely, in patients with acute or chronic blood loss, penetration of the ulcer into the abdominal cavity or adjacent organs produces shock, anemia, peritonitis, or pancreatitis. If inflammation and edema are extensive, acute or chronic gastric outlet obstruction can occur. *In a child with a normal diet for age, iron deficiency anemia may suggest peptic ulceration.* Other gastric causes of iron deficiency anemia include autoimmune gastritis, gastric hyperplasia, and possible Jervell and Lange-Nielson syndrome (*KCNQ1* mutations).

Diagnosis

Esophagogastroduodenoscopy is the method of choice to establish the diagnosis of peptic ulcer disease. It can be safely performed in all ages by experienced pediatric gastroenterologists. Endoscopy allows the direct visualization of esophagus, stomach, and duodenum, identifying the specific lesions. Biopsy specimens must be obtained from the esophagus, stomach, and duodenum for histologic assessment as well as to screen for the presence of *H. pylori* infection. Endoscopy also provides the opportunity for hemostatic therapy including clipping, injection, and the use of thermal coagulation.

Primary Ulcers

Helicobacter pylori Gastritis

H. pylori is among the most common bacterial infections in humans. *H. pylori* is a Gram-negative, S -shaped rod that produces urease, catalase, and oxidase, which might play a role in the pathogenesis of peptic ulcer disease. The mechanism of acquisition and transmission of *H. pylori* is unclear, although the most likely mode of transmission is fecal–oral or oral–oral. Viable *H. pylori* organisms can be cultured from the stool or vomitus of infected patients. Risk factors such as low socioeconomic status in childhood or affected family members also influence the prevalence. All children infected with *H. pylori* develop histologic chronic active gastritis but are often asymptomatic. In children, *H. pylori* infection can manifest with abdominal pain or vomiting and, less often, refractory iron deficiency anemia or growth retardation. *H. pylori* can be associated, though rarely, with chronic autoimmune thrombocytopenia.

Chronic colonization with *H. pylori* can predispose children to a significantly increased risk of developing a duodenal ulcer, gastric cancer such as adenocarcinoma, or mucosa-associated lymphoid tissue lymphomas. The relative risk of gastric carcinoma is 2.3-8.7 times greater in infected adults as compared to uninfected subjects. *H. pylori* is classified by the World Health Organization as a group I carcinogen.

Anemia, idiopathic thrombocytopenic purpura, short stature, and sudden infant death syndrome (SIDS) have also been reported as possible extragastric manifestations of *H. pylori* infection. In one published study, *H. pylori* infection has been correlated with cases of SIDS, but there is no evidence to suggest that *H. pylori* plays a role in the pathogenesis of SIDS.

The **diagnosis** of *H. pylori* infection is made histologically by demonstrating the organism in the biopsy specimens (Fig. 361.1). The most recent consensus report recommends against using antibody-based tests (IgG, IgA) for *H pylori* in serum, whole blood, urine, and saliva in the clinical setting.[13] C-urea breath tests and stool antigen tests are reliable noninvasive methods of detecting *H. pylori* infection in patients who do not require endoscopic evaluation. Patients should stop proton pump inhibitor (PPI) therapy 2 wk prior to testing as negative results on therapy may represent false negatives. Nonetheless, for symptomatic children with suspected *H. pylori* infection, an initial upper endoscopy is recommended to evaluate and confirm *H. pylori* disease. The range of endoscopic findings in children with *H. pylori* infection varies from being grossly normal to the presence of nonspecific gastritis with prominent rugal folds, nodularity (Fig. 361.2), or ulcers. Because the antral mucosa appears to be endoscopically normal in a significant number of children with primary *H. pylori* gastritis, gastric biopsies should always be obtained from the body and antrum of the stomach regardless of the endoscopic appearance. If *H. pylori* is identified, even in a child with no symptoms, eradication therapy should be offered (Tables 361.2 and 361.3). Successful *H pylori* eradication is associated with cure of peptic ulcer disease and very low risk of relapse. Therefore, monitoring the success of therapy is mandatory in these patients 4-6 wk after stopping antibiotics and at least 2 wk after stopping PPI therapy. Eradication can be tested with the 13C-urea breath (13C-UBT) test or stool antigen test. If there is an eradication failure, the patient should receive rescue therapy (Fig. 361.3). Because of a significant incidence of *H. pylori* resistance to clarithromycin, other treatment options are recommended if the community resistance rate is >15% or if it is unknown.

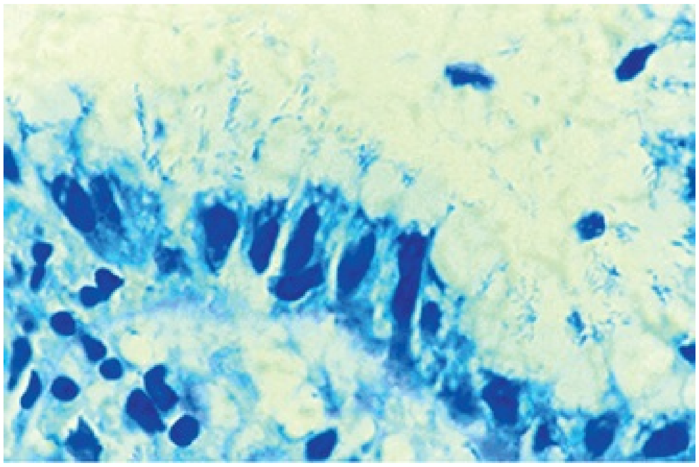

FIG. 361.1 Appearance of *Helicobacter pylori* on the gastric mucosal surface with Giemsa stain (high-power view). (From Campbell DI, Thomas JE: *Helicobacter pylori* infection in paediatric practice, *Arch Dis Child Educ Pract Ed* 90:ep25–ep30, 2005.)

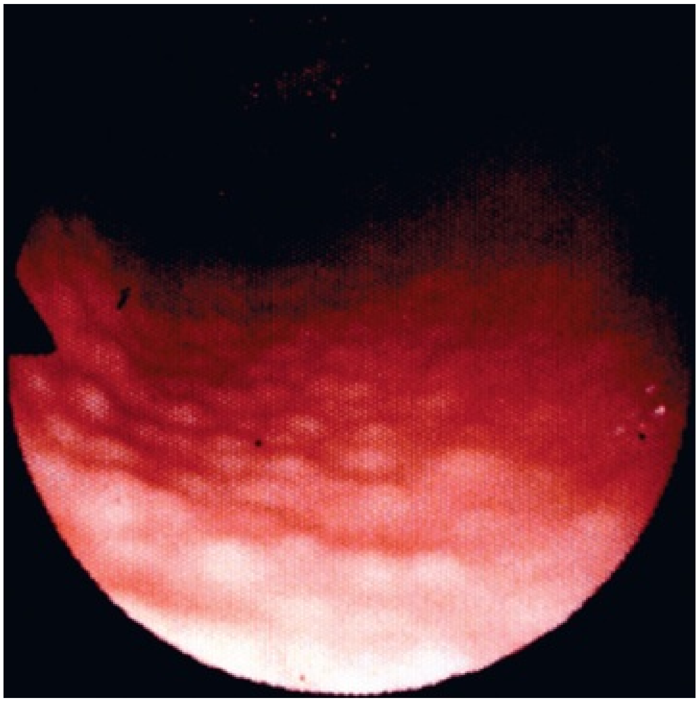

FIG. 361.2 Endoscopic view of lymphoid modular hyperplasia of the gastric antrum. (From Campbell DI, Thomas JE: *Helicobacter pylori* infection in paediatric practice, *Arch Dis Child Educ Pract Ed* 90:ep25–ep30, 2005.)

Table 361.2

Recommended Eradication Therapies for *Helicobacter pylori* –Associated Disease in Children

MEDICATIONS	DOSE		DURATION OF TREATMENT
Proton pump inhibitor	1 mg/kg/dose twice a day		1 mo
ANTIBIOTICS	**WEIGHT**	**DOSE**	**DURATION OF TREATMENT**
Amoxicillin	15-24 kg	500 mg twice a day	14 days
	25-34 kg	750 mg twice a day	
	>35 kg	1,000 mg twice a day	
Clarithromycin	15-24 kg	250 mg twice a day	14 days
	25-34 kg	500 mg in AM , 250 mg in PM	
	>35 kg	500 mg twice a day	
Metronidazole	15-24 kg	250 mg twice a day	14 days
	25-34 kg	500 mg in AM , 250 mg in PM	
	>35 kg	500 mg twice a day	

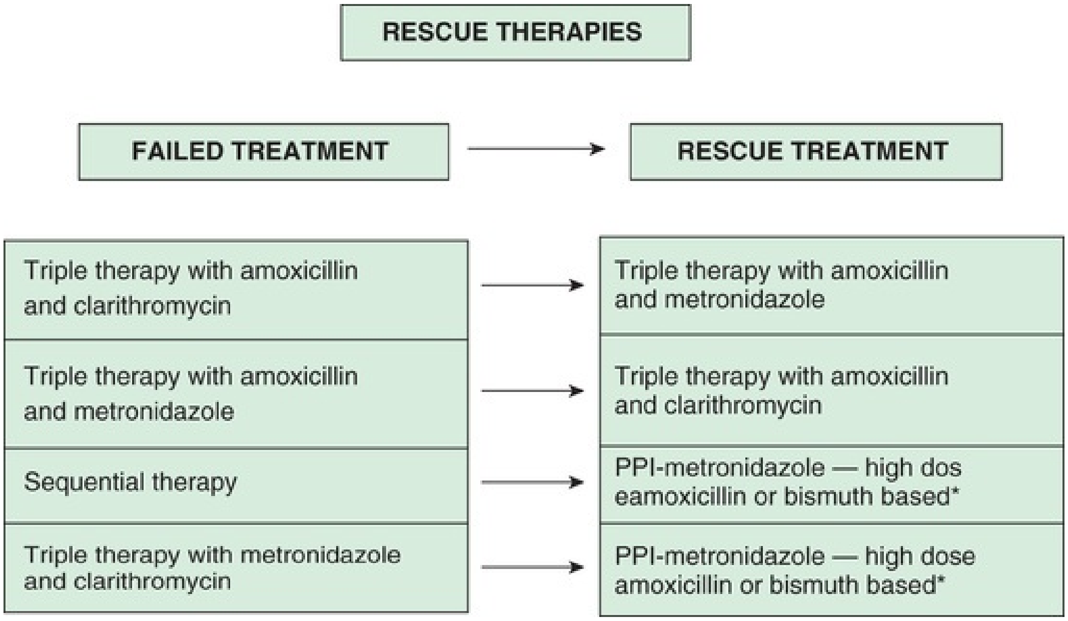
Depending on previous antibiotic use history, recommended combinations are Amoxicillin + Clarithromycin + PPI OR Amoxicillin + Metronidazole + PPI OR Clarithromycin + Metronidazole + PPI. (Modified from Jones NL, Koletzko S, Goodman K, et al: Joint ESPGHAN/NASPGHAN Guidelines for the Management of Helicobacter pylori in Children and Adolescents, *J Pediatr Gastroenterol Nutr* 64(6):991–1003, 2017.)

Table 361.3

Antisecretory Therapy With Pediatric Dosages

MEDICATION	PEDIATRIC DOSE	HOW SUPPLIED
H_2 RECEPTOR ANTAGONISTS		
Ranitidine	4-10 mg/kg/day Divided 2 or 3 × a day	Syrup: 75 mg/5 mL Tablets: 75, 150, 300 mg
Famotidine	1-2 mg/kg/day Divided twice a day	Syrup: 40 mg/5 mL Tablets: 20, 40 mg
Nizatidine	5-10 mg/kg/day divided twice a day Older than 12 yr: 150 mg twice a day	Solution: 15 mg/mL Capsule 150, 300 Tablet: 75 mg
PROTON PUMP INHIBITORS		
Omeprazole	1.0-3.3 mg/kg/day weigh < 20 kg: 10 mg/day weigh > 20 kg: 20 mg/day Approved for use in those older than 2 yr	Capsules: 10, 20, 40 mg
Lansoprazole	0.8-4 mg/kg/day weigh < 30 kg: 15 mg/day weigh > 30 kg: 30 mg/day Approved for use in those older than 1 yr	Capsules: 15, 30 mg Powder packet: 15, 30 mg SoluTab: 15, 30 mg
Rabeprazole	1-11 yr (weigh < 15 kg): 5 mg/day 1-11 yr (weigh > 15 kg): 10 mg/day >12 yr: 20 mg tablet	Delayed release capsule: 5, 10 mg Delayed release tablet: 20 mg
Pantoprazole	1-5 yr: 0.3-1.2 mg/kg/day (limited data) >5 yr of age:	Tablet: 20, 40 mg Powder pack: 40 mg

	weigh > 15 kg to < 40 kg: 20 mg/day weigh > 40 kg: 40 mg/day	
Esomeprazole	1 mo - < 1 yr old weigh 3 kg to 5 kg: 2.5 mg weigh > 5 kg to 7.5 kg: 5 mg weigh > 7.5 kg to 12 kg: 10 mg 1-11 yr old weigh < 20 kg: 10 mg weigh > 20 kg: 20 mg Approved for use 1 mo and older	Capsules: 20, 40 Delayed release single dose packs: 2.5, 5, 10, 20 mg
Dexlansoprazole	12-17 yr: 30-60 mg Approved for use in 12-17 yr	Capsules: 30, 60
Omeprazole sodium bicarbonate	Not approved for use < 18 yr at time of publication	Capsules: 20, 40 Powder for oral suspension: 20 mg, 40 mg
CYTOPROTECTIVE AGENTS		
Sucralfate	40-80 mg/kg/day	Suspension: 1,000 mg/5 mL Tablet: 1,000 mg



RESCUE THERAPIES
FAILED TREATMENT
RESCUE TREATMENT
Triple therapy with amoxicillin and clarithromycin
Triple therapy with amoxicillin and metronidazole
Triple therapy with amoxicillin and metronidazole
Triple therapy with amoxicillin and clarithromycin
Sequential therapy
PPI-metronidazole — high dos eamoxicillin or bismuth based*
Triple therapy with metronidazole and clarithromycin
PPI-metronidazole — high dose amoxicillin or bismuth based*

FIG. 361.3 Rescue therapy for failed eradication of *H. pylori* . *Bismuth-based therapy with tetracycline instead of amoxicillin if patients >8 yr. Bismuth dose is 262 mg four times a day for patients 8–10 yr and 524 mg four times a day for those >10 yr. (See Tables 361.2 and 361.3 .) In adolescents, levofloxacin or tetracycline can be considered. High-dose amoxicillin ranges from 750 mg twice a day for body weight 15–24 kg, 1000 mg twice a day for 25–34 kg, and 1500 mg twice a day for >35 kg. (Adapted from Jones NL, Koletzko S, Goodman K, et al: Joint ESPGHAN/NASPGHAN guidelines for the management of *Helicobacter pylori* in children and adolescents, *J Pediatr Gastroenterol Nutr* 64:991–1003, 2017.)

Idiopathic Ulcers

H. pylori –negative peptic ulcers in children who have no history of taking NSAIDs represent 15–20% of pediatric peptic ulcers. The pathogenesis of idiopathic ulcer remains uncertain. These patients do not have nodularity in the gastric antrum or histologic evidence of gastritis. In idiopathic ulcers, acid suppression *alone* is the preferred effective treatment. Either PPIs or H_2 receptor antagonists may be used. Idiopathic ulcers have a high recurrence rate after discontinuing antisecretory therapy. These children should be followed closely, and if symptoms recur, antisecretory therapy should be restarted. It is also important to consider uncommon but possible conditions like Crohn disease, cytomegalovirus (CMV), and Zollinger-Ellison syndrome.

Secondary Ulcers

Aspirin and Other Nonsteroidal Antiinflammatory Drugs

NSAIDs produce mucosal injury by direct local irritation and by inhibiting cyclooxygenase (COX) and prostaglandin formation. Prostaglandins enhance mucosal resistance to injury; therefore a decrease in prostaglandin production increases the risk of mucosal injury. The severe erosive gastropathy produced by NSAIDs can ultimately result in bleeding ulcers or gastric perforations. The location of these ulcers is more common in the stomach than in the duodenum, and usually in the antrum. Use of COX-2-selective NSAIDs can also cause ulcerations in the GI tract.

“Stress” Ulceration

Stress ulceration usually occurs within 24 hr of onset of a critical illness in which physiologic stress is present. In many cases, the patients bleed from gastric erosions, rather than ulcers. Approximately 25% of the critically ill children in a pediatric intensive care unit have macroscopic evidence of gastric bleeding. Preterm and term infants in the neonatal intensive care unit can also develop gastric mucosal lesions and can present with upper GI bleeding or perforated ulcers. Although prophylactic measures to prevent stress ulcers in children are not standardized, drugs that inhibit gastric acid production are often used in the pediatric intensive care unit to reduce the rate of gastric erosions or ulcers.

Treatment

The management of acute hemorrhage includes serial monitoring of pulse, blood pressure, and hematocrit to ensure hemodynamic stability and avoid significant hypovolemia and anemia. Normal saline can be used to resuscitate a patient who has poor intravascular volume status. This can be followed by packed red blood cell transfusions for significant symptomatic anemia. The patient's blood should be typed and cross matched, and a large-bore catheter should be placed for fluid or blood replacement. A nasogastric tube should be placed to determine if the bleeding has stopped. Significant anemia can occur after fluid resuscitation as a consequence of equilibration or continued blood loss (which can also cause shock). In adults, a conservative threshold for transfusion (<7 g/dL vs. 9 g hemoglobin) resulted in improved survival and fewer episodes of rebleeding. Fortunately, most acute peptic ulcer bleeding stops spontaneously.

Patients with suspected peptic ulcer hemorrhage should receive high-dose intravenous (IV) PPI therapy, which lowers the risk of rebleeding. Some centers also use octreotide, which lowers splanchnic blood flow and gastric acid production; others use a prokinetic agent to improve endoscopic visualization.

Once the patient is hemodynamically stable, endoscopy within 24 hr is indicated to identify the source of bleeding and to treat a potential bleeding site. Methods used to achieve hemostasis include mechanical devices (clipping), injection therapy (diluted epinephrine 1:10,000), and thermal therapy (heater probe). Ulcer therapy has two goals: ulcer healing and elimination of the primary cause. Other important considerations are relief of symptoms and prevention of complications. The first-line drugs for the treatment of gastritis and peptic ulcer disease in children are PPIs and H_2 receptor antagonists (see Table 361.3). PPIs are more potent in ulcer healing. Cytoprotective agents can also be used as adjunct therapy if mucosal lesions are present. Antibiotics in combination with a PPI must be used for the treatment of *H. pylori* -associated ulcers (see Table 361.2 and Fig. 361.3).

H_2 -receptor antagonists (ranitidine, famotidine, nizatidine) competitively inhibit the binding of histamine at the H_2 subtype receptor of the gastric parietal cell. PPIs block the gastric parietal cell H^+ /K^+ –adenosine triphosphatase pump in a dose-dependent fashion, reducing basal and stimulated gastric acid secretion. Seven PPIs are available in the United States: omeprazole, lansoprazole, pantoprazole, esomeprazole, rabeprazole, dexlansoprazole, and omeprazole/sodium bicarbonate. Apart from the last 2, they are all approved in children and adolescents. They are well tolerated with only minor adverse effects, such as diarrhea (1–4%), headache (1–3%), and nausea (1%). When one considers therapeutic efficacy, the evidence suggests that all PPIs have comparable efficacy in treatment of peptic ulcer disease using standard doses and are superior to H_2 -receptor antagonists. PPIs have their greatest effect when given before a meal. Pantoprazole and esomeprazole are the only PPI available in IV form in United States. IV PPI should be used in acute upper GI bleeding. Twice-a-day IV PPI is as effective as continuous infusion and the current recommendation is to start with IV PPI and change to the oral form after evaluating their rebleeding risk at the time of endoscopy. Long-term PPI therapy may result in hypomagnesemia and the risk of QT prolongation, as well as vitamin B12 and iron deficiencies and small bowel bacterial overgrowth. Conflicting results from multiple studies suggest a possible increased risk of community-acquired and ventilator-associated pneumonias as well as *Clostridium difficile* infection.

Treatment of *Helicobacter pylori* –Related Peptic Ulcer Disease

In pediatrics, antibiotics and bismuth salts have been used in combination with PPIs to treat H. pylori infection (see Table 361.2). Eradication rates in children range from 68 to 92% when the dual or triple therapy is used for 4-6 wk. The ulcer healing rate ranges from 91 to 100%. Triple therapy yields a higher cure rate than dual therapy. The optimal regimen for the eradication of *H. pylori* infection in children has yet to be established, but the use of a PPI in combination with clarithromycin and amoxicillin or metronidazole for 2 wk is a well-tolerated and recommended triple therapy (see Table 361.2). Although children younger than 5 yr of age can become reinfected, the most common reason for treatment failure is poor compliance or antibiotic resistance. *H. pylori* has become more resistant to clarithromycin or metronidazole because of the extensive use of these antibiotics for other infections. In the case of resistant *H. pylori* infection, sequential treatment or rescue therapy with different antibiotics are acceptable options (see Fig. 361.3). The sequential treatment regimen is a 10-day treatment consisting of a PPI and amoxicillin (both twice daily) administered for the first 5 days followed by triple therapy consisting of a PPI, clarithromycin, and metronidazole for the remaining 5 days. Levofloxacin, rifabutin, or furazolidone can be used with amoxicillin and bismuth as a rescue therapy depending on the age of the patient. Knowledge of the community's *H. pylori* resistance pattern to clarithromycin or metronidazole might help choose the initial or rescue therapy; if it is unknown, one should assume resistance.

Surgical Therapy

Since the discovery of *H. pylori* and the availability of modern medical management, peptic ulcer disease requiring surgical treatment has become extremely rare. The indications for surgery remain uncontrolled bleeding, perforation, and obstruction. Since the introduction of H_2 -receptor antagonists, the recognition and treatment of *H. pylori,* and the use of PPIs, the incidence of surgery for bleeding and perforation has decreased dramatically.

361.1

Zollinger-Ellison Syndrome

Samra S. Blanchard, Steven J. Czinn

Zollinger-Ellison syndrome is a rare syndrome characterized by refractory, severe peptic ulcer disease caused by gastric hypersecretion due to the autonomous secretion of gastrin by a neuroendocrine tumor, a gastrinoma. Clinical presentations are similar to those of peptic ulcer disease with the addition of diarrhea. The diagnosis is suspected by the presence of recurrent, multiple, or atypically located ulcers. More than 98% of patients have elevated fasting gastrin levels. Zollinger-Ellison syndrome is common in patients with

multiple endocrine neoplasia 1 and rare with **neurofibromatosis** and **tuberous sclerosis** . Prompt and effective management of increased gastric acid secretion is essential in the management. **PPIs are the drug of choice due to their long duration of action and potency.** H_2 -receptor antagonists are also effective, but higher doses are required than those used in peptic ulcer disease.

CHAPTER 362

Inflammatory Bowel Disease

Ronen E. Stein, Robert N. Baldassano

The term *inflammatory bowel disease* (IBD) is used to represent 2 distinctive disorders of idiopathic chronic intestinal inflammation: Crohn disease and ulcerative colitis. Their respective etiologies are poorly understood, and both disorders are characterized by unpredictable exacerbations and remissions. The most common time of onset of IBD is during the preadolescent/adolescent era and young adulthood. A bimodal distribution has been shown with an early onset at 10-20 yr of age and a second, smaller peak at 50-80 yr of age. Approximately 25% of patients present before 20 yr of age. IBD may begin as early as the 1st yr of life, and an increased incidence among young children has been observed since the turn of the 20th century. Children with early-onset IBD are more likely to have colonic involvement. In developed countries, these disorders are the major causes of chronic intestinal inflammation in children beyond the first few yr of life. A third, less-common category, *indeterminate colitis* , represents approximately 10% of pediatric patients.

Genetic and environmental influences are involved in the pathogenesis of IBD. The prevalence of Crohn disease in the United States is much lower for Hispanics and Asians than for whites and blacks. The risk of IBD in family members of an affected person has been reported in the range of 7–30%; a child whose parents both have IBD has a >35% chance of acquiring the disorder. Relatives of a patient with ulcerative colitis have a greater risk of acquiring ulcerative colitis than Crohn disease, whereas relatives of a patient with Crohn disease have a greater risk of acquiring this disorder; the 2 diseases can occur in the same family. The risk of occurrence of IBD among relatives of patients with Crohn disease is somewhat greater than for patients with ulcerative colitis.

The importance of genetic factors in the development of IBD is noted by a higher chance that both twins will be affected if they are monozygotic rather than dizygotic. The concordance rate in twins is higher in Crohn disease (36%) than in ulcerative colitis (16%). Genetic disorders that have been associated with IBD include Turner syndrome, the Hermansky-Pudlak syndrome, glycogen storage disease type Ib, and various immunodeficiency disorders. In 2001, the first IBD gene, *NOD2*, was identified through association mapping. A few months later, the IBD 5 risk haplotype was identified. These early successes were followed by a long period without notable risk factor discovery. Since 2006, the year of the first published genome-wide array study on IBD, there has been an exponential growth in the set of validated genetic risk factors for IBD (Table 362.1).

Table 362.1

Selection of Most Important Genes Associated With Inflammatory Bowel Disease and the Most Commonly Associated Physiological Functions and Pathways

	GENE NAME	ASSOCIATED DISEASE	GENE FUNCTION AND ASSOCIATED PATHWAYS	PHYSIOLOGICAL FUNCTION
NOD2	Nucleotide-binding oligomerization domain-containing protein 2	Crohn disease	Bacterial recognition and response, NFκB activation and autophagy and apoptosis	Innate mucosal defense
IL10	Interleukin 10	Crohn disease	Antiinflammatory cytokine, NFκB inhibition, JAK-STAT regulation	Immune tolerance
IL10RA	Interleukin 10 receptor A	Crohn disease	Antiinflammatory cytokine receptor, NFκB inhibition, JAK-STAT regulation	Immune tolerance
IL10RB	Interleukin 10 receptor B	Crohn disease	Antiinflammatory cytokine receptor, NFκB inhibition, JAK-STAT regulation	Immune tolerance
IL23R	Interleukin 23 receptor	Crohn disease and ulcerative colitis	Immune regulation, proinflammatory pathways—JAK-STAT regulation	Interleukin 23/T helper 17
TKY2	Tyrosine kinase 2	Crohn disease and ulcerative colitis	Inflammatory pathway signaling (interleukin 10 and 6 etc) through intracellular activity	Interleukin 23/T helper 17
IRGM	Immunity related GTPase M	Crohn disease	Autophagy and apoptosis in cells infected with bacteria	Autophagy
ATG16L1	Autophagy related 16 like 1	Crohn disease	Autophagy and apoptotic pathways	Autophagy
SLC22A4	Solute carrier family 22 member 4	Crohn disease	Cellular antioxidant transporter	Solute transporters
CCL2	C-C motif chemokine ligand 2	Crohn disease	Cytokine involved in chemotaxis for monocytes	Immune cell recruitment
CARD9	Caspase recruitment domain family member 9	Crohn disease and ulcerative colitis	Apoptosis regulation and NFκB pathway activation	Oxidative stress

IL2	Interleukin 2	Ulcerative colitis	Cytokine involved in immune cell activation	T-cell regulation
MUC19	Mucin 19	Crohn disease and ulcerative colitis	Gel-forming mucin protein	Epithelial barrier

JAK-STAT, Janus kinase-signal transducers and activators of transcription; *NFκB,* nuclear factor κ-light chain enhancer of activated B cells.

From Ashton JJ, Ennis S, Beattie RM: Early-onset paediatric inflammatory bowel disease, *Lancet* 1:147–158, 2017, Table 1, p 148.

A perinuclear antineutrophil cytoplasmic antibody is found in approximately 70% of patients with ulcerative colitis compared with <20% of those with Crohn disease and is believed to represent a marker of genetically controlled immunoregulatory disturbance. Approximately 55% of those with Crohn disease are positive for anti–*Saccharomyces cerevisiae* antibody. Since the importance of these were first described, multiple other serologic and immune markers of Crohn disease and ulcerative colitis have been recognized.

IBD is caused by dysregulated or inappropriate immune response to environmental factors in a genetically susceptible host. An abnormality in intestinal mucosal immunoregulation may be of primary importance in the pathogenesis of IBD, involving activation of cytokines, triggering a cascade of reactions that results in bowel inflammation. These cytokines are recognized as known or potential targets for IBD therapies.

Multiple environmental factors are recognized to be involved in the pathogenesis of IBD, none more critical than the gut microbiota. The increasing incidence of IBD over time is likely in part attributable to alterations in the microbiome. Evidence includes association between IBD and residence in or immigration to industrialized nations, a *Western diet* , increased use of antibiotics at a younger age, high rates of vaccination, and less exposure to microbes at a young age. While gut microbes likely play an important role in the pathogenesis of IBD, the exact mechanism needs to be elucidated further. Some environmental factors are disease specific; for example, cigarette smoking is a risk factor for Crohn disease but paradoxically protects against ulcerative colitis.

It is usually possible to distinguish between ulcerative colitis and Crohn disease by the clinical presentation and radiologic, endoscopic, and histopathologic findings (Table 362.2). It is not possible to make a definitive diagnosis in approximately 10% of patients with chronic colitis; this disorder is called *indeterminate colitis*. Occasionally, a child initially believed to have ulcerative colitis on the basis of clinical findings is subsequently found to have Crohn colitis. This is particularly true for the youngest patients, because Crohn disease in this patient population can more often manifest as exclusively colonic inflammation, mimicking ulcerative colitis. The medical treatments of Crohn disease and ulcerative colitis overlap.

Table 362.2

Comparison of Crohn Disease and Ulcerative Colitis

FEATURE	CROHN DISEASE	ULCERATIVE COLITIS
Rectal bleeding	Sometimes	Common
Diarrhea, mucus, pus	Variable	Common
Abdominal pain	Common	Variable
Abdominal mass	Common	Not present
Growth failure	Common	Variable
Perianal disease	Common	Rare
Rectal involvement	Occasional	Universal
Pyoderma gangrenosum	Rare	Present
Erythema nodosum	Common	Less common
Mouth ulceration	Common	Rare
Thrombosis	Less common	Present
Colonic disease	50–75%	100%
Ileal disease	Common	None except backwash ileitis
Stomach–esophageal disease	More common	Chronic gastritis can be seen
Strictures	Common	Rare
Fissures	Common	Rare
Fistulas	Common	Rare
Toxic megacolon	None	Present
Sclerosing cholangitis	Less common	Present
Risk for intestinal cancers	Increased	Greatly increased
Discontinuous (skip) lesions	Common	Not present
Transmural involvement	Common	Unusual
Crypt abscesses	Less common	Common
Granulomas	Common	None
Linear ulcerations	Uncommon	Common
Perinuclear antineutrophil cytoplasmic antibody–positive	<20%	70%

Extraintestinal manifestations occur slightly more commonly with Crohn disease than with ulcerative colitis (Table 362.3). Growth retardation is seen in 15–40% of children with Crohn disease at diagnosis. Decrease in height velocity occurs in nearly 90% of patients with Crohn disease diagnosed in childhood or adolescence. Of the extraintestinal manifestations that occur with IBD, joint, skin, eye, mouth, and hepatobiliary involvement tend to be associated with colitis, whether ulcerative or Crohn. The presence of some manifestations, such as peripheral arthritis, erythema nodosum, and anemia, correlates with activity of the bowel disease. Activity of pyoderma gangrenosum correlates less well with activity of the bowel disease, whereas sclerosing cholangitis, ankylosing spondylitis, and sacroiliitis do not correlate with intestinal disease. Arthritis occurs in 3 patterns: migratory peripheral arthritis involving primarily large joints, ankylosing spondylitis, and sacroiliitis. The peripheral arthritis of IBD tends to be nondestructive. Ankylosing spondylitis begins in the 3rd decade and occurs most commonly in patients with ulcerative colitis who have the human leukocyte antigen B27 phenotype. Symptoms include low back pain and morning stiffness; back, hips, shoulders, and sacroiliac joints are typically affected. Isolated sacroiliitis is usually asymptomatic but is common when a careful search is performed. Among the skin manifestations, erythema nodosum is most common. Patients with erythema nodosum or pyoderma gangrenosum have a high likelihood of having arthritis as well. Glomerulonephritis, uveitis, and a hypercoagulable state are other rare manifestations that occur in childhood. Cerebral thromboembolic disease has been described in children with IBD.

Table 362.3

Extraintestinal Complications of Inflammatory Bowel Disease

MUSCULOSKELETAL
Peripheral arthritis Granulomatous monoarthritis Granulomatous synovitis Rheumatoid arthritis Sacroiliitis Ankylosing spondylitis Digital clubbing and hypertrophic osteoarthropathy Periostitis Osteoporosis, osteomalacia Rhabdomyolysis Pelvic osteomyelitis Recurrent multifocal osteomyelitis Relapsing polychondritis
SKIN AND MUCOUS MEMBRANES
Oral lesions Cheilitis Aphthous stomatitis, glossitis Granulomatous oral Crohn disease Inflammatory hyperplasia fissures and cobblestone mucosa Peristomatitis vegetans
DERMATOLOGIC
Erythema nodosum Pyoderma gangrenosum Sweet syndrome Metastatic Crohn disease Psoriasis

Epidermolysis bullosa acquisita Perianal skin tags Polyarteritis nodosa Melanoma and nonmelanoma skin cancers
OCULAR
Conjunctivitis Uveitis, iritis Episcleritis Scleritis Retrobulbar neuritis Chorioretinitis with retinal detachment Crohn keratopathy Posterior segment abnormalities Retinal vascular disease
BRONCHOPULMONARY
Chronic bronchitis with bronchiectasis Chronic bronchitis with neutrophilic infiltrates Fibrosing alveolitis Pulmonary vasculitis Small airway disease and bronchiolitis obliterans Eosinophilic lung disease Granulomatous lung disease Tracheal obstruction
CARDIAC
Pleuropericarditis Cardiomyopathy Endocarditis Myocarditis
MALNUTRITION
Decreased intake of food • Inflammatory bowel disease • Dietary restriction Malabsorption • Inflammatory bowel disease • Bowel resection • Bile salt depletion • Bacterial overgrowth
Intestinal losses • Electrolytes • Minerals • Nutrients Increased caloric needs • Inflammation • Fever
HEMATOLOGIC/ONCOLOGIC
Anemia: iron deficiency (blood loss) Vitamin B12 (ileal disease or resection, bacterial overgrowth, folate deficiency) Anemia of chronic inflammation Anaphylactoid purpura (Crohn disease) Hyposplenism Autoimmune hemolytic anemia Coagulation abnormalities Increased activation of coagulation factors Activated fibrinolysis Anticardiolipin antibody

Increased risk of arterial and venous thrombosis with cerebrovascular stroke, myocardial infarction, peripheral arterial, and venous occlusions Systemic lymphoma (nonenteric)
RENAL AND GENITOURINARY
Metabolic • Urinary crystal formation (nephrolithiasis, uric acid, oxylate) Hypokalemic nephropathy Inflammation • Retroperitoneal abscess • Fibrosis with ureteral obstruction • Fistula formation Glomerulitis Membrane nephritis Renal amyloidosis, nephrotic syndrome
PANCREATITIS
Secondary to medications (sulfasalazine, 6-mercaptopurine, azathioprine, parenteral nutrition) Ampullary Crohn disease Granulomatous pancreatitis Decreased pancreatic exocrine function Sclerosing cholangitis with pancreatitis
HEPATOBILIARY
Primary sclerosing cholangitis Small duct primary sclerosing cholangitis (pericholangitis) Carcinoma of the bile ducts Fatty infiltration of the liver Cholelithiasis Autoimmune hepatitis
ENDOCRINE AND METABOLIC
Growth failure, delayed sexual maturation Thyroiditis Osteoporosis, osteomalacia
NEUROLOGIC
Peripheral neuropathy Meningitis Vestibular dysfunction Pseudotumor cerebri Cerebral vasculitis Migraine

362.1

Chronic Ulcerative Colitis

Ronen E. Stein, Robert N. Baldassano

Keywords

incidence
extraintestinal manifestations
fulminant colitis
5-aminosalicylate
immunomodulator
biologic corticosteroid
surgery

Ulcerative colitis, an idiopathic chronic inflammatory disorder, is localized to the colon and spares the upper gastrointestinal (GI) tract. Disease usually begins in the rectum and extends proximally for a variable distance. When it is localized to the rectum, the disease is ulcerative proctitis, whereas disease involving the entire colon is pancolitis. Approximately 50–80% of pediatric patients have extensive colitis, and adults more commonly have distal disease. Ulcerative *proctitis* is less likely to be associated with systemic manifestations, although it may be less responsive to treatment than more-diffuse disease. Approximately 30% of children who present with ulcerative proctitis experience proximal spread of the disease. Ulcerative colitis has rarely been noted to present in infancy. Dietary protein intolerance can easily be misdiagnosed as ulcerative colitis in this age group. Dietary protein intolerance (cow's milk protein) is a transient disorder; symptoms are directly associated with the intake of the offending antigen.

The incidence of ulcerative colitis has increased but not to the extent of the increase in Crohn disease; incidence varies with country of origin. The age-specific incidence rates of pediatric ulcerative colitis in North America is 2/100,000 population. The prevalence of ulcerative colitis in northern European countries and the United States varies from 100 to 200/100,000 population. Men are slightly more likely to acquire ulcerative colitis than are women; the reverse is true for Crohn disease.

Clinical Manifestations

Blood, mucus, and pus in the stool as well as diarrhea are the typical presentation of ulcerative colitis. Constipation may be observed in those with proctitis. Symptoms such as tenesmus, urgency, cramping abdominal pain (especially with bowel movements), and nocturnal bowel movements are common. The mode of onset ranges from insidious with gradual progression of symptoms to acute and fulminant (Table 362.4 and Figs. 362.1 and 362.2). Fever, severe anemia, hypoalbuminemia, leukocytosis, and more than 5 bloody stools per day for 5 days define **fulminant colitis** . Chronicity is an important part of the diagnosis; it is difficult to know if a patient has a subacute, transient infectious colitis or ulcerative colitis when a child has had 1-2 wk of symptoms. Symptoms beyond this duration often prove to be secondary to IBD. Anorexia, weight loss, and growth failure may be present, although these complications are more typical of Crohn disease.

Table 362.4

Montreal Classification of Extent and Severity of Ulcerative Colitis

- E1 (proctitis): inflammation limited to the rectum
- E2 (left-sided; distal): inflammation limited to the splenic flexure
- E3 (pancolitis): inflammation extends to the proximal splenic flexure
- S0 (remission): no symptoms
- S1 (mild): 4 or less stools per day (with or without blood), absence of systemic symptoms, normal inflammatory markers
- S2 (moderate): 4 stools per day, minimum signs of systemic symptoms
- S3 (severe): 6 or more bloody stools per day, pulse rate of ≥90 beats/min, temperature ≥37.5°C (99.5°F), hemoglobin concentration <105 g/L, erythrocyte sedimentation rate ≥30 mm/hr

E, extent; *S,* severity.

FIG. 362.2 Ulcerative colitis phenotypes by Montreal Classification. Symptoms and treatment strategy can differ based on extent of disease. (Illustration by Jill Gregory. Printed with permission of ©Mount Sinai Health System.)

Extraintestinal manifestations that tend to occur more commonly with ulcerative colitis than with Crohn disease include pyoderma gangrenosum, sclerosing cholangitis, chronic active hepatitis, and ankylosing spondylitis. Iron deficiency can result from chronic blood loss as well as decreased intake. Folate deficiency is unusual but may be accentuated in children treated with sulfasalazine, which interferes with folate absorption. Chronic inflammation and the elaboration of a variety of inflammatory cytokines can interfere with erythropoiesis and result in the anemia of chronic disease. Secondary amenorrhea is common during periods of active disease.

The clinical course of ulcerative colitis is marked by remission and relapse, often without apparent explanation. After treatment of initial symptoms, approximately 5% of children with ulcerative colitis have a prolonged remission (longer than 3 yr). Approximately 25% of children presenting with severe ulcerative colitis require colectomy within 5 yr of diagnosis, compared with only 5% of those presenting with mild disease. It is important to consider the possibility of enteric infection with recurrent symptoms; these infections can mimic a flare-up or actually provoke a recurrence. The use of nonsteroidal antiinflammatory drugs is considered by some to predispose to exacerbation.

It is generally believed that the risk of colon cancer begins to increase after 8-10 yr of disease and can then increase by 0.5–1% per yr. The risk is delayed by approximately 10 yr in patients with colitis limited to the descending colon. Proctitis alone is associated with virtually no increase in risk over the general population. Because colon cancer is usually preceded by changes of mucosal dysplasia, it is recommended that patients who have had ulcerative colitis for longer than 8-10 yr be screened with colonoscopy and biopsies every 1-2 yr. Although this is the current standard of practice, it is not clear if morbidity and mortality are changed by this approach. Two competing concerns about this plan of management remain unresolved. The original studies may have overestimated the risk of colon cancer and, therefore, the need for surveillance has been overemphasized; and screening for dysplasia might not be adequate for preventing colon cancer in ulcerative colitis if some cancers are not preceded by dysplasia.

Differential Diagnosis

The major conditions to exclude are infectious colitis, allergic colitis, and Crohn colitis. Every child with a new diagnosis of ulcerative colitis should have stool cultured for enteric pathogens, stool evaluation for *Clostridium difficile*, ova and parasites, and perhaps serologic studies for amebae (Table 362.5). Cytomegalovirus infection can mimic ulcerative colitis or be associated with an exacerbation of existing disease, usually in immunocompromised patients. The most difficult distinction is from Crohn disease because the colitis of Crohn disease can initially appear identical to that of ulcerative colitis, particularly in younger children. The gross appearance of the colitis or development of small bowel disease eventually leads to the correct diagnosis; this can occur years after the initial presentation.

Table 362.5

Infectious Agents Mimicking Inflammatory Bowel Disease

AGENT	MANIFESTATIONS	DIAGNOSIS	COMMENTS
BACTERIAL			
Campylobacter jejuni	Acute diarrhea, fever, fecal blood, and leukocytes	Culture	Common in adolescents, may relapse
Yersinia enterocolitica	Acute → chronic diarrhea, right lower quadrant pain, mesenteric adenitis–pseudoappendicitis, fecal blood, and leukocytes Extraintestinal manifestations, mimics Crohn disease	Culture	Common in adolescents as fever of unknown origin, weight loss, abdominal pain
Clostridium difficile	Postantibiotic onset, watery → bloody diarrhea, pseudomembrane on sigmoidoscopy	Cytotoxin assay	May be nosocomial Toxic megacolon possible
Escherichia coli O157:H7	Colitis, fecal blood, abdominal pain	Culture and typing	Hemolytic uremic syndrome
Salmonella	Watery → bloody diarrhea, foodborne, fecal leukocytes, fever, pain, cramps	Culture	Usually acute
Shigella	Watery → bloody diarrhea, fecal leukocytes, fever, pain, cramps	Culture	Dysentery symptoms
Edwardsiella tarda	Bloody diarrhea, cramps	Culture	Ulceration on endoscopy
Aeromonas hydrophila	Cramps, diarrhea, fecal blood	Culture	May be chronic Contaminated drinking water
Plesiomonas shigelloides	Diarrhea, cramps	Culture	Shellfish source
Tuberculosis	Rarely bovine, now Mycobacterium tuberculosis Ileocecal area, fistula formation	Culture, purified protein derivative, biopsy	Can mimic Crohn disease
PARASITES			
Entamoeba histolytica	Acute bloody diarrhea and liver abscess, colic	Trophozoite in stool, colonic mucosal flask ulceration, serologic tests	Travel to endemic area
Giardia lamblia	Foul-smelling, watery diarrhea, cramps, flatulence, weight loss; no colonic involvement	“Owl”-like trophozoite and cysts in stool; rarely duodenal intubation	May be chronic
AIDS-ASSOCIATED ENTEROPATHY			
Cryptosporidium	Chronic diarrhea, weight loss	Stool microscopy	Mucosal findings not like inflammatory bowel disease

Isospora belli	As in Cryptosporidium		Tropical location
Cytomegalovirus	Colonic ulceration, pain, bloody diarrhea	Culture, biopsy	More common when on immunosuppressive medications

At the onset, the colitis of hemolytic uremic syndrome may be identical to that of early ulcerative colitis. Ultimately, signs of microangiopathic hemolysis (the presence of schistocytes on blood smear), thrombocytopenia, and subsequent renal failure should confirm the diagnosis of hemolytic-uremic syndrome. Although Henoch-Schönlein purpura can manifest as abdominal pain and bloody stools, it is not usually associated with colitis. Behçet disease can be distinguished by its typical features (see Chapter 186). Other considerations are radiation proctitis, viral colitis in immunocompromised patients, and ischemic colitis (Table 362.6). In infancy, dietary protein intolerance can be confused with ulcerative colitis, although the former is a transient problem that resolves on removal of the offending protein, and ulcerative colitis is extremely rare in this age group. Hirschsprung disease can produce an enterocolitis before or within months after surgical correction; this is unlikely to be confused with ulcerative colitis.

Diagnosis

The diagnosis of ulcerative colitis or ulcerative proctitis requires a typical presentation in the absence of an identifiable specific cause (see Tables 362.5 and 362.6) and typical endoscopic and histologic findings (see Tables 362.2 and 362.4). One should be hesitant to make a diagnosis of ulcerative colitis in a child who has experienced symptoms for <2-3 wk until infection has been excluded. When the diagnosis is suspected in a child with subacute symptoms, the physician should make a firm diagnosis only when there is evidence of chronicity on colonic biopsy. Laboratory studies can demonstrate evidence of anemia (either iron deficiency or the anemia of chronic disease) or hypoalbuminemia. Although the sedimentation rate and C-reactive protein are often elevated, they may be normal even with fulminant colitis. An elevated white blood cell count is usually seen only with more-severe colitis. Fecal calprotectin levels are usually elevated and are increasingly recognized to be a more sensitive and specific marker of GI inflammation than typical laboratory parameters. Barium enema is suggestive but not diagnostic of acute (Fig. 362.3) or chronic burned-out disease (Fig. 362.4).

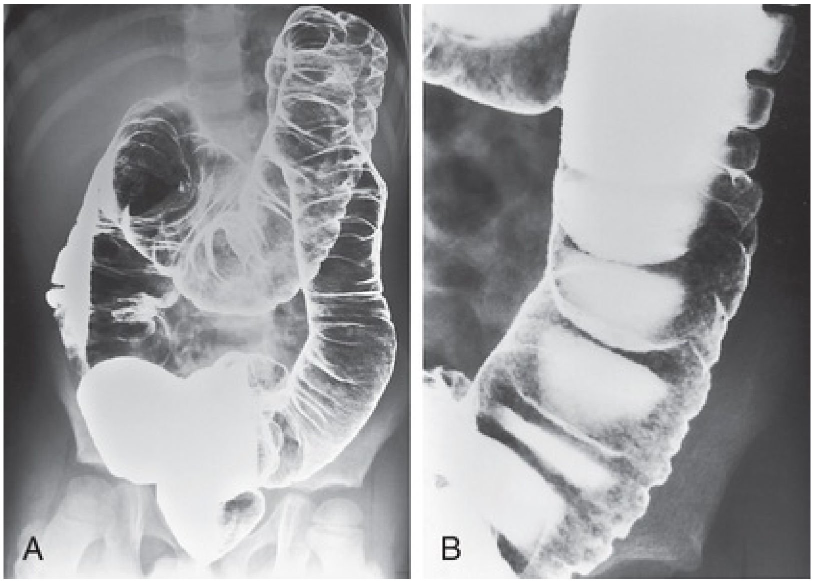

FIG. 362.3 Ulcerative colitis. Double-contrast barium enema in a 5 yr old boy who had had intermittent intestinal and extraintestinal symptoms since the age of 3 yr. A, Small ulcerations are distributed uniformly about the colonic circumference and continuously from the rectum to the proximal transverse colon. This pattern of involvement is typical of ulcerative colitis. B, In this coned view of the sigmoid in the same patient, small ulcerations are represented by fine spiculation of the colonic contour in tangent and by fine stippling of the colon surface en face. (From Hoffman AD: The child with diarrhea. In Hilton SW, Edwards DK, editors: *Practical pediatric radiology,* ed 2, Philadelphia, 1994, WB Saunders, p 260.)

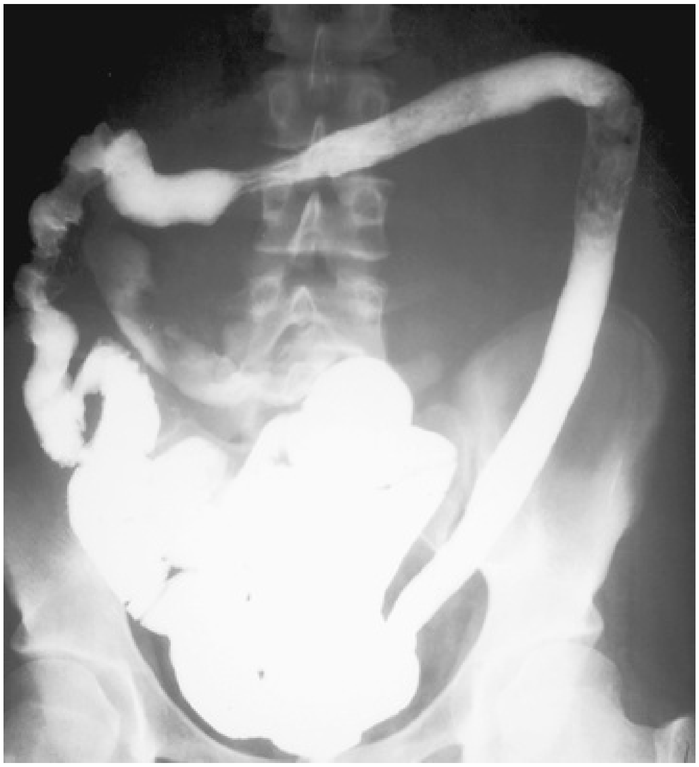

FIG. 362.4 Ulcerative colitis: late changes. This single-contrast barium enema shows the late changes of ulcerative colitis in a 15 yr old girl. The colon is featureless, reduced in caliber, and shortened. Dilation of the terminal ileum (backwash ileitis) is present. (From The child with diarrhea. In Hoffman AD, Hilton SW, Edwards DK, editors: *Practical pediatric radiology,* ed 2, Philadelphia, 1994, WB Saunders, p 262.)

The diagnosis of ulcerative colitis must be confirmed by endoscopic and histologic examination of the colon (see Fig. 362.1). Classically, disease starts in the rectum with a gross appearance characterized by erythema, edema, loss of vascular pattern, granularity, and friability. There may be a *cutoff* demarcating the margin between inflammation and normal colon, or the entire colon may be involved. There may be some variability in the intensity of inflammation even in those areas involved. Flexible sigmoidoscopy can confirm the diagnosis; colonoscopy can evaluate the extent of disease and rule out Crohn colitis. A colonoscopy should not be performed when fulminant colitis is suspected because of the risk of provoking *toxic megacolon* or causing a perforation during the procedure. The degree of colitis can be evaluated by the gross appearance of the mucosa. One does not generally see discrete ulcers, which would be more suggestive of Crohn colitis. The endoscopic findings of ulcerative colitis result from microulcers, which give the appearance of a diffuse abnormality. With very severe chronic colitis, pseudopolyps may be seen. Biopsy of involved bowel demonstrates evidence of acute and chronic mucosal inflammation. Typical histologic findings are cryptitis, crypt abscesses, separation of crypts by inflammatory cells, foci of acute inflammatory cells, edema, mucus depletion, and branching of crypts. The last finding is not seen in infectious colitis. Granulomas, fissures, or full-thickness involvement of the bowel wall (usually on surgical rather than endoscopic biopsy) suggest Crohn disease.

Perianal disease , except for mild local irritation or anal fissures associated with diarrhea, should make the clinician think of Crohn disease. Plain radiographs of the abdomen might demonstrate loss of haustral markings in an air-filled colon or marked dilation with toxic megacolon. With severe colitis, the colon may become dilated; a diameter of >6 cm, determined radiographically, in an adult suggests toxic megacolon. If it is necessary to examine the colon radiologically in a child with severe colitis (to evaluate the extent of involvement or to try to rule out Crohn disease), it is sometimes helpful to perform an upper GI contrast series with small bowel follow-through and then look at delayed films of the colon. A barium enema is contraindicated in the setting of a potential toxic megacolon.

Treatment

Medical

A medical *cure* for ulcerative colitis is not available; treatment is aimed at controlling symptoms and reducing the risk of recurrence, with a secondary goal of minimizing steroid exposure. The intensity of treatment varies with the severity of the symptoms.

The first drug class to be used with mild or mild-to-moderate colitis is an aminosalicylate. Sulfasalazine is composed of a sulfur moiety linked to the active ingredient 5-aminosalicylate (5-ASA). This linkage prevents the premature absorption of the medication in the upper GI tract, allowing it to reach the colon, where the 2 components are separated by bacterial cleavage. The dose of sulfasalazine is 30-100 mg/kg/24 hr (divided into 2-4 doses). Generally, the dose is not more than 2-4 g/24 hr. Hypersensitivity to the sulfa component is the major side effect of sulfasalazine and occurs in 10–20% of patients. Because of poor tolerance, sulfasalazine is used less commonly than other, better tolerated 5-ASA preparations (mesalamine, 50-100 mg/kg/day; balsalazide 2.25-6.75 g/day). Sulfasalazine and the 5-ASA preparations effectively treat active ulcerative colitis and prevent recurrence. It is recommended that the medication be continued even when the disorder is in remission. These medications might also modestly decrease the lifetime risk of colon cancer.

Approximately 5% of patients have an *allergic reaction* to 5-ASA, manifesting as rash, fever, and bloody diarrhea, which can be difficult to distinguish from symptoms of a flare of ulcerative colitis. 5-ASA can also be given in enema or suppository form and is especially useful for proctitis. Hydrocortisone enemas are used to treat proctitis as well, but they are probably not as effective. A combination of oral and rectal 5-ASA as well as monotherapy with rectal preparation has been shown to be more effective than just oral 5-ASA for distal colitis. Extended release budesonide may also induce remission in patients with mild-to-moderate ulcerative colitis.

Probiotics are effective in adults for maintenance of remission for ulcerative colitis, although they do not induce remission during an active flare. The most promising role for probiotics has been to prevent pouchitis, a common complication following colectomy and ileal–pouch anal anastomosis surgery.

Children with moderate to severe pancolitis or colitis that is unresponsive to 5-ASA therapy should be treated with corticosteroids, most commonly prednisone. The usual starting dose of prednisone is 1-2 mg/kg/24 hr (40-60 mg maximum dose). This medication can be given once daily. With severe colitis, the dose can be divided twice daily and can be given intravenously. Steroids are considered an effective medication for acute flares, but they are not appropriate maintenance medications because of loss of effect and side effects, including growth retardation, adrenal suppression, cataracts, osteopenia, aseptic necrosis of the head of the femur, glucose intolerance, risk of infection, mood disturbance, and cosmetic effects.

For a hospitalized patient with persistence of symptoms despite intravenous steroid treatment for 3-5 days, escalation of therapy or surgical options should be considered. The validated pediatric ulcerative colitis activity index can be used to help determine current disease severity based on clinical factors and help determine who is more likely to respond to steroids and those who will likely require escalation of therapy (Table 362.7).

Table 362.7

Pediatric Ulcerative Colitis Activity Index

ITEM	POINTS

(1) Abdominal Pain	
No pain	0
Pain can be ignored	5
Pain cannot be ignored	10
(2) Rectal Bleeding	
None	0
Small amount only, in <50% of stools	10
Small amount with most stools	20
Large amount (>50% of the stool content)	30
(3) Stool Consistency of Most Stools	
Formed	0
Partially formed	5
Completely unformed	10
(4) Number of Stools Per 24 hr	
0-2	0
3-5	5

(5) Nocturnal Stools (Any Episode Causing Wakening)	
No	0
Yes	10
(6) Activity Level	
No limitation of activity	0
Occasional limitation of activity	5
Severe restricted activity	10
Sum of Index (0-85)	

With medical management, most children are in remission within 3 mo; however, 5–10% continue to have symptoms unresponsive to treatment beyond 6 mo. Many children with disease requiring frequent corticosteroid therapy are started on immunomodulators such as azathioprine (2.0-2.5 mg/kg/day) or 6-mercaptopurine (1-1.5 mg/kg/day). Uncontrolled data suggest a corticosteroid-sparing effect in many treated patients. This is not an appropriate choice in a steroid nonresponsive patient with acute severe colitis because of longer onset of action. Lymphoproliferative disorders are associated with thiopurine use. Cyclosporine, which is associated with improvement in some children with severe or fulminant colitis, is rarely used owing to its high side-effect profile, its inability to change the natural history of disease, and the increasing use of infliximab, a chimeric monoclonal antibody to tumor necrosis factor (TNF)-α, which is also effective in cases of fulminant colitis. Infliximab is effective for induction and maintenance therapy in children and adults with moderate to severe disease. TNF blocking agents are associated with an increased risk of infection (particularly tuberculosis) and malignancies (lymphoma, leukemia). Adalimumab is also approved for treatment of moderate to severe ulcerative colitis in adults. Vedolizumab, a humanized monoclonal antibody that inhibits adhesion and migration of leukocytes into the GI tract, is approved for the treatment of ulcerative colitis in adults. Tofacitinib, an oral Janus kinase inhibitor, is also approved for treatment of moderate to severe adult ulcerative colitis. A specific combination of 3-4 wide-spectrum oral antibiotics given over 2-3 wk may be effective in treating severe pediatric ulcerative colitis refractory to other therapies but is being further studied in children.

Surgical

Colectomy is performed for intractable disease, complications of therapy, and fulminant disease that is unresponsive to medical management. No clear benefit of the use of total parenteral nutrition or a continuous enteral elemental diet in the treatment of severe ulcerative colitis has been noted. Nevertheless, parenteral nutrition is used if oral intake is insufficient so that the patient will be nutritionally ready for surgery if medical management fails. With any medical treatment for ulcerative colitis, the clinician should always weigh the risk of the medication or therapy against the fact that colitis can be successfully treated surgically.

Surgical treatment for intractable or fulminant colitis is total colectomy. The optimal approach is to combine colectomy with an endorectal pull-through, where a segment of distal rectum is retained and the mucosa is stripped from this region. The distal ileum is pulled down and sutured at the internal anus with a J pouch created from ileum immediately above the rectal cuff. This procedure allows the child to maintain continence. Commonly, a temporary ileostomy is created to protect the delicate anastomosis between the sleeve of the pouch and the rectum. The ileostomy is usually closed within several months, restoring bowel continuity. At that time, stool frequency is often increased but may be improved with loperamide. The major complication of this operation is *pouchitis,* which is a chronic inflammatory reaction in the pouch, leading to bloody diarrhea, abdominal pain, and, occasionally, low-grade fever. The cause of this complication is unknown, although it is more common when the ileal pouch has been constructed for ulcerative colitis than for other indications (e.g., familial polyposis coli). Pouchitis is seen in 30–40% of patients who had ulcerative colitis. It commonly responds to treatment with oral metronidazole or ciprofloxacin. Probiotics have also been shown to decrease the rate of pouchitis as well as the recurrence of pouchitis following antibiotic therapy.

Support

Psychosocial support is an important part of therapy for this disorder. This may include adequate discussion of the disease manifestations and management between patient and physician, psychologic counseling for the child when necessary, and family support from a social worker or family counselor. Patient support groups have proved helpful for some families. Children with ulcerative colitis should be encouraged to participate fully in age-appropriate activities; however, activity may need to be reduced during periods of disease exacerbation.

Prognosis

The course of ulcerative colitis is marked by remissions and exacerbations. Most children with this disorder respond initially to medical management. Many children with mild manifestations continue to respond well to medical management and may stay in remission on a prophylactic 5-ASA preparation for long periods. An occasional child with mild onset, however, experiences intractable symptoms later. Beyond the 1st decade of disease, the risk of development of colon cancer begins to increase rapidly. The risk of colon cancer may be diminished with surveillance colonoscopies beginning after 8-10 yr of disease. Detection of significant dysplasia on biopsy would prompt colectomy.

surgery

Crohn disease, an idiopathic, chronic inflammatory disorder of the bowel, involves any region of the alimentary tract from the mouth to the anus. Although there are many similarities between ulcerative colitis and Crohn disease, there are also major differences in the clinical course and distribution of the disease in the GI tract (see Table 362.2). The inflammatory process tends to be eccentric and segmental, often with skip areas (normal regions of bowel between inflamed areas). Although inflammation in ulcerative colitis is limited to the mucosa (except in toxic megacolon), GI involvement in Crohn disease is often *transmural* .

Compared to adult-onset disease, pediatric Crohn disease is more likely to have extensive anatomic involvement. At initial presentation, more than 50% of patients have disease that involves ileum and colon (ileocolitis), 20% have exclusively colonic disease, and upper GI involvement (esophagus, stomach, duodenum) is seen in up to 30% of children. Isolated small bowel disease is much less common in the pediatric population compared to adults. Isolated colonic disease is common in children younger than 8 yr of age and may be indistinguishable from ulcerative colitis. Anatomic location of disease tends to extend over time in children.

Crohn disease tends to have a bimodal age distribution, with the first peak beginning in the teenage years. The incidence of Crohn disease has been increasing. In the United States, the reported incidence of pediatric Crohn disease is 4.56/100,000 and the pediatric prevalence is 43/100,000 children.

Clinical Manifestations

Crohn disease can be characterized as inflammatory, stricturing, or penetrating. Patients with small bowel disease are more likely to have an obstructive pattern (most commonly with right lower quadrant pain) characterized by fibrostenosis, and those with colonic disease are more likely to have symptoms resulting from inflammation (diarrhea, bleeding, cramping). Disease phenotypes often change as duration of disease lengthens (inflammatory becomes structuring and/or penetrating) (Figs. 362.5 and 362.6).

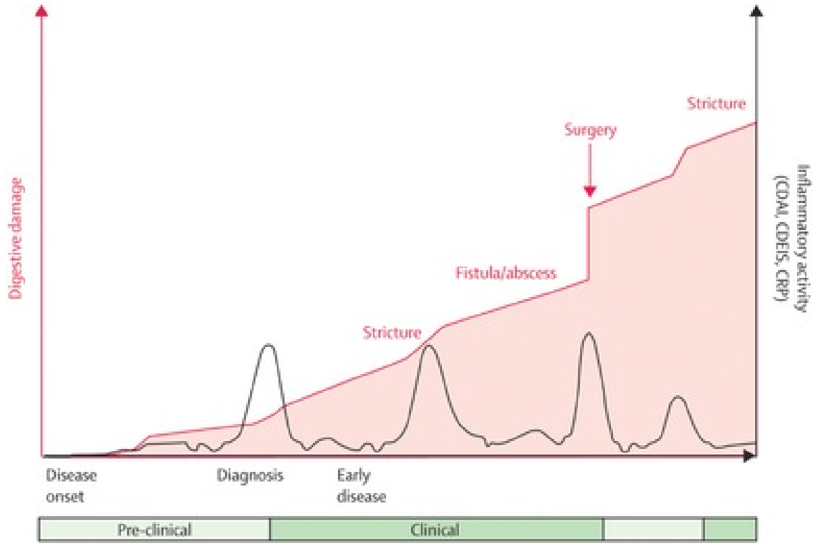

FIG. 362.5 The Lémann Score. Exemplary visualization of the Lémann score, a new technique to score and study intestinal damage in Crohn

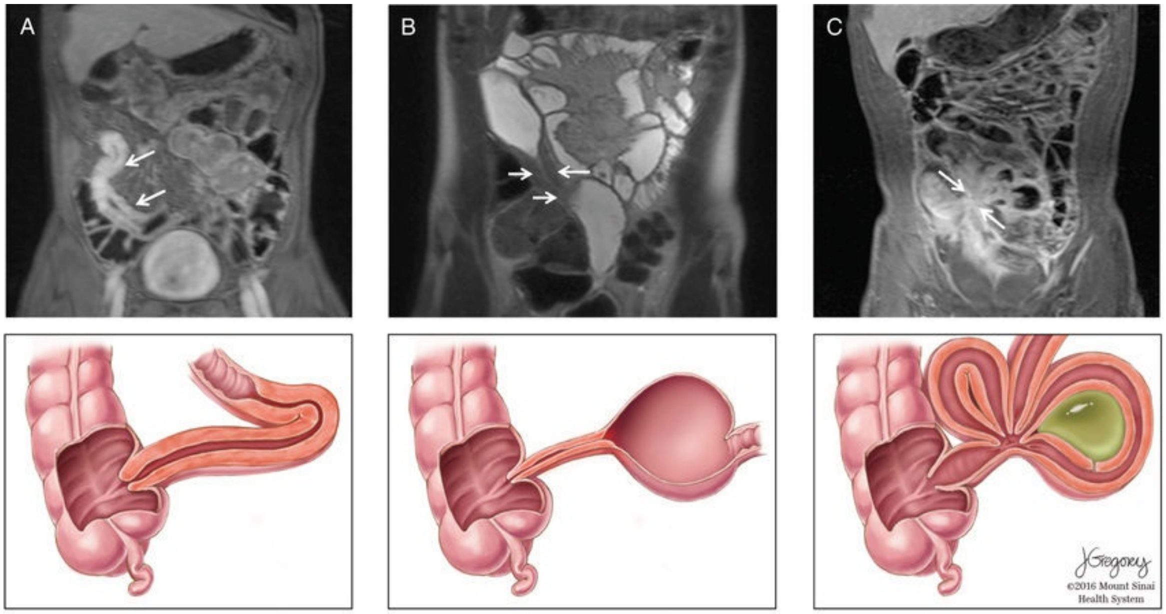
disease. *CDAI,* Crohn disease activity index; *CDEIS,* Crohn disease of endoscopic severity; *CRP,* C-reactive protein. (From Baumgart DC, Sandborn WJ: Crohn's disease, *Lancet* 380:1590–1602, 2012, Fig. 5, p 1596.)



- Diarrhea
- Abdominal pain
- Weight loss
- Low-grade fever
- Fatigue
- Growth retardation
- Malnourishment

- Postprandial pain
- Bloating
- Nausea and vomiting
- Occlusion/subocclusion

- Symptoms depend on the location of fistulae
- Enterourinary fistula: fecaluria, pneumaturia, recurrent UTI
- Rectovaginal fistula: dispareunia, stool discharge through the vagina
- Enteroenteric fistula: asymptomatic, abdominal abscesses

FIG. 362.6 Behavior of CD as per Montreal classification represented in MRE and illustrated with typical symptoms **A,** T1-weighted MRE imaging with fat saturation after injection of gadolinium chelates shows mural thickening and enhancement in the distal ileum *(arrows)* in a patient with active CD. **B,** T2-weighted MRE imaging shows a narrowed luminal segment with thickened wall and upstream dilation *(arrows)* , suggesting the presence of a stricture. **C,** T1-weighted MRE imaging with fat saturation after injection of gadolinium chelates shows multiple converging enhancing loops of small bowel suggestive of enteroenteric fistulas *(arrows)* . Lower illustration shows a deep and transmural fissure or ulcer leading to the formation of an abscess. *CD,* Crohn disease; *MRE,* magnetic resonance enterography; *UTI,* urinary tract infection. (Illustration by Jill Gregory. Printed with permission of ©Mount Sinai Health System. From Torres J, Mehandru S, Colombel JF, Peyrin-Biroulet L: Crohn's disease, *Lancet* 389:1741–1754, 2017, Fig. 1, p 1744.)

Systemic signs and symptoms are more common in Crohn disease than in ulcerative colitis. Fever, malaise, and easy fatigability are common. Growth failure with delayed bone maturation and delayed sexual development can precede other symptoms by 1 or 2 yr and is at least twice as likely to occur with Crohn disease as with ulcerative colitis. Children can present with growth failure as the only manifestation of Crohn disease. Decreased height velocity occurs in about 88% of prepubertal patients diagnosed with Crohn disease, and this often precedes GI symptoms. Causes of growth failure include inadequate caloric intake, suboptimal absorption or excessive loss of nutrients, the effects of chronic inflammation on bone metabolism and appetite, and the use of corticosteroids during treatment. Primary or secondary amenorrhea and pubertal delay are common. In contrast to ulcerative colitis, perianal disease is common (tag, fistula, deep fissure, abscess). Gastric or duodenal involvement may be associated with recurrent vomiting and epigastric pain. Partial small bowel obstruction, usually secondary to narrowing of the bowel lumen from *inflammation* or *stricture* , can cause symptoms of cramping abdominal pain (especially with meals), borborygmus, and intermittent abdominal distention (Figs. 362.7 and 362.8). Stricture should be suspected if the child notes relief of symptoms in association with a sudden sensation of gurgling of intestinal contents through a localized region of the abdomen. Inflammatory obstruction versus fibrotic stricture-induced obstruction may be distinguished by positron emission tomography/magnetic resonance imaging (PET/MRI), which will direct specific therapy (Fig. 362.9).

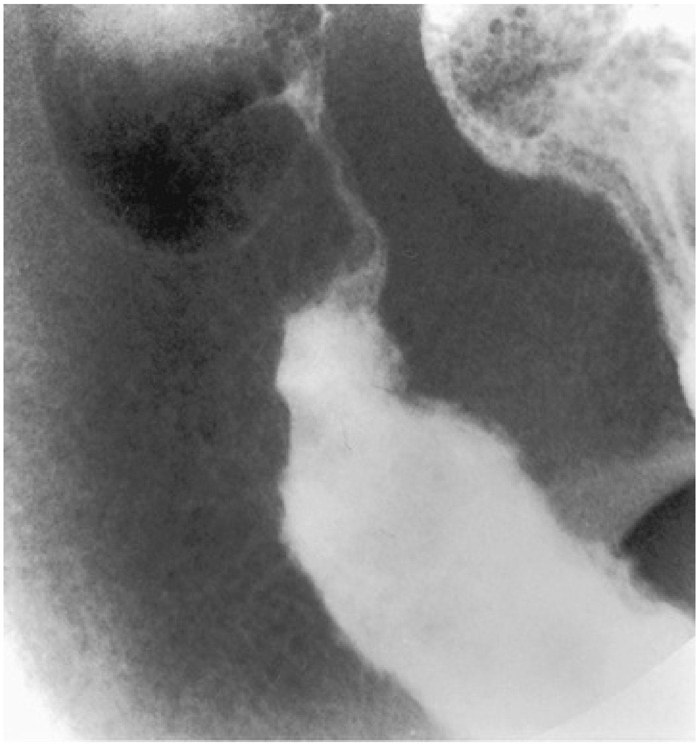


FIG. 362.7 Stenotic Crohn disease. Severe stenosis of the terminal ileum is present in this 16 yr old boy. Inflammatory effacement of the mucosal folds and small ulcerations characterize the proximal nonstenotic segment. (From Hoffman AD: The child with diarrhea. In Hilton SW, Edwards DK, editors: *Practical pediatric radiology,* ed 2, Philadelphia, 1994, WB Saunders, p 267.)

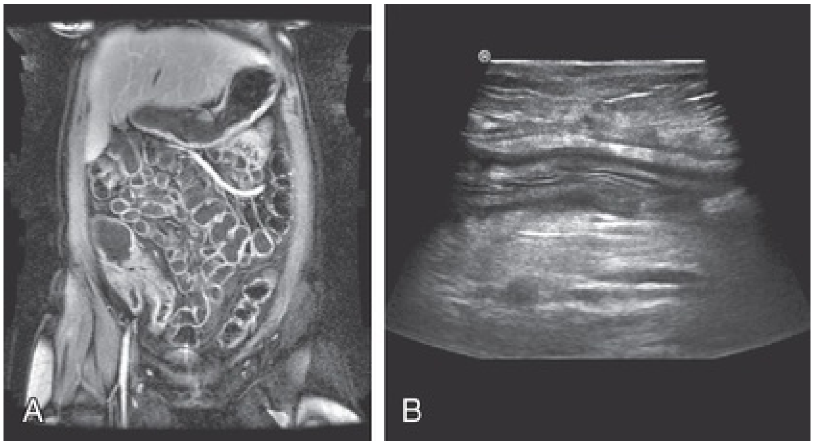

FIG. 362.8 Stenosis in Crohn disease. **A,** Magnetic resonance enterography of Crohn disease restricted to the terminal ileum (Montreal category L1) with inflammatory stenosis. **B,** Ultrasound image of an intestinal stenosis in Crohn disease. (From Baumgart DC, Sandborn WJ:

Crohn's disease, *Lancet* 380:1590–1602, 2012, Fig. 4, p 1596.)

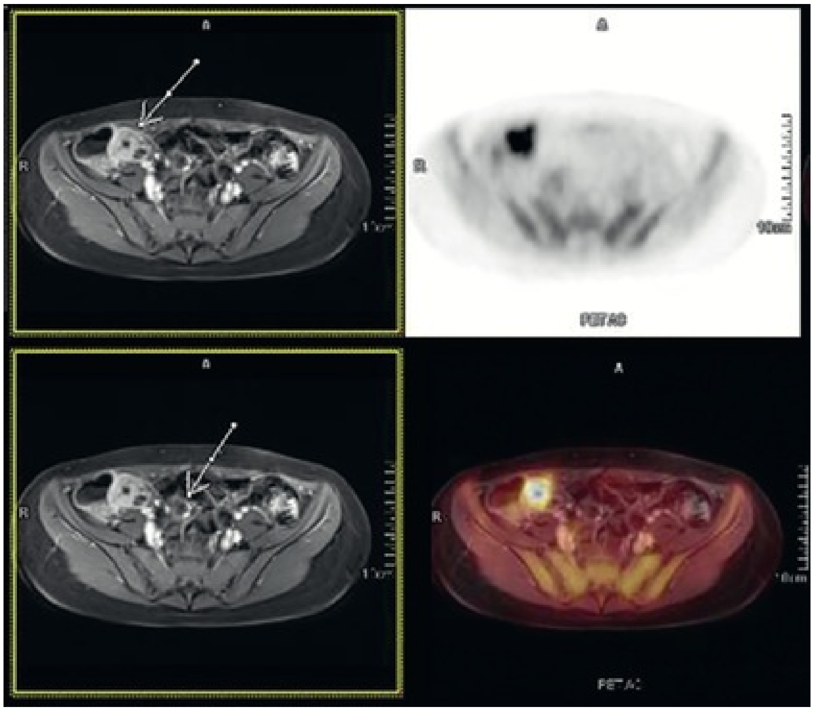

FIG. 362.9 PET/MR (PET, positron emission tomography; MR, magnetic resonance) co-registration and fusion *(right image in the bottom row)* showing a fibrotic stricture of the last bowel loop *(top, arrow)* with active inflammation, and concomitant inflammation of the ileocolic mesentery *(bottom, arrow)* . (From Pellino G, Nicolai E, Catalano OA, et al: PET/MR versus PET/CT imaging: impact on the clinical management of small-bowel Crohn's disease, *J Crohn Colitis* 10(3):277–285, 2017, Fig. 3.)

Penetrating disease is demonstrated by fistula formation. Enteroenteric or enterocolonic fistulas (between segments of bowel) are often asymptomatic but can contribute to malabsorption if they have high output or result in bacterial overgrowth (Fig. 362.10). Enterovesical fistulas (between bowel and urinary bladder) originate from ileum or sigmoid colon and appear as signs of urinary infection, pneumaturia, or fecaluria. Enterovaginal fistulas originate from the rectum, cause feculent vaginal drainage, and are difficult to manage. Enterocutaneous fistulas (between bowel and abdominal skin) often are caused by prior surgical anastomoses with leakage. Intraabdominal abscess may be associated with fever and pain but might have relatively few symptoms. Hepatic or splenic abscess can occur with or without a local fistula. Anorectal abscesses often originate immediately above the anus at the crypts of Morgagni. The patterns of perianal fistulas are complex because of the different tissue planes. Perianal abscess is usually painful, but perianal fistulas tend to produce fewer symptoms than anticipated. Purulent drainage is commonly associated with perianal fistulas. Psoas abscess secondary to intestinal fistula can present as hip pain, decreased hip extension (psoas sign), and fever.

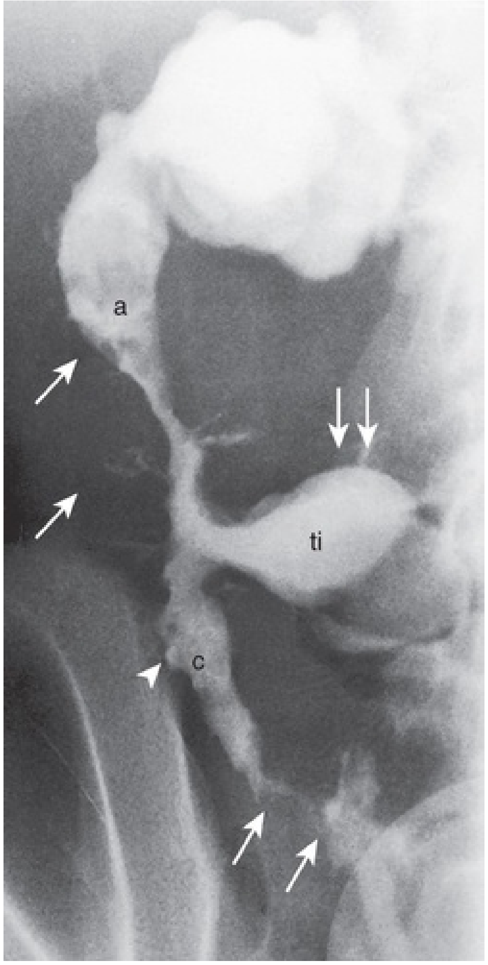

FIG. 362.10 Crohn disease: sinuses and fistula. Severe ileocolitis has resulted in an ileocecal fistula *(single arrows, lower)* and sinus formation in the ascending colon *(a) (arrows on platform). c,* Cecum *(arrowhead); ti,* terminal ileum *(paired arrows).* (From The child with diarrhea. In Hoffman AD, Hilton SW, Edwards DK, editors: *Practical pediatric radiology* , ed 2, Philadelphia, 1994, WB Saunders, p 268.)

Extraintestinal manifestations occur more commonly with Crohn disease than with ulcerative colitis; those that are especially associated with Crohn disease include oral aphthous ulcers, peripheral arthritis, erythema nodosum, digital clubbing, episcleritis, renal stones (uric acid, oxalate), and gallstones. Any of the extraintestinal disorders described in the section on IBD can occur with Crohn disease (see Table 362.3). The peripheral arthritis is nondeforming. The occurrence of extraintestinal manifestations usually correlates with the presence of colitis.

Extensive involvement of small bowel, especially in association with surgical resection, can lead to short bowel syndrome, which is rare in children. Complications of terminal ileal dysfunction or resection include bile acid malabsorption with secondary diarrhea and vitamin B_{12} malabsorption, with possible resultant deficiency. Chronic steatorrhea can lead to oxaluria with secondary renal stones. Increasing calcium intake can actually decrease the risk of renal stones secondary to ileal inflammation. The risk of cholelithiasis is also increased secondary to bile acid depletion.

A disorder with this diversity of manifestations can have a major impact on an affected child's lifestyle. Fortunately, the majority of children with Crohn disease are able to continue with their normal activities, having to limit activity only during periods of increased symptoms.

Differential Diagnosis

The most common diagnoses to be distinguished from Crohn disease are the infectious enteropathies (in the case of Crohn disease: acute terminal ileitis, infectious colitis, enteric parasites, and periappendiceal abscess) (see Tables 362.5 , 362.6 , and 362.8). *Yersinia* can cause many of the radiologic and endoscopic findings in the distal small bowel that are seen in Crohn disease. The symptoms of bacterial dysentery are more likely to be mistaken for ulcerative colitis than for Crohn disease. Celiac disease and *Giardia* infection have been noted to produce a Crohn-like presentation including diarrhea, weight loss, and protein-losing enteropathy. GI tuberculosis is rare but can mimic Crohn disease. Foreign-body perforation of the bowel (toothpick) can mimic a localized region with Crohn disease. Small bowel lymphoma can mimic Crohn disease but tends to be associated with nodular-filling defects of the bowel without ulceration or narrowing of the lumen. Bowel lymphoma is much less common in children than is Crohn disease. Recurrent functional abdominal pain can mimic the pain of small bowel Crohn disease. *Lymphoid nodular hyperplasia* of the terminal ileum (a normal finding) may be mistaken for Crohn ileitis. Right lower quadrant pain or mass with fever can be the result of periappendiceal abscess. This entity is occasionally associated with diarrhea as well.

Table 362.8

Differential Diagnosis of Presenting Symptoms of Crohn Disease

PRIMARY PRESENTING SYMPTOM	DIAGNOSTIC CONSIDERATIONS
Right lower quadrant abdominal pain, with or without mass	Appendicitis, infection (e.g., *Campylobacter, Yersinia* spp.), lymphoma, intussusception, mesenteric adenitis, Meckel diverticulum, ovarian cyst
Chronic periumbilical or epigastric abdominal pain	Irritable bowel syndrome, constipation, lactose intolerance, peptic disease
Rectal bleeding, no diarrhea	Fissure, polyp, Meckel diverticulum, rectal ulcer syndrome
Bloody diarrhea	Infection, hemolytic-uremic syndrome, Henoch-Schönlein purpura, ischemic bowel, radiation colitis
Watery diarrhea	Irritable bowel syndrome, lactose intolerance, giardiasis, *Cryptosporidium* infection, sorbitol, laxatives
Perirectal disease	Fissure, hemorrhoid (rare), streptococcal infection, condyloma (rare)
Growth delay	Endocrinopathy
Anorexia, weight loss	Anorexia nervosa
Arthritis	Collagen vascular disease, infection
Liver abnormalities	Chronic hepatitis

From Kugathasan S: Diarrhea. In Kliegman RM, Greenbaum LA, Lye PS, editors: *Practical strategies in pediatric diagnosis and therapy* , ed 2, Philadelphia, 2004, WB Saunders, p 287.

Growth failure may be the only manifestation of Crohn disease; other disorders such as growth hormone deficiency, gluten-sensitive enteropathy (celiac disease), Turner syndrome, or anorexia nervosa must be considered. If arthritis precedes the bowel manifestations, an initial diagnosis of juvenile idiopathic arthritis may be made. Refractory anemia may be the presenting feature and may be mistaken for a primary hematologic disorder. Chronic granulomatous disease of childhood can cause inflammatory changes in the bowel as well as perianal disease. Antral narrowing in this disorder may be mistaken for a stricture secondary to Crohn disease. Other immunodeficiencies or autoinflammatory conditions and monogenetic disorders may present with GI symptoms suggestive of IBD, particularly in very early or infant/toddler onset of disease (see Table 362.6).

Diagnosis

Crohn disease can manifest as a variety of symptom combinations (see Fig.

362.6). At the onset, symptoms may be subtle (growth retardation, abdominal pain alone); this explains why the diagnosis might not be made until 1 or 2 yr after the start of symptoms. The diagnosis of Crohn disease depends on finding typical clinical features of the disorder (history, physical examination, laboratory studies, and endoscopic or radiologic findings), ruling out specific entities that mimic Crohn disease, and demonstrating chronicity. The history can include any combination of abdominal pain (especially right lower quadrant), diarrhea, vomiting, anorexia, weight loss, growth retardation, and extraintestinal manifestations. Only 25% initially have the triad of diarrhea, weight loss, and abdominal pain. Most do not have diarrhea, and only 25% have GI bleeding.

Children with Crohn disease often appear chronically ill. They commonly have weight loss and growth failure, and they are often malnourished. The earliest sign of growth failure is decreased height velocity, which can be present in up to 88% of prepubertal patients with Crohn disease and typically precedes symptoms. Children with Crohn disease often appear pale, with decreased energy level and poor appetite; the latter finding sometimes results from an association between meals and abdominal pain or diarrhea. There may be abdominal tenderness that is either diffuse or localized to the right lower quadrant. A tender mass or fullness may be palpable in the right lower quadrant. Perianal disease, when present, may be characteristic. Large anal skin tags (1-3 cm diameter) or perianal fistulas with purulent drainage suggest Crohn disease. Digital clubbing, findings of arthritis, and skin manifestations may be present.

A complete blood cell count commonly demonstrates anemia, often with a component of iron deficiency, as well as thrombocytosis. Although the erythrocyte sedimentation rate and C-reactive protein are often elevated, they may be unremarkable. The serum albumin level may be low, indicating small bowel inflammation or protein-losing enteropathy. Fecal calprotectin and lactoferrin are increasingly being used as more sensitive and specific markers of bowel inflammation as compared to serologic parameters, and these are often elevated. Multiple serologic, immune, and genetic markers can also be abnormal, although the best utilization of these remains to be determined.

The small and large bowel and the upper GI tract should be examined by both endoscopic and radiologic studies in the child with suspected Crohn disease. Esophagogastroduodenoscopy and ileocolonoscopy should be performed to properly assess the upper GI tract, terminal ileum, and entire colon. Findings on colonoscopy can include patchy, nonspecific inflammatory changes (erythema, friability, loss of vascular pattern), aphthous ulcers, linear ulcers, nodularity, and strictures. Findings on biopsy may be only nonspecific chronic inflammatory changes. Noncaseating granulomas, similar to those of sarcoidosis, are the most characteristic histologic findings, although often they are not present. Transmural inflammation is also characteristic but can be identified only in surgical specimens.

Radiologic studies are necessary to assess the entire small bowel and investigate for evidence of structuring or penetrating disease. A variety of findings may be apparent on radiologic studies. Plain films of the abdomen may be normal or might demonstrate findings of partial small bowel obstruction or thumbprinting of the colon wall. An upper GI contrast study with small bowel follow-through might show aphthous ulceration and thickened, nodular folds as well as narrowing or stricturing of the lumen. Linear ulcers can give a cobblestone appearance to the mucosal surface. Bowel loops are often separated as a result of thickening of bowel wall and mesentery. Other manifestations on radiographic studies that suggest more-severe Crohn disease are fistulas between bowel (enteroenteric or enterocolonic), sinus tracts, and strictures (see Figs. 362.7 , 362.8 , and 362.10).

An upper GI contrast examination with small bowel follow-through has typically been the study of choice for imaging of the small bowel, but CT and magnetic resonance (MR) enterography and small bowel ultrasound are increasingly being used. MR and ultrasound have the advantage of not exposing the patient to ionizing radiation. CT and MR enterography can also assess for extraluminal findings such as abscesses and phlegmons. MR of the pelvis is also useful for delineating the extent of perianal involvement. PET/MRI may help define obstructing lesions as either inflammatory or fibrotic (see Fig. 362.9).

Video capsule endoscopy is another modality that allows for evaluation of the small bowel. This study can uncover mucosal inflammation or ulceration that might not have been detected by traditional imaging. However, video capsule endoscopy is contraindicated in the presence of stricturing disease, as surgical intervention would be required to remove a video capsule that is unable to pass through the bowel because a stricture. If there is concern for stricturing disease, a patency capsule can be swallowed prior to video capsule endoscopy to assess for passage through the GI tract.

Treatment

Crohn disease cannot be *cured* by medical or surgical therapy. The aim of treatment is to relieve symptoms and prevent complications of chronic inflammation (anemia, growth failure), prevent relapse, minimize corticosteroid exposure, and, if possible, effect mucosal healing.

Medical

The specific therapeutic modalities used depend on geographic localization of disease, severity of inflammation, age of the patient, and the presence of complications (abscess). Traditionally, a *step-up* treatment paradigm has been used in the treatment of pediatric Crohn disease, whereby early disease is treated with steroids and less immunosuppressive medications. Escalation of therapy would occur if disease severity increased, the patient was refractory to current medications, or for steroid dependence. A *top-down* approach has also been espoused, particularly in adults after multiple studies demonstrated superior efficacy. With this approach, patients with moderate to severe Crohn disease are treated initially with stronger, disease-modifying agents, with the goal of achieving mucosal healing, or deep remission, early in the disease course. This is thought to increase the likelihood of long-term remission while decreasing corticosteroid exposure. Improvements in remission and growth have been shown using a top-down approach in pediatrics and this treatment approach is being increasingly used among children. However, the precise role for this approach in pediatrics is still being determined.

5-Aminosalicylates

For mild terminal ileal disease or mild Crohn disease of the colon, an initial trial of mesalamine (50-100 mg/kg/day, maximum 3-4 g) may be attempted. Specific pharmaceutical preparations have been formulated to release the active 5-ASA compound throughout the small bowel, in the ileum and colon, or exclusively in the colon. Rectal preparations are used for distal colonic inflammation.

Antibiotics/Probiotics

Antibiotics such as metronidazole (10-22.5 mg/kg/day) are used for infectious complications and are first-line therapy for perianal disease (although perianal disease usually recurs when antibiotic is discontinued). Additionally, at low doses antibiotics may be effective for treatment of mild to moderate Crohn disease. To date, probiotics have not been shown to be effective in induction or maintenance of remission for pediatric Crohn disease.

Corticosteroids

Corticosteroids are used for acute exacerbations of pediatric Crohn disease because they effectively suppress acute inflammation, rapidly relieving symptoms (prednisone, 1-2 mg/kg/day, maximum 40-60 mg). The goal is to taper dosing as soon as the disease becomes quiescent. Clinicians vary in their tapering schedules, and the disease can flare during this process. There is no role for continuing corticosteroids as maintenance therapy because, in addition to their side effects, tolerance develops, and steroids do not change disease course or promote healing of mucosa. A special controlled ileal-release formulation of budesonide, a corticosteroid with local antiinflammatory activity on the bowel mucosa and high hepatic first-pass metabolism, is also used for mild to moderate ileal or ileocecal disease (adult dose: 9 mg daily). Ileal-release budesonide appears to be more effective than mesalamine in the treatment of active ileocolonic disease but is less effective than prednisone. Although less effective than traditional corticosteroids, budesonide does cause fewer steroid-related side effects.

Immunomodulators

Approximately 70% of patients require escalation of medical therapy within the 1st yr of pediatric Crohn disease diagnosis. Immunomodulators such as azathioprine (2.0-2.5 mg/kg/day) or 6-mercaptopurine (1.0-1.5 mg/kg/day) may be effective in some children who have a poor response to prednisone or who are steroid dependent. Because a beneficial effect of these drugs can be delayed for 3-4 mo after starting therapy, they are not helpful acutely. The early use of these agents can decrease cumulative prednisone dosages over the first 1-2 yr of therapy. Genetic variations in an enzyme system responsible for metabolism of these agents (thiopurine *S* -methyltransferase) can affect response rates and potential toxicity. Lymphoproliferative disorders have developed from thiopurine use in patients with IBD. Other common toxicities include hepatitis, pancreatitis, increased risk of skin cancer, increased risk of infection, and slightly increased risk of lymphoma.

Methotrexate is another immunomodulator that is effective in the treatment of active Crohn disease and has been shown to improve height velocity in the 1st yr of administration. The advantages of this medication include once-weekly dosing by either subcutaneous or oral route (15 mg/m^2 , adult dose 25 mg weekly) and a more-rapid onset of action (6-8 wk) than azathioprine or 6-

mercaptopurine. Folic acid is usually administered concomitantly to decrease medication side effects. Administration of ondansetron prior to methotrexate has been shown to diminish the risk of the most common side effect of nausea. The most common toxicity is hepatitis. The immunomodulators are effective for the treatment of perianal fistulas.

Biologic Therapy

Therapy with antibodies directed against mediators of inflammation is used for patients with Crohn disease. Infliximab, a chimeric monoclonal antibody to TNF-α, is effective for the induction and maintenance of remission and mucosal healing in chronically active moderate to severe Crohn disease, healing of perianal fistulas, steroid sparing, and preventing postoperative recurrence. Pediatric data additionally support improved growth with the administration of this medication. The onset of action of infliximab is quite rapid and it is initially given as 3 infusions over a 6 wk period (0, 2, and 6 wk), followed by maintenance dosing beginning every 8 wk. The durability of response to infliximab is variable and dose escalation (higher dose and/or decreased interval) is often necessary. Measurement of serum trough infliximab level prior to an infusion can help guide dosing decisions. Side effects include infusion reactions, increased incidence of infections (especially reactivation of latent tuberculosis), increased risk of lymphoma, and the development of autoantibodies. The development of antibodies to infliximab is associated with an increased incidence of infusion reactions and decreased durability of response. Regularly scheduled dosing of infliximab, as opposed to episodic dosing on an as-needed basis, is associated with decreased levels of antibodies to infliximab. A purified protein derivative test for tuberculosis should be done before starting infliximab.

Adalimumab, a subcutaneously administered, fully humanized monoclonal antibody against TNF-α, is effective for the treatment of chronically active moderate to severe Crohn disease in adults and children. After a loading dose, this is typically administered once every 2 wk, although dose escalation is sometimes required with this medication. Vedolizumab, a humanized monoclonal antibody that inhibits adhesion and migration of leukocytes into the GI tract, is approved for the treatment of Crohn disease in adults. Like infliximab, vedolizumab is initially given as 3 infusions over a 6 wk period followed by maintenance dosing beginning every 8 wk. However, the onset of action for vedolizumab is slower compared to infliximab and adalimumab. Therefore, concomitant therapies may be needed until response is demonstrated.

Dose escalation to every 4 wk may be necessary in some patients with loss-of-response but is being further studied. Ustekinumab, a monoclonal antibody against interleukins 12 and 23, was recently approved for treatment of chronically active moderate to severe Crohn disease in adults. A loading dose is given intravenously followed by maintenance dosing administered subcutaneously every 8 wk. New antiselective adhesion molecules and small molecule treatments, such as an oral SMAD7 antisense oligonucleotide that targets TGF-β signaling, are currently being tested.

Enteral Nutritional Therapy

Exclusive enteral nutritional therapy, whereby all of a patient's calories are delivered via formula, is an effective primary as well as adjunctive treatment. The enteral nutritional approach is as rapid in onset of response and as effective as the other treatments. Pediatric studies have suggested similar efficacy to prednisone for improvement in clinical symptoms, but enteral nutritional therapy is superior to steroids for actual healing of mucosa. Because affected patients have poor appetite and these formulas are relatively unpalatable, they are often administered via a nasogastric or gastrostomy infusion, usually overnight. The advantages are that it is relatively free of side effects, avoids the problems associated with corticosteroid therapy, and simultaneously addresses the nutritional rehabilitation. Children can participate in normal daytime activities. A major disadvantage of this approach is that patients are not able to eat a regular diet because they are receiving all of their calories from formula. A novel approach where 80–90% of caloric needs are provided by formula, allowing children to have some food intake, has been successful. For children with growth failure, this approach may be ideal, however.

High-calorie oral supplements, although effective, are often not tolerated because of early satiety or exacerbation of symptoms (abdominal pain, vomiting, or diarrhea). Nonetheless, they should be offered to children whose weight gain is suboptimal even if they are not candidates for exclusive enteral nutritional therapy. The continuous administration of nocturnal nasogastric feedings for chronic malnutrition and growth failure has been effective with a much lower risk of complications than parenteral hyperalimentation.

Surgery

Surgical therapy should be reserved for very specific indications. Recurrence rate after bowel resection is high (>50% by 5 yr); the risk of requiring additional surgery increases with each operation. Potential complications of surgery include development of fistula or stricture, anastomotic leak, postoperative partial small bowel obstruction secondary to adhesions, and short bowel syndrome. Surgery is the treatment of choice for localized disease of small bowel or colon that is unresponsive to medical treatment, bowel perforation, fibrosed stricture with symptomatic partial small bowel obstruction, and intractable bleeding. Intraabdominal or liver abscess sometimes is successfully treated by ultrasonographic or CT-guided catheter drainage and concomitant intravenous antibiotic treatment. Open surgical drainage is necessary if this approach is not successful. Growth retardation was once considered an indication for resection; without other indications, trial of medical and/or nutritional therapy is currently preferred.

Perianal abscess often requires drainage unless it drains spontaneously. In general, perianal fistulas should be managed by a combined medical and surgical approach. Often, the surgeon places a seton through the fistula to keep the tract open and actively draining while medical therapy is administered, to help prevent the formation of a perianal abscess. A severely symptomatic perianal fistula can require fistulotomy, but this procedure should be considered only if the location allows the sphincter to remain undamaged.

The surgical approach for Crohn disease is to remove as limited a length of bowel as possible. There is no evidence that removing bowel up to margins that are free of histologic disease has a better outcome than removing only grossly involved areas. The latter approach reduces the risk of short bowel syndrome. Laparoscopic approach is increasingly being used, with decreased postoperative recovery time. One approach to symptomatic small bowel stricture has been to perform a strictureplasty rather than resection. The surgeon makes a longitudinal incision across the stricture but then closes the incision with sutures in a transverse fashion. This is ideal for short strictures without active disease. The reoperation rate is no higher with this approach than with resection, whereas bowel length is preserved. Postoperative medical therapy with agents such as mesalamine, metronidazole, azathioprine, and, more recently, infliximab, is often given to decrease the likelihood of postoperative recurrence.

Severe perianal disease can be incapacitating and difficult to treat if unresponsive to medical management. Diversion of fecal stream can allow the area to be less active, but on reconnection of the colon, disease activity usually recurs.

Support

Psychosocial issues for the child with Crohn disease include a sense of being different, concerns about body image, difficulty in not participating fully in age-appropriate activities, and family conflict brought on by the added stress of this disease. Social support is an important component of the management of Crohn disease. Parents are often interested in learning about other children with similar problems, but children may be hesitant to participate. Social support and individual psychologic counseling are important in the adjustment to a difficult problem at an age that by itself often has difficult adjustment issues. Patients who are socially "connected" fare better. Ongoing education about the disease is an important aspect of management because children generally fare better if they understand and anticipate problems. The Crohn and Colitis Foundation of America has local chapters throughout the United States and supports several regional 1-wk camps for children with Crohn disease.

Prognosis

Crohn disease is a chronic disorder that is associated with high morbidity but low mortality. Symptoms tend to recur despite treatment and often without apparent explanation. Weight loss and growth failure can usually be improved with treatment and attention to nutritional needs. Up to 15% of patients with early growth retardation secondary to Crohn disease have a permanent decrease in linear growth. Osteopenia is particularly common in those with chronic poor nutrition and frequent exposure to high doses of corticosteroids. Dual energy x-ray absorptiometry can help identify patients at risk for developing osteopenia. Steroid-sparing agents, weight bearing exercise, and improved nutrition, including supplementation with vitamin D and calcium, can improve bone mineralization. Some of the extraintestinal manifestations can, in themselves, be major causes of morbidity, including sclerosing cholangitis, chronic active hepatitis, pyoderma gangrenosum, and ankylosing spondylitis.

The region of bowel-involved and complications of the inflammatory process tend to increase with time and include bowel strictures, fistulas, perianal disease, and intraabdominal or retroperitoneal abscess. Most patients with Crohn disease eventually require surgery for one of its many complications; the rate of reoperation is high. Surgery is unlikely to be curative and should be avoided except for the specific indications noted previously. An earlier, most aggressive medical treatment approach, with the goal of exacting mucosal healing may improve long-term prognosis, and this is an active area of investigation. The risk of colon cancer in patients with long-standing Crohn colitis approaches that associated with ulcerative colitis, and screening colonoscopy after 8-10 yr of colonic disease is indicated.

Despite these complications, most children with Crohn disease lead active, full lives with intermittent flare-up in symptoms.

362.3

Very Early Onset Inflammatory Bowel Disease

Ronen E. Stein, Robert N. Baldassano

Keywords

immunodeficiency
monogenic
indeterminate colitis
Crohn disease
ulcerative colitis
infant
toddler

IBD may be classified according to age at onset: pediatric onset (<17 yr), early onset (<10 yr), very early onset (<6 yr), infant/toddler onset (0-2 yr), and neonatal onset IBD (<28 days). The incidence of pediatric IBD is rising with the greatest rates of increase occurring among young children. Very early onset IBD (VEO-IBD) accounts for up to 15% of pediatric onset IBD with an estimated prevalence of 14/100,000 children. Approximately 1% of children with IBD are diagnosed below the age of 2 yr.

Although IBD is a complex disorder with genetics, the immune system, the microbiome, and environmental factors each contributing to its development, children with VEO-IBD are more likely to have a *monogenic* cause for their disease. Advances in genetic testing have led to the identification of novel genetic pathways linked to the development of VEO-IBD. Many of these pathways contain genes associated with primary immunodeficiencies (see Tables 362.1 and 362.6). Family history of IBD among first-degree relatives occurs more frequently in children diagnosed at a younger age. Approximately 44% of children diagnosed with ulcerative colitis under the age of 2 will have a first-degree relative with IBD compared to 19% of older children with IBD.

VEO-IBD has a distinct clinical phenotype characterized by a higher likelihood for extensive colonic involvement and a greater tendency for a more aggressive disease course that is refractory to conventional therapies. However, there is a spectrum of clinical presentations within this population, including patients with milder forms of the disease and a more traditional disease course. Younger patients with IBD can present with any combination of diarrhea, abdominal pain, vomiting, and growth failure. Severe perirectal disease can be present and is often associated with monogenic forms of VEO-IBD, including those caused by interleukin 10 receptor gene mutations.

Diagnosis of IBD is ultimately confirmed by upper endoscopy and ileocolonoscopy. Classic histological findings of IBD can be seen, although atypical findings, such as the presence of extensive epithelial apoptosis, could indicate the presence of monogenic disease. Most children with VEO-IBD will have isolated colonic inflammation on ileocolonoscopy. However, the inflammation can be extensive and involve the entire colon making it challenging to differentiate between Crohn disease and ulcerative colitis; 11–22% of patients with VEO-IBD are diagnosed with *indeterminate colitis* at diagnosis. Additionally, an initial diagnosis of ulcerative colitis occurs in approximately 60% of VEO-IBD patients. However, because children with VEO-IBD are more likely to have disease extension over time, a number of patients felt to have indeterminate colitis or ulcerative colitis at diagnosis may eventually be reclassified as having Crohn disease later in life.

The differential diagnosis of VEO-IBD is similar to older children and adults including infectious and allergic colitis (see Table 362.5). However, primary immunodeficiencies, such as chronic granulomatous disease, common variable immunodeficiency, severe combined immunodeficiency, Wiskott-Aldrich Syndrome and immunodysregulation, polyendocrinopathy, and enteropathy, X-linked are higher on the differential (see Table 362.6). Therefore, immunological evaluation is a critical component of diagnosis and management. History of autoimmunity, atypical infections, recurrent infections, skin disorders, and/or hair abnormalities could indicate an underlying immunodeficiency. Laboratory evaluation could include dihydrorhodamine cytometric testing, quantitative immunoglobulins, vaccine titers, as well as testing of B and T cell function. More targeted immunological testing is guided by clinical history. Genetic testing modalities, such as whole exome sequencing, are helpful in identifying rare monogenic pathways responsible for development of the disease.

There are no official consensus guidelines regarding treatment of children with VEO-IBD. Younger children are more likely to fail conventional therapies, such as 5-ASA, immunomodulators, and biologics, and require surgical intervention. Surgical decisions must be made with caution in very young children as disease extension from the colon to the small intestine can occur with time. More extensive and severe disease at presentation could explain the higher rates of treatment failure among younger children. However, other children may fail conventional therapies if the inflammation is being driven by a monogenic disease process that is not targeted by conventional therapies. Therefore, for children with an underlying primary immunodeficiency or a novel monogenic disease process, the specific disease pathway involved may influence treatment choices. In some cases, bone marrow transplantation may be a necessary treatment for the underlying disease process.

CHAPTER 363

Eosinophilic Gastroenteritis

Ronen E. Stein, Robert N. Baldassano

Eosinophilic gastroenteritis consists of a group of rare and poorly understood disorders that have in common gastric and small intestine infiltration with eosinophils and peripheral eosinophilia. The esophagus and large intestine may also be involved. Tissue eosinophilic infiltration can be seen in mucosa, muscularis, or serosa. The mucosal form is most common and is diagnosed by identifying large numbers of eosinophils in biopsy specimens of gastric antrum or small bowel. Endoscopy may reveal gastritis or colitis, ulceration, and thickened mucosal folds as well as nodules. This condition clinically overlaps the dietary protein hypersensitivity disorders of the small bowel and colon. Peripheral eosinophilia may be absent. The differential diagnosis also includes celiac disease, chronic granulomatous disease, connective tissue disorders and vasculitides (eosinophilic granulomatosis with polyangiitis), multiple infections (particularly parasites), hypereosinophilic syndrome, early inflammatory bowel disease, medications (tacrolimus, enalapril, naproxen, interferon, rifampicin, azathioprine), and rarely malignancy. Many patients have allergies to multiple foods, seasonal allergies, atopy, eczema, and asthma. Serum immunoglobulin E is commonly elevated. Laboratory abnormalities may include hypoalbuminemia, iron deficiency anemia, and elevated liver enzymes.

The presentation of eosinophilic gastroenteritis is nonspecific. Clinical symptoms often correlate with which layers of the gastrointestinal tract are affected. Mucosal involvement can produce nausea, vomiting, diarrhea, abdominal pain, gastrointestinal bleeding, protein-losing enteropathy, or malabsorption. Involvement of the muscularis can produce obstruction (especially of the pylorus) or intussusception, whereas serosal activity produces abdominal distention and eosinophilic ascites. Presentation in infants can be similar to pyloric stenosis. Laboratory testing often reveals peripheral eosinophilia, elevated serum immunoglobulin E levels, hypoalbuminemia, and anemia.

The disease usually runs a chronic, debilitating course with sporadic severe exacerbations. Although almost always effective for the treatment of isolated eosinophilic esophagitis (see Chapter 350), elemental diets are not always successful for the treatment of eosinophilic gastroenteritis. Orally administered cromolyn sodium and montelukast are sometimes successful. Many patients require treatment for acute disease exacerbations with systemic corticosteroids, which are often effective. Systemic corticosteroids may also be needed long-term. Oral budesonide, a corticosteroid with local anti-inflammatory activity on the bowel mucosa and limited systemic absorption due to high hepatic first-pass metabolism, can be attempted for long-term therapy.

CHAPTER 364

Disorders of Malabsorption

Raanan Shamir

All disorders of malabsorption are associated with diminished intestinal absorption of one or more dietary nutrients. Malabsorption can result from a defect in the nutrient **digestion** in the intestinal lumen or from defective mucosal **absorption.** Malabsorption disorders can be categorized into generalized mucosal abnormalities usually resulting in malabsorption of multiple nutrients (Table 364.1) or malabsorption of specific nutrients (carbohydrate, fat, protein, vitamins, minerals, and trace elements) (Table 364.2). Almost all the malabsorption disorders are accompanied by chronic diarrhea, which further worsens the malabsorption (Chapter 367).

Table 364.1

Malabsorption Disorders and Chronic Diarrhea Associated With Generalized Mucosal Defect

MUCOSAL DISORDERS
Gluten-sensitive enteropathy (celiac disease) Cow's milk and other protein-sensitive enteropathies Eosinophilic enteropathy
PROTEIN-LOSING ENTEROPATHY
Lymphangiectasia (congenital and acquired) Disorders causing bowel mucosal inflammation, Crohn disease
CONGENITAL BOWEL MUCOSAL DEFECTS
Microvillous inclusion disease Tufting enteropathy Carbohydrate-deficient glycoprotein syndrome Enterocyte heparan sulfate deficiency Enteric anendocrinosis (*NEUROG 3*, *PCSK1* mutations) Tricho-hepatic-enteric syndrome
IMMUNODEFICIENCY DISORDERS
Congenital immunodeficiency disorders Selective immunoglobulin A deficiency (can be associated with celiac disease)

  - Severe combined immunodeficiency
  - Agammaglobulinemia
  - X-linked hypogammaglobulinemia
  - Wiskott-Aldrich syndrome
  - Common variable immunodeficiency disease
  - Chronic granulomatous disease

ACQUIRED IMMUNE DEFICIENCY

- HIV infection
- Immunosuppressive therapy and post–bone marrow transplantation

AUTOIMMUNE ENTEROPATHY

- IPEX (*i* mmune dysregulation, *p* olyendocrinopathy, *e* nteropathy, *X* -linked inheritance)
- IPEX-like syndromes
- Autoimmune polyglandular syndrome type 1

MISCELLANEOUS

- Immunoproliferative small intestinal disease
- Short bowel syndrome
- Blind loop syndrome
- Radiation enteritis
- Protein–calorie malnutrition
- Crohn disease
- Pseudoobstruction

Table 364.2

Classification of Malabsorption Disorders and Chronic Diarrhea Based on the Predominant Nutrient Malabsorbed

CARBOHYDRATE MALABSORPTION

- Lactose malabsorption
- Congenital lactase deficiency
- Hypolactasia (adult type)
- Secondary lactase deficiency
- Congenital sucrase isomaltase deficiency
- Glucose galactose malabsorption

FAT MALABSORPTION

- Exocrine pancreatic insufficiency
  - Cystic fibrosis
  - Shwachman-Diamond syndrome
  - Johanson-Blizzard syndrome
  - Pearson syndrome
- Secondary exocrine pancreatic insufficiency
  - Chronic pancreatitis
  - Protein–calorie malnutrition
  - Decreased pancreozymin/cholecystokinin secretion
- Isolated enzyme deficiency
  - Enterokinase deficiency
  - Trypsinogen deficiency
  - Lipase/colipase deficiency
- Disrupted enterohepatic circulation of bile salts
  - Cholestatic liver disease
  - Bile acid synthetic defects
  - Deconjugation of bile acids (bacterial overgrowth)

- Bile acid malabsorption (terminal ileal disease)
- Intestinal brush border disorders
  - Allergic enteropathy
  - Autoimmune enteropathy
  - Disorders in formation and transport of chylomicrons by enterocytes to the lymphatics
  - Abetalipoproteinemia
  - Homozygous hypobetalipoproteinemia
  - Chylomicron retention disease (Anderson disease)
- Disorders of lymph flow
  - Lymphangiectasia primary/secondary

PROTEIN/AMINO ACID MALABSORPTION

- Lysinuric protein intolerance (defect in dibasic amino acid transport)
- Hartnup disease (defect in free neutral amino acids)
- Blue diaper syndrome (isolated tryptophan malabsorption)
- Oasthouse urine disease (defect in methionine absorption)
- Lowe syndrome (lysine and arginine malabsorption)
- Enterokinase deficiency
- Protein-losing enteropathy
  - *DGAT1* mutation
  - Congenital disorders of glycosylation
  - CD55 deficiency

MINERAL AND VITAMIN MALABSORPTION

- Congenital chloride diarrhea
- Congenital sodium absorption defect
- Acrodermatitis enteropathica (zinc malabsorption)
- Menkes disease (copper malabsorption)
- Vitamin D–dependent rickets
- Folate malabsorption
- Congenital
- Secondary to mucosal damage (celiac disease)
- Vitamin B_{12} malabsorption
- Autoimmune pernicious anemia
- Decreased gastric acid (H_2 blockers or proton pump inhibitors)
- Terminal ileal disease (e.g., Crohn disease) or resection
- Inborn errors of vitamin B_{12} transport and metabolism
- Primary hypomagnesemia

DRUG INDUCED

- Sulfasalazine: folic acid malabsorption
- Cholestyramine: calcium and fat malabsorption
- Anticonvulsant drugs such as phenytoin (causing vitamin D deficiency and folic acid and calcium malabsorption)
- Gastric acid suppression: vitamin B_{12}
- Methotrexate: mucosal injury

Clinical Approach

The clinical features depend on the extent and type of the malabsorbed nutrient. The common presenting features, especially in toddlers with malabsorption, are diarrhea, abdominal distention, and failure to gain weight, with a fall in growth chart percentiles. Physical findings include abdominal distention, muscle wasting, and the disappearance of the subcutaneous fat, with subsequent loose skinfolds (Fig. 364.1). The nutritional consequences of malabsorption are more dramatic in toddlers because of the limited energy reserves and higher proportion of calorie intake being used for weight gain and linear growth. In older children, malnutrition can result in growth retardation, as is commonly seen in children with late diagnosis of celiac disease (CD). If malabsorption is left untreated, linear growth slows, and with prolonged malnutrition, death can follow (see Chapter 57). This extreme outcome is usually restricted to children living in the developing world, where resources to provide enteral and parenteral nutrition support may be limited. Nonetheless, monogenetic causes often produce failure to thrive in all countries. Specific findings on examination can guide toward a specific disorder; edema is usually associated with protein-losing enteropathy (PLE), digital clubbing with cystic fibrosis and CD, perianal excoriation and gaseous abdominal distention with carbohydrate malabsorption, perianal and circumoral rash with acrodermatitis enteropathica, abnormal hair with Menkes syndrome, tricho-hepato-enteric syndrome (THE) and the typical facial features diagnostic of the Johanson-Blizzard syndrome.

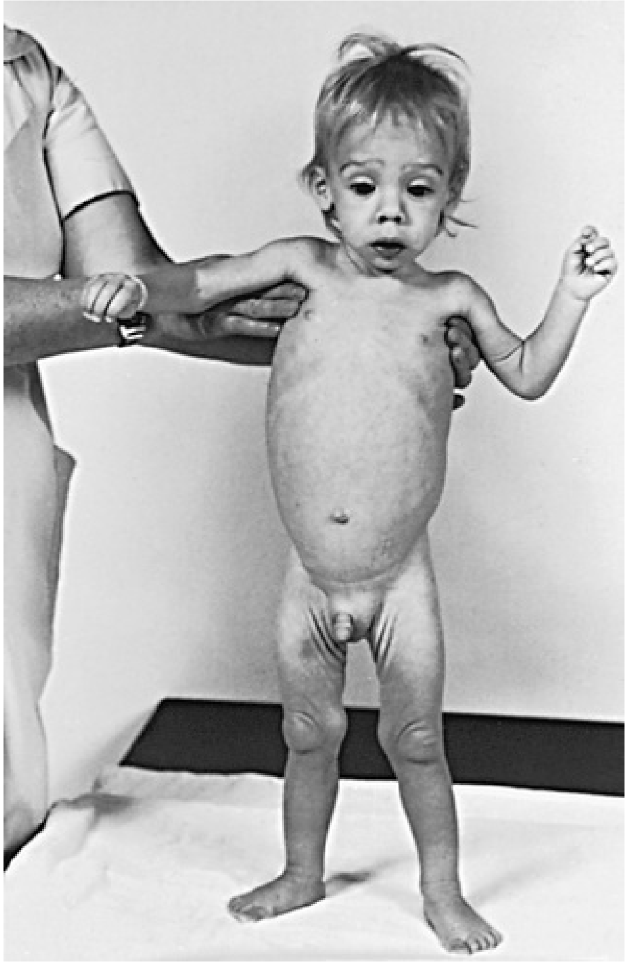

FIG. 364.1 An 18 mo old boy with active celiac disease. Note the loose skinfolds, marked proximal muscle wasting, and distended abdomen. The child looks ill.

Many children with malabsorption disorders have a good appetite as they try to compensate for the fecal protein and energy losses. In exocrine pancreatic insufficiency, fecal losses of up to 40% of ingested protein and energy do not lead to malnutrition, as long as they are compensated by an increased appetite. In conditions associated with villous atrophy or inflammation (CD, postinfectious enteropathy), fecal protein and energy losses are usually modest, but associated anorexia and reduced food intake results in malnutrition.

The nutritional assessment is an important part of clinical evaluation in children with malabsorptive disorders (see Chapter 55). Long-term calcium and vitamin D malabsorption can lead to reduced bone mineral density and metabolic bone disease (often resistant to oral vitamin D), with increased risk of bone fractures. Vitamin K malabsorption, irrespective of the underlying mechanism (fat malabsorption, mucosal atrophy), can result in coagulopathy.

Severe PLE is often associated with malabsorption syndromes (CD, congenital disorders of glycosylation, intestinal lymphangiectasia) and causes hypoalbuminemia and edema. Other nutrient deficiencies include iron malabsorption causing microcytic anemia and low reticulocyte count, low serum folate levels in conditions associated with mucosal atrophy, especially in the proximal part of the small intestinal tract and low serum vitamin A and vitamin E concentrations in fat malabsorption.

The evaluation of a child with malabsorption should be proceed in a stepwise manner. Clinical history alone might not be sufficient to make a specific diagnosis, but it can direct the pediatrician toward a more structured and rational investigative approach. Diarrhea is the main clinical expression of malabsorption. The onset of diarrhea in early infancy suggests a congenital defect (Table 364.3). In secretory diarrhea caused by disorders such as congenital chloride diarrhea (CCD) and microvillus inclusion disease (MVID), the stool is watery and voluminous and can be mistaken for urine (see Chapter 367). The onset of symptoms after the introduction of a particular food into a child's diet can provide diagnostic clues, such as with sucrose in sucrase-isomaltase deficiency. The nature of the diarrhea may be helpful: explosive watery diarrhea suggests carbohydrate malabsorption; loose, bulky stools are associated with CD; and pasty and yellowish offensive stools suggest an exocrine pancreatic insufficiency. Stool color is usually not helpful; green stool with undigested “peas and carrots” can suggest rapid intestinal transit in toddler's diarrhea, which by itself is a self-limiting condition unassociated with failure to thrive.

Table 364.3

Diarrheal Diseases Appearing in the Neonatal Period

CONDITION	CLINICAL FEATURES
Congenital enteropathy	
Microvillus inclusion disease Tufting enteropathy	Secretory diarrhea Secretory diarrhea
Congenital intestinal transport defect	
Congenital glucose–galactose malabsorption Congenital bile acid malabsorption Congenital chloride diarrhea Congenital sodium diarrhea (*GUCY2C* mutation)	Acidic diarrhea Steatorrhea Secretory diarrhea, metabolic alkalosis Hydramnion, secretory diarrhea
Congenital isolated enzyme deficiency	
Congenital lactase deficiency Congenital enterokinase deficiency Congenital trypsinogen deficiency	Acidic diarrhea Failure to thrive, edema Failure to thrive, edema

Congenital lipase and/or colipase deficiency	Failure to thrive, oily stool
Enteric anendocrinosis (*NEUROG 3* mutation)	Hyperchloremic acidosis, failure to thrive
Immunodeficiency and autoinflammatory diseases (see Table 362.6)	Failure to thrive, opportunistic infections, eczema

Following medical history, physical examination and laboratory testing (see next Chapter 364.1), intestinal biopsies may assist in the diagnosis. This is usually done for chronic rather than acute diseases (that can be self-limited). Generalized mucosal villous atrophy (flat mucosa) may be associated with malabsorption of multiple *macronutrients* and *micronutrients* and has a wide range of differential diagnoses (see Chapter 364.2).

364.1

Evaluation of Children With Suspected Intestinal Malabsorption

Firas Rinawi, Raanan Shamir

Keywords

Steatorrhea
protein-losing enteropathy
carbohydrate malabsorption

The investigation is guided by the history and physical examination. In a child presenting with chronic or recurrent diarrhea, the initial work-up should include stool cultures and antibody tests for parasites; stool microscopy for ova and parasites such as *Giardia* ; and fecal leukocytes and calprotectin or lactoferrin to exclude inflammatory disorders. Stool pH and reducing substances for carbohydrate malabsorption, stool osmolality to differentiate between osmotic and secretory diarrhea and quantitative stool fat examination and α_1 -antitrypsin to demonstrate fat and protein malabsorption, respectively, should also be determined. Fecal stool elastase-1 can determine exocrine pancreatic insufficiency.

A complete blood count, including peripheral smear for microcytic anemia, lymphopenia (lymphangiectasia), neutropenia (Shwachman syndrome), and acanthocytosis (abetalipoproteinemia) is useful. If CD is suspected, serum immunoglobulin (Ig) A and tissue transglutaminase (TG2) antibody levels should be determined. Depending on the initial test results, more specific investigations can be planned.

Investigations for Carbohydrate Malabsorption

The measurement of carbohydrate in the stool for pH and the amount of reducing substances is a simple screening test when available. An acidic stool with >2+ reducing substance suggests carbohydrate malabsorption. Sucrose or starch in the stool is not recognized as a reducing sugar until after hydrolysis with hydrochloric acid, which converts them to reducing sugars.

Breath hydrogen test is used to identify the specific carbohydrate that is malabsorbed. After an overnight fast, the suspected sugar (lactose, sucrose, fructose, or glucose) is administered as an oral solution (carbohydrate load up to 2 g/kg, maximum total of 25 g, depending on the specific carbohydrate type). In malabsorption, the sugar is not digested or absorbed in the small bowel; it passes on to the colon and is metabolized by the normal gut microflora. One of the products of this process is hydrogen gas, which is absorbed through the colon mucosa and excreted in the breath. Increased hydrogen concentration in the breath samples suggests carbohydrate malabsorption. A rise in breath hydrogen of 20 ppm above the baseline preferably with associated symptoms is considered a positive test. The child should not be on antibiotics at the time of the test, because colonic flora is essential for fermenting the sugar.

Small bowel mucosal biopsies can measure mucosal disaccharidase (lactase, sucrase, maltase, palatinase) concentrations directly. In primary enzyme deficiencies the mucosal enzyme levels are low and small bowel mucosal morphology is normal. Primary enzymatic deficiencies can be diagnosed by genetic testing (see Chapters 364.9 and 367). Partial or total villous atrophy due to disorders such as CD, or following acute rotavirus gastroenteritis can result in secondary disaccharidase deficiency and transient lactose intolerance (see Chapter 364.2 for differential diagnosis of villous atrophy). The disaccharidase levels revert to normal after mucosal healing.

Investigations for Fat Malabsorption

The presence of fat globules in the stool suggests fat malabsorption. The ability to assimilate fat varies with age; a premature infant can absorb only 65–75% of dietary fat, a full-term infant absorbs almost 90%, and an older child absorbs more than 95% of fat while on a regular diet. Quantitative determination of fat malabsorption requires a 3-day stool collection for evaluation of fat excretion and determination of the coefficient of fat absorption:

$$\text{Coefficient of fat absorption } \% = (\text{fat intake} - \text{fecal fat losses}/\text{fat intake}) \times 100$$

where fat intake and fat losses are in grams. Because fecal fat balance studies are cumbersome, expensive, and unpleasant to perform, simpler tests are often preferred. Among these stool tests, the acid steatocrit test is the most reliable. When BA deficiency is suspected of being the cause of fat malabsorption, the evaluation of BA levels in duodenal fluid aspirate may be useful. Intestinal mucosal abnormalities affect not only fat absorption, but also steatorrhea, and are usually far less severe in intestinal mucosal disorders (CD, cow's milk protein enteropathy) than in exocrine pancreatic insufficiency.

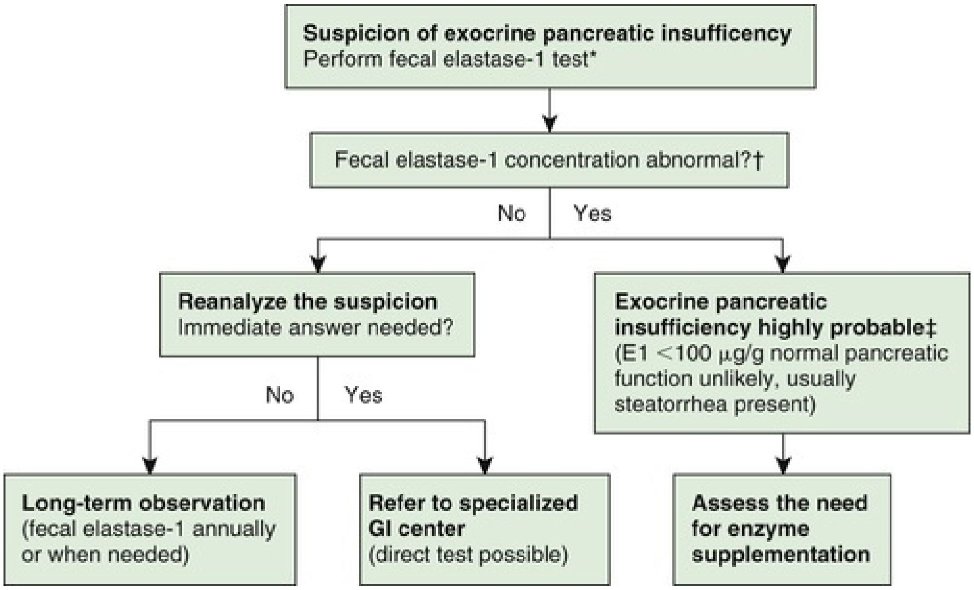
Exocrine pancreatic insufficiency and other fat malabsorption disorders (see Table 364.2) are usually associated with deficiencies of fat-soluble vitamins A, D, E, and K. Serum concentrations of vitamins A, D, and E can be measured. A prolonged prothrombin time is an indirect test to assess vitamin K malabsorption and subsequent deficiency.

Investigations for Protein-Losing Enteropathy

Dietary and endogenous proteins secreted into the bowel are almost completely absorbed and minimal amounts of protein from these sources passes into the colon. The majority of the stool nitrogen is derived from gut bacterial proteins. Excessive bowel protein loss usually manifests as hypoalbuminemia. Because the most common cause of hypoalbuminemia in children is a renal disorder, urinary protein excretion must be determined. Other potential causes of hypoalbuminemia include acute infection, liver disease (reduced production) and inadequate protein intake. Very rarely hypoalbuminemia can result from an extensive skin disorder (burns) causing protein loss via the skin. Measurement of stool α_1 -antitrypsin is a useful screening test for PLE. This serum protein has a molecular weight similar to albumin; however, unlike albumin it is resistant to digestion in the gastrointestinal (GI) tract. Excessive α_1 -antitrypsin excretion in the stool should prompt further investigations to identify the specific cause of gut or stomach (Menetrier disease) protein loss.

Investigations for Exocrine Pancreatic Function

Cystic fibrosis (Chapter 432) is the most common cause of exocrine pancreatic insufficiency in children; therefore, a sweat chloride test must be performed before embarking on invasive tests to investigate possible exocrine pancreatic insufficiency (Fig. 364.2). Many cases of cystic fibrosis are detected by neonatal genetic screening programs; occasional rare mutations are undetected.



Suspicion of exocrine pancreatic insuffiency
Perform fecal elastase-1 test*
Fecal elastase-1 concentration abnormal?†
No
Yes
Reanalyze the suspicion
Immediate answer needed?
No
Yes
Exocrine pancreatic insufficiency highly probable‡
(E1 <100 µg/g normal pancreatic function unlikely, usually steatorrhea present)
Long-term observation
(fecal elastase-1 annually or when needed)
Refer to specialized GI center
(direct test possible)
Assess the need for enzyme supplementation

FIG. 364.2 **Algorithm for assessment of exocrine pancreatic function. *If not available, use another test. Perform appropriate imaging studies of the pancreas. †In case of borderline values, consider repeating the test with 3 independent samples. ‡Consider differential diagnosis (especially consider mucosal villous atrophy and dilution effect of watery stool).** ***GI*** **, Gastrointestinal. (Modified from Walkowiak J, Nousia-Arvanitakis S, Henker J, et al: Indirect pancreatic function tests in children,** ***J Pediatr Gastroenterol Nutr*** **40[2]:107–114, 2005.)**

Fecal elastase-1 estimation is a sensitive test to assess exocrine pancreatic function in chronic cystic fibrosis and pancreatitis. Elastase-1 is a stable endoprotease unaffected by exogenous pancreatic enzymes. One disadvantage of the fecal elastase-1 test is the lack of full differentiation between primary exocrine pancreatic insufficiency and exocrine pancreatic dysfunction secondary to intestinal villous atrophy. The proximal small bowel is the site for pancreozymin/cholecystokinin production; the latter is the hormone that stimulates enzyme secretion from the exocrine pancreas. Mucosal atrophy can lead to diminished pancreozymin/cholecystokinin secretion and subsequently to exocrine pancreatic insufficiency. Fecal elastase-1 can also give a false-positive result during acute episodes of diarrhea.

Serum trypsinogen concentration can also be used as a screening test for exocrine pancreatic insufficiency. In cystic fibrosis, the levels are greatly elevated early in life, and then they gradually fall, so that by 5-7 yr of age, most patients with cystic fibrosis with pancreatic insufficiency have subnormal levels. Patients with cystic fibrosis and adequate exocrine pancreatic function tend to have normal or elevated levels. In such patients, observing the trend in serial serum trypsinogen estimation may be useful in monitoring exocrine pancreatic function. In Shwachman syndrome, another condition associated with exocrine pancreatic insufficiency, the serum trypsinogen level is low.

Other tests for pancreatic insufficiency (nitroblue tetrazolium–paraaminobenzoic acid test and pancreolauryl test) measure urine or breath concentrations of substances released and absorbed across the mucosal surface following pancreatic digestion. These tests lack specificity and are rarely used in clinical practice.

The gold standard test for exocrine pancreatic function is direct analysis of duodenal aspirate for volume, bicarbonate, trypsin, and lipase upon secretin, and pancreozymin/cholecystokinin stimulation. This involves duodenal intubation (see Chapter 375).

Investigations for Intestinal Mucosal Disorders

Establishing a specific diagnosis for malabsorption often requires histologic examination of small bowel mucosal biopsies. These are obtained during endoscopy, which allows multiple biopsies to be performed, because mucosal involvement can be patchy, especially in CD. Periodic acid–Schiff (PAS) staining of mucosal biopsies and electron microscopy are necessary in congenital diarrhea to assess congenital microvillus atrophy. Bowel mucosal lesions can also be segmental in cases of IL. In these situations, radiographic small bowel series, repeated ultrasonographies or lymphoscintigraphy can identify a region of thickened bowel responsible for protein loss. Intestinal biopsies can detect infectious agents such as *Giardia lamblia* . During endoscopy, mucosal biopsies can be obtained to measure mucosal disaccharidase activities. Duodenal aspirates can be performed to measure pancreatic enzyme concentration as well as quantitative bacterial cultures.

Imaging Procedures

Plain radiographs and barium contrast studies might suggest a site and cause of intestinal motility disorders. Although flocculations of barium and dilated bowel with thickened mucosal folds have been attributed to diffuse malabsorptive lesions such as CD, these abnormalities are nonspecific. Diffuse fluid-filled bowel loops during sonography also suggest malabsorption.

gluten free diet

Etiology and Epidemiology

CD is an immune-mediated systemic disorder elicited by gluten in wheat and related prolamines from rye and barley in genetically susceptible individuals, and is characterized by the presence of a variable combination of gluten-dependent clinical manifestations, CD–specific antibodies, human leukocyte antigen (HLA)-DQ2 or DQ8 haplotypes, and enteropathy. CD–specific antibodies comprise autoantibodies against TG2 including endomysial antibodies (EMAs), and antibodies against deamidated forms of gliadin peptides.

CD is a common disorder with about 1% prevalence of biopsy-proven disease. It is thought to be rare in Central Africa and East Asia. Although CD develops in genetically susceptible individuals, environmental factors might affect the risk of developing CD or the timing of its presentation. Neither breastfeeding during gluten introduction nor any breastfeeding has been shown to reduce the risk of CD. The earlier introduction of gluten is associated with the earlier development of CD autoimmunity (positive serology) and CD, but the cumulative incidence of each in later childhood is not affected. It is advised to introduce gluten into the infant's diet anytime between 4 and 12 mo of age. Infectious agents have been hypothesized to play a causative role as frequent rotavirus infections were shown to be associated with an increased risk of developing CD. It is plausible that the contact with gliadin at a time when there is an ongoing intestinal inflammation alters intestinal permeability, and the enhanced antigen presentation can increase the risk of developing CD, at least in a subset of persons. The mode of delivery, socioeconomic status, season of birth, and the use of drugs have been associated with the risk of developing CD, but the evidence is contradictory.

Genetics and Pathogenesis

A genetic predisposition is suggested by the family aggregation and the concordance in monozygotic twins, which approaches 100%. The strongest association is with HLA-DQ2.5 (1 or 2 copies encoded by DQA1 *05 [for the alpha] and DQB1*02 genes [for the beta chain]). Such a DQ molecule has been found to be present in more than 90% of CD patients. The highly homologous DQ2.2 molecule confers a much lower risk, while the data available on DQ2-negative CD patients indicate that they almost invariably are HLA-DQ8–positive (DQA1*0301/DQB1*0302). A gene dosage effect has been proved in prospective studies, and a molecular hypothesis for such a phenomenon has been proposed, based on the impact of the number and quality of the HLA-DQ2 molecules on gluten peptide presentation to T cells. The HLA locus is the most significant and dominant gene associated with CD; however, other loci known to contribute to CD have been documented. Most have been found to be associated with other autoimmune diseases such as type 1 diabetes. Interestingly, very few polymorphisms associated with CD are in coding regions, as they often are in binding sites for transcription factors, then affecting gene expression.

CD is a T-cell–mediated chronic inflammatory disorder with an autoimmune component. Altered processing by intraluminal enzymes, changes in intestinal permeability and activation of innate immunity mechanisms precede the activation of the adaptive immune response. Immunodominant epitopes from gliadin are highly resistant to intraluminal and mucosal digestion; incomplete degradation favors the immunostimulatory and toxic effects of these sequences. Some gliadin peptides (p31-43) activate innate immunity, in particular they induce interleukin (IL)-15. The latter, but also type 1 interferons, may alter the tolerogenic phenotype of dendritic cells, resulting in lamina propria T-cell activation by other peptides presented in the context of HLA-DQ2 or HLA-DQ8 molecules. Gliadin-specific T-cell responses are enhanced by the action of TG2: the enzyme converts particular glutamine residues into glutamic acid, which results in higher affinity of these gliadin peptides for HLA-DQ2 or HLA-DQ8.

The pattern of cytokines produced following gliadin activation is dominated by interferon-γ (T-helper type 1 skewed); IL-21 is also upregulated. In downstream T-cell activation a complex remodeling of the mucosa takes place, involving increased levels of metalloproteinases and growth factors, which leads to the classical histologic finding of a flat mucosa. A severe impairment of intraepithelial lymphocytes (IELs) homeostasis is present in CD. IL-15 is implicated in the expression of natural killer receptors CD94 and NKG2D, as well as in epithelial expression of stress molecules, thus enhancing cytotoxicity, cell apoptosis, and villous atrophy. The most evident expression of autoimmunity is the presence of serum antibodies to TG2. However, the mechanisms leading to autoimmunity are largely unknown, as well as their pathogenetic significance. *Potential* CD, in which TG2 antibodies can be detected in situ without any histologic abnormality, shows that the production of antibodies does not necessarily lead to intestinal damage. The finding that IgA deposits on extracellular TG2 are not limited to the intestine but can be found in the liver, lymph nodes, and muscles indicates that TG2 is accessible to the gut-derived autoantibodies, turning CD into a systemic disease.

Clinical Presentation and Associated Disorders

Clinical features of CD vary considerably. Intestinal symptoms are more common in children whose disease is diagnosed *within the first 2 yr of life* ; failure to thrive, chronic diarrhea, vomiting, abdominal distention, muscle wasting, anorexia, and irritability are present in most cases (Fig. 364.3). Occasionally there is constipation, with cases presenting with intussusception. As the age at presentation of the disease shifts to later in childhood, and with the more extensive use of serologic screening tests, extraintestinal manifestations, without any accompanying digestive symptoms, have increasingly become recognized, affecting almost all organs (Table 364.4). One of the most common extraintestinal manifestation of CD is iron-deficiency anemia, which is usually unresponsive to iron therapy. Osteoporosis may be present; in contrast to adults, it can be reversed by a gluten-free diet, with restoration of normal peak bone densitometric values. Other extraintestinal manifestations include short stature, delayed puberty, arthritis and arthralgia, epilepsy with bilateral occipital calcifications, peripheral neuropathies, isolated hypertransaminasemia, dental enamel hypoplasia, and aphthous stomatitis. The mechanisms responsible for the severity and the variety of clinical presentations remain obscure. Nutritional deficiencies or abnormal immune responses have been advocated. Silent CD is recognized, mainly in asymptomatic first-degree relatives of CD patients and in subjects affected by diseases associated with CD (Table 364.5). Small bowel biopsy in silent/subclinical CD reveals severe mucosal damage consistent with CD. Potential CD is defined when patients have positive CD–specific antibodies, but without documented small bowel damage (Table 364.6).

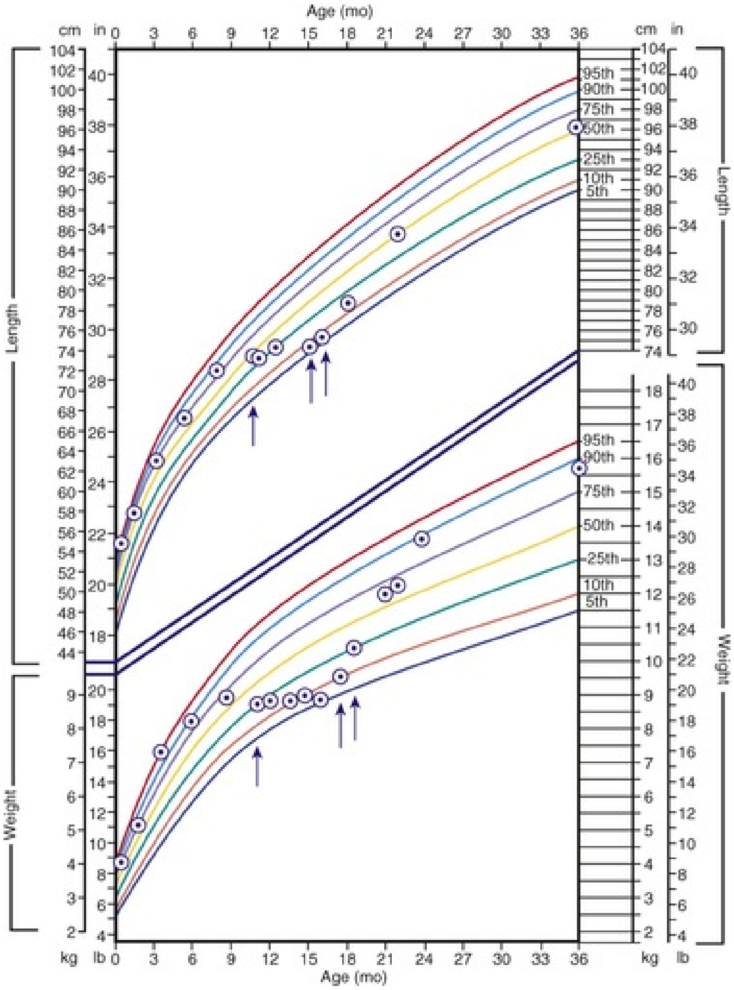

FIG. 364.3 Gluten-sensitive enteropathy. Growth curve demonstrates initial normal growth from 0 to 9 mo, followed by onset of poor appetite with intermittent vomiting and diarrhea after initiation of gluten-containing diet *(single arrow)* . After biopsy conformed diagnosis and treatment with gluten-free diet *(double arrow)* , growth improves.

Table 364.4

Extraintestinal Manifestations of Celiac Disease

MANIFESTATION	PROBABLE CAUSE(S)
CUTANEOUS	
Ecchymoses and petechiae	Vitamin K deficiency; rarely, thrombocytopenia
Edema	Hypoproteinemia
Dermatitis herpetiformis	Epidermal (type 3) tTG autoimmunity
Follicular hyperkeratosis and dermatitis	Vitamin A malabsorption, vitamin B complex malabsorption
ENDOCRINOLOGIC	
Amenorrhea, infertility, impotence, delayed puberty	Malnutrition, hypothalamic-pituitary dysfunction, immune dysfunction
Secondary hyperparathyroidism	Calcium and/or vitamin D malabsorption with hypocalcemia
HEMATOLOGIC	
Anemia	Iron, folate, vitamin B_{12} , or pyridoxine deficiency
Hemorrhage	Vitamin K deficiency; rarely, thrombocytopenia due to folate deficiency
Thrombocytosis, Howell-Jolly bodies	Hyposplenism
HEPATIC	
Elevated liver biochemical test levels Autoimmune hepatitis	Lymphocytic hepatitis Autoimmunity
MUSCULAR	
Atrophy	Malnutrition due to malabsorption
Tetany	Calcium, vitamin D, and/or magnesium malabsorption
Weakness	Generalized muscle atrophy, hypokalemia
NEUROLOGIC	
Peripheral neuropathy	Deficiencies of vitamin B_{12} and thiamine; immune-based neurologic dysfunction
Ataxia	Cerebellar and posterior column damage
Demyelinating central nervous system lesions	Immune-based neurologic dysfunction
Seizures	Unknown
SKELETAL	
Osteopenia, osteomalacia, and osteoporosis	Malabsorption of calcium and vitamin D, secondary hyperparathyroidism, chronic inflammation
Osteoarthropathy	Unknown
Pathologic fractures	Osteopenia and osteoporosis
OTHER	
Enamel hypoplasia	Vitamin D, calcium malabsorption
Anxiety, schizophrenia	Unknown, uncertain
Pulmonary hemosiderosis	Unknown, uncertain
Aphthous stomatitis	Unknown

tTG , tissue transglutaminase.

Table 364.5

National Institute for Health and Care Excellence Guidelines on the Indications That Should Prompt Testing for Celiac Disease

CELIAC TESTING RECOMMENDED
• Persistent unexplained abdominal or gastrointestinal symptoms • Faltering growth • Prolonged fatigue • Unexpected weight loss • Severe or persistent mouth ulcers • Unexplained iron, vitamin B12, or folate deficiency • Type 1 diabetes • Autoimmune thyroid disease • Irritable bowel syndrome • First degree relatives of people with coeliac disease • Dermatitis herpetiformis
CELIAC TESTING SHOULD BE CONSIDERED
• Metabolic bone disorders (reduced bone mineral density or osteomalacia) • Unexplained neurological symptoms (particularly peripheral neuropathy or ataxia) • Unexplained subfertility or recurrent miscarriage • Persistently increased concentrations of liver enzymes with unknown cause • Dental enamel defects • Down syndrome • Turner syndrome • William syndrome • Selective IgA deficiency

IgA , immunoglobulin-A.

Table 364.6

Clinical Spectrum of Celiac Disease

SYMPTOMATIC
Frank malabsorption symptoms and signs (e.g., chronic diarrhea, failure to thrive, weight loss) Extraintestinal symptoms and signs (e.g., anemia, fatigue, hypertransaminasemia, neurologic disorders, short stature, dental enamel defects, arthralgia, aphthous stomatitis)
SILENT
No apparent symptoms in spite of histologic evidence of villous atrophy In most cases identified by serologic screening in at-risk groups (see Table 364.1)
LATENT
Subjects who have a normal intestinal histology, but at some other time have shown a gluten-dependent enteropathy
POTENTIAL

Subjects with positive celiac disease serology but without evidence of altered intestinal histology. Patients may or may not have symptoms and signs of disease and may or may not develop a gluten-dependent enteropathy later

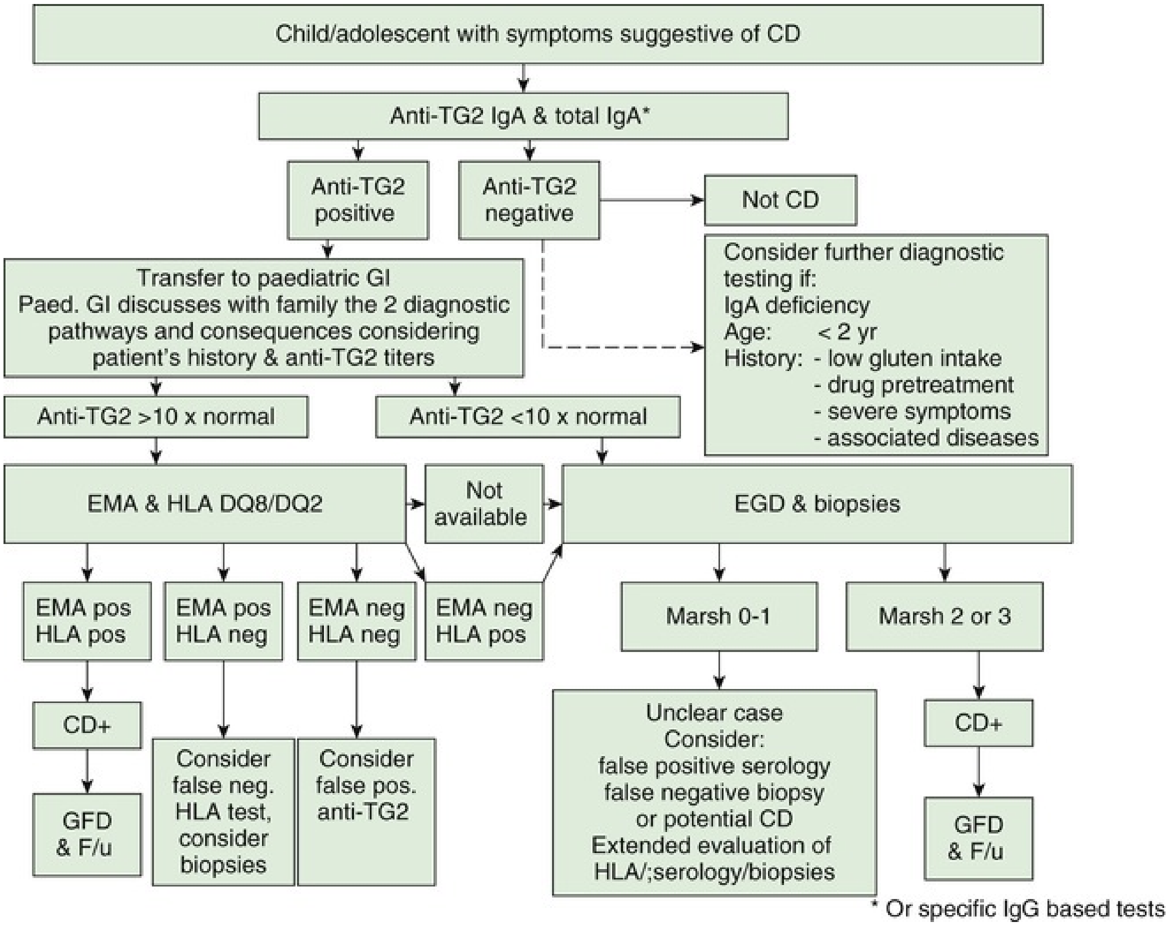
Some diseases—many with an autoimmune pathogenesis—are found with a higher-than-normal incidence in CD patients. Among these are type 1 diabetes, autoimmune thyroid disease, Addison disease, Sjögren syndrome, rheumatoid arthritis, autoimmune cholangitis, autoimmune hepatitis, and primary biliary cholangitis. Such associations have been interpreted as a consequence of the sharing of identical HLA haplotypes, but a direct role of gluten in promoting autoimmunity cannot be excluded. The relation between CD and other autoimmune diseases is poorly defined; once those diseases are established, they are not influenced by a gluten-free diet. Other associated conditions include selective IgA deficiency and Down, Turner, and Williams syndromes.

Diagnosis

The diagnosis of CD is based on a combination of symptoms, antibodies, HLA status, and duodenal histology. The initial approach to symptomatic patients is to test for anti-TG2 IgA antibodies and for total IgA in serum to exclude IgA deficiency. If IgA anti-TG2 antibodies are negative, and serum total IgA is normal for age, CD is unlikely to be the cause of the symptoms. If anti-TG2 antibody testing is positive the patients should be referred to a pediatric gastroenterologist for further diagnostic workup, which depends on the serum antibody levels.

IgA anti-TG2 decline if the patient is on a gluten free diet. In patients with selective IgA deficiency, testing is recommended with IgG antibodies to TG2.

Patients with positive anti-TG2 antibody levels <10 times the upper limit of normal should undergo upper endoscopy with multiple biopsies. In patients with positive anti-TG2 antibody levels at or >10 times the upper limit of normal, blood should be drawn for HLA and EMA testing. If the patient is positive for EMA antibodies and positive for DQ2 or DQ8 HLA testing, the diagnosis of CD is confirmed, a life-long gluten-free diet is started and the patient is followed for the improvement of symptoms and the decline of antibodies. HLA testing is almost always positive; thus, it is possible that HLA testing will not be necessary in the future to establish diagnosis. In the rare case of negative results for HLA and/or anti-EMA in a child with TG2 antibody titers >10 times the upper limits of normal, the diagnostic workup should be extended, including repeated testing and duodenal biopsies (Fig. 364.4). In asymptomatic persons belonging to high-risk groups, CD should always be diagnosed using duodenal biopsies (Fig. 364.5). When biopsies are indicated, at least 4 fragments should be obtained from the descending part of the duodenum and at least 1 from the duodenal bulb. The diagnosis is confirmed by an antibody decline and preferably a clinical response to a gluten-free diet. CD is not the only cause for villous atrophy (Table 364.7). Gluten challenge and biopsies will only be necessary in selected cases in which diagnostic uncertainty remains.



Child/adolescent with symptoms suggestive of CD
Anti-TG2 IgA & total IgA*

Treatment

The only treatment for CD is lifelong strict adherence to a gluten-free diet. This requires a wheat-, barley-, and rye-free diet (Tables 364.8 and 364.9). Despite evidence that oats are safe for most patients with CD, there is concern regarding the possibility of contamination of oats with gluten during harvesting, milling, and shipping. Nevertheless, it seems wise to add oats to the gluten-free diet only when the latter is well established, so that possible adverse reactions can be readily identified. There is a consensus that all CD patients should be treated with a gluten-free diet regardless of the presence of symptoms. However, whereas it is relatively easy to assess the health improvement after treatment of CD in patients with clinical symptoms of the disease, it proves difficult in persons with asymptomatic CD. The nutritional risks, particularly osteopenia and increased risk for other autoimmune disorders, are those mainly feared for subjects who have silent CD and continue on a gluten-containing diet. Little is known about the health risks in untreated patients with potential CD.

Table 364.8

Principles of Initial Dietary Therapy for Patients With Celiac Disease

Avoid all foods containing wheat, rye, and barley gluten (pure oats usually safe).
Avoid malt unless clearly labeled as derived from corn.
Use only rice, corn, maize, buckwheat, millet, amaranth, quinoa, sorghum, potato or potato starch, soybean, tapioca, and teff, bean, and nut flours.
Wheat starch and products containing wheat starch should only be used if they contain <20 ppm gluten and are marked “gluten free.”
Read all labels and study ingredients of processed foods.
Beware of gluten in medications, supplements, food additives, emulsifiers, or stabilizers.
Limit milk and milk products initially if there is evidence of lactose intolerance.
Avoid all beers, lagers, ales, and stouts (unless labeled gluten free).
Wine, most liqueurs, ciders, and spirits, including whiskey and brandy, are allowed.

ppm , Parts per million.

Type II RCD
Type I RCD

FIG. 364.6 Diagnostic algorithm for the approach to patients with nonresponsive celiac disease. **Nonresponsive celiac disease* may be defined as persistent symptoms and signs despite 6-12 mo of dietary gluten avoidance. Abnormal TTG can last even 2-3 yr. † Causes of non-celiac small intestinal villus atrophy that may be misdiagnosed as celiac disease include autoimmune enteropathy, tropical sprue, SIBO, hypogammaglobulinemia, combined variable immunodeficiency, collagenous sprue, eosinophilic enteritis, Crohn disease, and peptic duodenitis. ‡ Conditions that present clinically in a fashion similar to celiac disease but where villus atrophy is not evident

include IBS, food intolerances, SIBO, eosinophilic enteritis, Crohn disease, and microscopic colitis. § Positive serologic testing for celiac disease despite 12 mo of treatment with a GFD suggest that there may be ongoing gluten ingestion. ‖ *Refractory celiac disease (RCD)* is defined as persistent or recurrent malabsorptive symptoms and signs, with small intestinal villus atrophy despite a strict GFD for more than 12 mo and in the absence of other disorders including overt lymphoma. ¶ Abnormal intestinal lymphocytes may be identified by immunohistochemistry of intraepithelial lymphocytes or by flow cytometry showing an increased number of CD3-positive cells that lack CD8 or by the identification of clonal T-cell receptor gene rearrangement by molecular analysis. *EMA* , Endomysial antibody; *DGP* , deamidated gliadin peptide; *GFD* , gluten-free diet; *HLA* , human leukocyte antigen; *tTGA* , tissue transglutaminase antibody. (Adapted from Rubio-Tapia A, Murray JA. Classification and management of refractory coeliac disease. *Gut* 59:547–57, 2010; and Rubio-Tapia A, Hill ID, Kelly CP, et al. ACG clinical guidelines: Diagnosis and management of celiac disease. *Am J Gastroenterol* 108:656–76, 2013.)

The Codex Alimentarius Guidelines define gluten-free food item for food containing <20 ppm (equivalent to 20 mg gluten in 1 kg of product); however, although analytical methods for gluten detection have reached a satisfactory degree of sensitivity, more information is needed on the daily gluten amount that may be tolerated by CD patients. The data available so far seem to suggest that the threshold should be set to <50 mg/day, although individual variability makes it difficult to set a universal threshold.

It is important that an experienced dietician with specific expertise in CD counseling educates the family and the child about dietary restriction. Compliance with a gluten-free diet can be difficult, especially in adolescents. It is recommended that children with CD be monitored with periodic visits for assessment of symptoms, growth, physical examination, complete blood count, thyroid diseases, and adherence to the gluten-free diet. Periodic measurements of TG2 antibody levels to document reduction in antibody titers can be helpful as indirect evidence of adherence to a gluten-free diet, although they are insensitive to slight dietary transgressions. If compliance is uncertain, bone health should be assessed.

The Spectrum of Gluten-Related Disorders

CD is not the only disorder related to gluten ingestion. Symptoms in IgE-mediated wheat allergy are usually immediate (urticaria, angioedema, asthma, exercise-induced anaphylaxis). Diagnosis is based on dietary challenge, in vitro assay for specific IgE and skin testing.

Non-celiac gluten sensitivity (NCGS) is a poorly understood condition.

Diagnosis is suspected in patients who do not have CD or wheat allergy, and yet show GI and non-GI symptoms upon ingestion of gluten- or wheat-containing food. In the general population, the incidence of self-reported gluten avoidance varies from 0.5 to 13%. Similar symptoms are often experienced by patients with irritable bowel syndrome (IBS), and some patients with IBS respond positively to a gluten-free diet.

Defects of Enterocyte Differentiation and Polarization

This group mainly includes 2 conditions characterized by typical histological and ultrastructural lesions in the intestinal biopsies, microvillus inclusion disease (MVID) and congenital tufting enteropathy (CTE). Tricho-hepato-enteric syndrome (THE) or syndromic/phenotypic diarrhea is also usually classified in this group.

Microvillus Inclusion Disease (Congenital Microvillus Atrophy)

MVID is an autosomal recessive disorder, which manifests at birth with profuse watery *secretory diarrhea* . A late-onset variant, with onset 2-3 mo postnatal has also been described. It is the most severe cause of congenital diarrhea involving the development of the intestinal mucosa. Light microscopy of the small bowel mucosa demonstrates diffuse thinning of the mucosa, with hypoplastic villus atrophy and no inflammatory infiltrate. Diagnosis is performed with light microscopy using PAS and CD10 staining, which shows a very thin or absent brush border, together with positive PAS and CD10 intracellular inclusions. Electron microscopy shows enterocytes with absent or sparse microvilli. The apical cytoplasm of the enterocytes contains electron-dense secretory granules; the hallmark is the presence of microvilli within involutions of the apical membrane (Fig. 364.7). Polyhydramnios is observed on prenatal sonography, and neonates usually present very early onset of severe watery diarrhea (up to 200-330 mL/kg/day) causing dehydration and failure to thrive. Despite parenteral nutrition, diarrhea continues, and initial fluid management is difficult. MVID and Fanconi syndrome that have been described in two patients may complicate management because of the additional features of a renal tubular acidosis, phosphaturia, rickets, and renal fluid losses. Mutations of the *MYO5B* gene coding for a nonconventional motor protein, myosin Vb, are associated with MVID in a cohort of patients suffering from early-onset MVID.

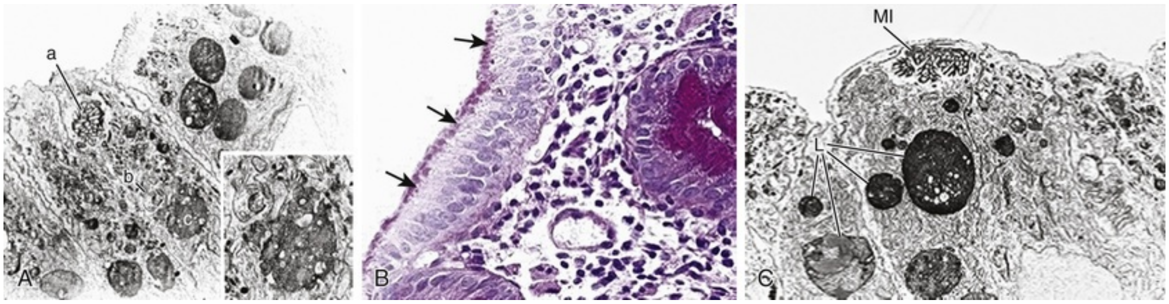

FIG. 364.7 **Microvillus inclusion disease. A, From top to bottom: microvillus inclusion *(a)* , a granule with few microvilli *(b)* , and a lysosome *(c)* detected in the same enterocyte. *Inset:* Higher magnification of *b* and *c* ×11,000, inset ×21,500. B, Microvillus inclusion disease. Periodic acid-Schiff (PAS) staining highlights abundant PAS-positive material *(arrows)* in the apical part of the enterocyte cytoplasm. C, Microvillus inclusion disease. The villous enterocyte lack brush-border microvilli, whereas their apical cytoplasm contains a microvillus inclusion *(MI)* and numerous lysosomes *(L)* ×5,500. (*A,* From Morroni M, Cangiotti AM, Guarino A, et al: Unusual ultrastructural features in microvillous inclusion disease: a report of two cases, *Virchows Arch* 448[6]:805–810, 2006.)**

MYO5B mutations result in mislocalization of apical proteins and disrupted enterocyte polarization, leading to MVID. Another gene, the t-SNARE syntaxin3 *(STX3)* , has been described in patients with MVID and a milder phenotype. Patients with mutations in the STX3 binding protein *STXBP2/Munc18-2* , causing familial hemophagocytic lymphohistiocytosis type 5, also show microvillus atrophy and histologic findings reminiscent of MVID. Loss of STX3 or Munc18-2 inhibits the fusion of vesicles with the apical membrane, resulting in the intracellular retention of apical proteins. *MYO5B* mutations have also been identified in several patients with progressive familial intrahepatic cholestasis (PFIC)-like phenotype with normal serum gamma-glutamyl transferase activity and without intestinal disease.

Tufting Enteropathy (Congenital Tufting Enteropathy)

CTE (intestinal epithelial dysplasia) manifests in the first few weeks of life with persistent watery diarrhea. CTE accounts for a small fraction of infants with *intractable diarrhea of infancy* . The distinctive feature on small intestinal mucosal biopsy is focal epithelial tufts (teardrop-shaped groups of closely packed enterocytes with apical rounding of the plasma membrane) involving 80–90% of the epithelial surface. The typical pathology does not appear immediately after birth; other enteropathies may show tufts on the epithelial surface.

CTE is a phenotypic and genetic heterogenous condition. Genetic studies identified mutations in epithelial cell adhesion molecule *(EPCAM)* gene in 73% of patients and mutations in hepatocyte growth factor activator inhibitor type 2 *SPINT2/HAI2* gene in 21%. No identified mutations are identified in a minority of patients. The phenotype associated with mutations of *EPCAM* is usually an isolated congenital diarrhea without associated extra digestive symptoms, except late-onset arthritis or superficial punctuate keratitis. In the *syndromic* form of CTE, diarrhea is associated with 1 or more of these same anomalies: superficial punctate keratitis (100%), choanal atresia (50%), esophageal or intestinal atresia, anal imperforation, hair dysplasia, skin hyperlaxity, bone abnormalities, hexadactylia, and facial dysmorphism.

No specific treatment exists, thus, as for MVID, management requires permanent parenteral nutrition (PN) with possible intestinal transplantation (see Chapter 365).

Tricho-Hepato-Enteric Syndrome (Syndromic Diarrhea)

THE, also known as *syndromic diarrhea* (SD), is a congenital enteropathy manifesting with early onset of severe diarrhea. Patients are born small for gestational age and present with diarrhea starting in the first 6 mo of life. They have an abnormal phenotype, including facial dysmorphism with prominent forehead, broad nose, and hypertelorism with a distinct abnormality of hair, **trichorrhexis nodosa** . Hairs are woolly, easily removed, and poorly pigmented. Abnormal cutaneous lesions including café-au-lait on the lower limbs may be observed. Liver disease affects about half of the patients with extensive fibrosis or cirrhosis. Cardiac abnormalities and colitis have been reported sporadically, as well as one case involving polyhydramnios, placental abnormalities, and congenital hemochromatosis. Patients may have defective antibody responses despite normal serum Ig levels and defective antigen-specific skin tests despite positive proliferative responses in vitro. Patients with THE can also present as very-early-onset inflammatory bowel disease (IBD). Small bowel biopsies show nonspecific villus atrophy with or without mononuclear cell infiltration of the lamina propria, and without specific histologic abnormalities involving the epithelium. Mutations in either tetratricopeptide repeat domain 37 *(TTC37)* gene (60%) or *SKIV2L* (40%) have been identified as cause of THE syndrome. Enterocytes with *TTC37* mutations, show reduced expression of brush-border-associated NHE-2 and -3, aquaporin-7, the Na+/I- symporter, and the H+/K+-ATPase or mislocalization relative to their normal pattern. Prognosis of this type of intractable diarrhea of infancy is poor. The long-term follow-up of these children reported that at 15 years about 50% of patients were alive or have been weaned off PN. The main complications are liver disease and infections. Most of the children achieve short final stature and half are slightly developmentally delayed.

Defects in Enteroendocrine Cells Differentiation

This class of congenital diarrheas is characterized by abnormal enteroendocrine cells development or function. The genes causing these disorders encode either transcription factors essential for the development of all or a subset of enteroendocrine cells, or cellular proteins/endopeptidases that are required for the production of active hormones from prohormones. The conditions manifest with *osmotic* diarrhea and in some, additional systemic endocrine disorders. The treatment is nutritional support and hormonal replacement if needed. Four genes have been associated with the diseases classified in this group: *NEUROG3*, *RFX6*, *ARX*, and *PCSK1* .

Enteric Anendocrinosis

NEUROG3 is a key transcription factor that controls the fate of endocrine cells in both the pancreas and intestine. Mutations of the *NEUROG3* gene produce generalized mucosal malabsorption, vomiting, diarrhea, failure to thrive, dehydration, and a hyperchloremic metabolic acidosis. Oral alimentation with anything other than water produces diarrhea. Villus-crypt architecture in small bowel biopsies is normal, but staining for neuroendocrine cells (e.g., employing antichromogranin antibodies) demonstrates a complete absence of this secretory cell lineage with the preservation of goblet cells and Paneth cells.

Proprotein Convertase 1/3 Deficiency

Autosomal recessive proprotein convertase 1/3 (PC1/3) deficiency, caused by mutations in the *PCSK1* gene, is characterized by severe congenital malabsorptive diarrhea, early-onset obesity, and other endocrine abnormalities. All functional hormones produced by endocrine cells, including those in the gut, are processed by a specific Ca2+-dependent serine endoprotease named proprotein convertase 1/3 (also known as neuroendocrine convertase 1). Chronic watery, neonatal onset diarrhea is described in infants with hyperinsulinism, hypoglycemia, hypogonadism, and hypoadrenalism. A small bowel biopsy reveals a nonspecific enteropathy.

Growth hormone deficiency, adrenal insufficiency, central diabetes insipidus, and hypogonadism are commonly observed.

Mitchell-Riley Syndrome

Mitchell-Riley syndrome is a complex clinical phenotype that includes severe intrauterine growth restriction, neonatal diabetes, GI anomalies (annular pancreas, intestinal malrotation, gallbladder agenesis, abnormal biliary tract) and chronic *osmotic* diarrhea. Several probands previously reported with Mitchell-Riley syndrome had *RFX6* mutations. DNA-binding protein RFX6 (regulatory factor X6; encoded by *RFX6*) is a winged helix transcription factor downstream of neurogenin-3 signal required for islet cell development and enteroendocrine cell function. Immunofluorescence staining in RFX6 knockout mice shows that pancreatic endocrine cells are present, but do not express the islet cell hormones including insulin, glucagon, somatostatin, or ghrelin.

Aristaless-Related Homeobox Gene Mutations

Aristaless-related homeobox (Arx) gene encodes a homeodomain containing a transcription factor required for the normal development of mouse and human enteroendocrine cells. *Arx* expression is detected in a subset of neurogenin3-

positive endocrine progenitors and is also found in a subset of hormone-producing cells. In mice, removal of *Arx* from the developing endoderm results in a decrease of some enteroendocrine cell types, such as gastrin, glucagon/GLP-1, CCK, secretin secreting cells and an increase of somatostatin-expressing cells. Mutations in the *ARX* gene are associated with a complex clinical phenotype of X-linked intellectual disability, seizures, lissencephaly, abnormal genitalia, and occasionally congenital diarrhea.

Autoimmune Enteropathy

The term autoimmune enteropathy describes a subgroup of infants with severe, protracted diarrhea, no response to dietary restriction, the presence of circulating gut autoantibodies and/or associated autoimmune diseases and the lack of severe immunodeficiency. Symptoms of autoimmune enteropathy usually occur after the first 6 mo of life, presenting with chronic diarrhea, PLE, malabsorption, and failure to thrive. The diagnosis is based on the endoscopic and histologic identification of inflammation mainly of the *small bowel* but also of the colon. Histologic findings in the small bowel include partial or complete villus atrophy, crypt hyperplasia, and an increase in chronic inflammatory cells in the lamina propria. Marked intraepithelial lymphocytosis reminiscent of CD can be present in a subset of patients. Cryptitis and crypt abscesses can also be seen and may obscure the presence of apoptosis. Immunologic analyses indicate the presence of autoantibodies including *anti–enterocyte antibodies (present in ∼85% of patients)* , as well as *anti–autoimmune enteropathy-related 75 kDa antigen* .

The differential diagnosis of pediatric autoimmune enteropathy includes other immune-mediated disorders, such as food sensitivity enteropathies (e.g., cow milk intolerance and celiac disease), Crohn disease and graft-versus-host disease. It is essential to exclude an underlying primary immune deficiency, particularly in boys with other autoimmune features because some have **IPEX syndrome** (see Chapter 152.5). Different phenotypes of IPEX syndrome patients, as well as IPEX-like forms of autoimmune enteropathy that are *FOXP3* -independent are described involving females with or without extraintestinal autoimmune disorders.

Treatment options are limited and are based on nutritional support, including parenteral nutrition and glucocorticoids followed by immunosuppressive drugs. Hematopoietic stem cell transplantation is indicated in patients with a known molecular defect, such as IPEX syndrome.

Autoimmune Polyglandular Syndrome Type 1

See Chapter 151 .

Defects in Lipids Transport and Metabolism)

See Chapter 104.3 .

After uptake from the lumen, fatty acids and monoacylglycerol are transported to the endoplasmic reticulum (ER). In the ER they are converted to triglycerides in several metabolic steps, the last of which is dependent on acyl CoA:diacylglycerol acyltransferase 1 (DGAT1). Apolipoprotein B (ApoB) and microsomal triglycerides transfer protein (MTTP) act in concert to incorporate triglycerides into chylomicrons. The newly formed chylomicrons bud from the ER in a prechylomicron transport vesicle (PCTV), which subsequently fuses with the Golgi, a process that is dependent on Sar1b. The chylomicron is then transported in a vesicle to the basal membrane, where it exits the cell.

Abetalipoproteinemia

Abetalipoproteinemia (Bassen-Kornzweig syndrome) is a rare autosomal recessive disorder of lipoprotein metabolism associated with severe fat malabsorption/steatorrhea from birth (see Chapter 104.3). Children fail to thrive during the 1st yr of life, have stools that are pale, foul smelling, and bulky. The abdomen is distended, and deep tendon reflexes are absent because of peripheral neuropathy, which is secondary to vitamin E deficiency. Intellectual development tends to be slow. After 10 yr of age, intestinal symptoms are less severe, ataxia may develop, with loss of position and vibration sensation, and the onset of intention tremors. These latter symptoms reflect involvement of the posterior columns, cerebellum, and basal ganglia. In adolescence, in the absence of adequate supplement of vitamin E, atypical retinitis pigmentosa develops.

The diagnosis is suggested by the presence of acanthocytes in the peripheral blood smear and extremely low plasma levels of cholesterol (<50 mg/dL); triglycerides are also very low (<20 mg/dL). Chylomicrons and very-low-density lipoproteins are not detectable, and the low-density lipoprotein (LDL) fraction is virtually absent from the circulation. Marked triglyceride accumulation in villus enterocytes occurs in the duodenal mucosa. Patients with abetalipoproteinemia have mutations of the *MTTP* gene. MTTP catalyzes the transfer of triglycerides to nascent ApoB particles in the ER.

Specific treatment is not available. Nutritional support and large supplements of the fat-soluble vitamins A, D, E, and K should be given. Vitamin E (100-200 mg/kg/24 hr) appears to arrest neurologic and retinal degeneration. Limiting long-chain fat intake can alleviate intestinal symptoms; medium-chain triglycerides (MCTs) can be used to supplement fat intake.

Homozygous Hypobetalipoproteinemia

Homozygous hypobetalipoproteinemia (see Chapter 104.3) is a dominantly inherited condition associated with mutations in the *APOB* gene, encoding ApoB, the apolipoprotein of the nascent chylomicron. The homozygous form is indistinguishable from abetalipoproteinemia. The parents of these patients, as heterozygotes, have reduced plasma LDL and apoprotein-B concentrations, whereas the parents of patients with abetalipoproteinemia have normal levels. On transmission electron microscopy of small bowel biopsies, the size of lipid vacuoles in enterocytes differentiates between abetalipoproteinemia and hypobetalipoproteinemia: many small vacuoles are present in hypobetalipoproteinemia, and larger vacuoles are seen in abetalipoproteinemia.

Chylomicron Retention Disease (Anderson Disease)

Chylomicron retention disease (CRD) is a rare autosomal recessive disorder caused by mutations in the *SAR1B* gene. *SAR1B* mutations result in defective trafficking of nascent chylomicrons in pre-chylomicron transport vesicles between the ER and the Golgi apparatus, interfering with the successful assembly of chylomicrons and their delivery to the lamina propria. The patients with CRD have steatorrhea, chronic diarrhea, and failure to thrive. Acanthocytosis is rare and neurologic manifestations are less severe than those observed in abetalipoproteinemia. Plasma cholesterol levels are moderately reduced (<75 mg/dL) and fasting triglycerides are normal, but the fat-soluble vitamins, particularly A and E, are very low. Treatment is early aggressive therapy with fat-soluble vitamins and modification of dietary fat intake, as in the treatment of abetalipoproteinemia.

DGAT1 Mutation

DGAT1 encodes for diacyl CoA:diacylglycerol acyl transferase (DGAT) that converts diacylglycerides to triglycerides by adding an acyl CoA moiety. In the small intestine, DGAT1 helps to reassemble the triglycerides, whereas in the liver it produces triglycerides from fatty acids synthesized de novo or taken up from the circulation. The mechanism by which *DGAT1* mutations causes diarrhea is unclear but is likely to involve the build-up of DGAT1 lipid substrates in the enterocytes or in the gut lumen. Mutations in *DGAT1* gene have been reported in patients presenting with failure to thrive, PLE, hypoalbuminemia, early-onset diarrhea, and oral vitamin D refractory rickets.

Wolman Disease

Wolman disease is a rare, lethal lipid storage disease that leads to lipid accumulation in multiple organs, including the small intestine. In addition to vomiting, severe diarrhea, and hepatosplenomegaly, patients have steatorrhea as a result of lymphatic obstruction. Insufficient free cholesterol available for steroidogenesis in adrenal glands results in adrenal insufficiency; a characteristic pattern of subcapsular adrenal calcification represents a distinctive marker of disease. Deficiency of lysosomal acid lipase (LAL) is the underlying cause of disease (see Chapter 104.4). LAL is a lysosomal enzyme that hydrolyzes cholesteryl esters and triglycerides within endo-lysosomes. Loss-of-function mutations in the *LIPA* gene are associated with variable phenotypes. Homozygous and compound heterozygous mutations, resulting in complete LAL deficiency, cause Wolman disease. Mutations associated with residual LAL activity cause cholesteryl ester storage disease, a less severe disorder exhibiting a variable phenotype. Common features in infants, children, and adults include elevated serum aminotransferase levels, dyslipidemia, hepatomegaly, liver fibrosis, and cirrhosis. Wolman disease may also present with neonatal cholestasis and severe liver disease as its main feature already in infancy. Hemophagocytic lymphohistiocytosis has been reported in few infants with Wolman disease. The hallmark of the disease is the presence of *adrenal calcification* seen on imaging, and definite diagnosis is done genetically.

Hematopoietic stem cell transplantation has been reported in few patients with variable outcome. A recombinant human enzyme-replacement therapy for LAL deficiency is approved for use in patients suffering from LAL deficiency. This treatment has allowed a small number of infants with Wolman disease to achieve a relatively normal growth rate and to improve survival. In older children and adults, the enzyme has corrected their dyslipidemia and produced significant improvement in markers of hepatic function.

Tangier Disease

See Chapter 104 .

Cellular free cholesterol is mobilized, along with phospholipid, through the export pump ABCA1, resulting in the transfer to an extracellular ApoA-I acceptor and the formation of discoidal high-density lipoprotein (HDL) cholesterol. Loss-of-function mutations in *ABCA1* genes in patients with Tangier disease cause cholesterol accumulation in the intestine, spleen, tonsils, relapsing neuropathy, orange-brown spots on the colon and ileum, and diarrhea in association with decreased plasma cholesterol levels (ApoA-I and A-II), with virtually no detectable plasma HDL. Specific therapy for Tangier disease has not yet been established.

Sitosterolemia

See Chapter 104.4 .

Sitosterol and other sterols are preferentially secreted back into the intestinal lumen through the sterol pump, paired half-transporters ABCG5/G8. Mutations of the *ABCG5* (sterolin-1) and *ABCG8* (sterolin-2) transporters result in the defective efflux of sterol and leads to the increased absorption of dietary sterols. The disorder is associated with tendon xanthomas, increased atherosclerosis, and hemolysis. Plasma levels of phytosterols (mainly sitosterol) are typically >10 mg/dL.

Bile Acid Malabsorption

Bile acids (BA) are detergent compounds secreted by and excreted from the liver, and are responsible for the solubilization of the dietary lipids, aiding in their digestion and absorption. Approximately 95% of BAs are reabsorbed in the terminal ileum and transported back to the liver, the enterohepatic circulation. The apical Na+-dependent bile salt transporter (ASBT) or ileal BA transporter (IBAT) is responsible for the active reuptake of BAs in the terminal ileum. Mutation in the *ASBT/SLC10A2* gene are very rare and are responsible for *primary* BA malabsorption, a disease associated with congenital diarrhea, steatorrhea, and reduced plasma cholesterol levels. Unabsorbed BA stimulate chloride excretion in the colon, resulting in diarrhea. *Secondary* BA malabsorption can result from ileal disease, such as in Crohn disease, and following ileal resection. The diagnosis of BA malabsorption is typically based on reduced BA retention of radiolabeled ^{75} Selenium-homocholic acid taurine (^{75} SeHCAT), increased BA synthesis (serum C4) or increased fecal BA loss. In clinical practice, diagnosis is often based on the response to BA sequestrants (e.g., cholestyramine or colesevelam), which are also the treatment of choice for this disorder.

Chronic neonatal-onset diarrhea has also been described in autosomal recessive cerebrotendinous xanthomatosis, which is caused by an inborn error of BA synthesis resulting from 27-hydroxylase deficiency. These children also present with juvenile-onset cataracts and developmental delay. Neonatal cholestasis has also been described as a presenting feature. Tendon xanthomas develop in the 2nd and 3rd decades of life. The diagnosis is important to establish, because treatment is effective when employing oral chenodeoxycholic acid.

Protein-Losing Enteropathy

PLE is a rare entity caused by a variety of intestinal and extraintestinal disorders and characterized by excessive enteric loss of plasma proteins. The clinical presentation of patients with PLE is variable and depends upon the underlying cause, but generally includes edema and hypoproteinemia. Impaired synthesis (malnutrition, liver disease), protein loss through other organs (kidney or skin) or redistribution (septic states) have to be excluded before considering PLE. The disorders causing PLE can be divided into those due to protein loss from an inflamed or abnormal mucosal surface or from derangements in intestinal lymphatics, such as in primary or secondary **IL** (Table 364.10).

Table 364.10
Causes of Protein-Losing Enteropathy

PROTEIN-LOSING ENTEROPATHY		**AGENT, DISEASES (*GENE*)**
Gastrointestinal infections	Viral infections Bacterial and parasitic diseases Gastrointestinal infestations	CMV, rotavirus *Salmonella, Shigella, Campylobacter, Clostridium difficile, Helicobacter pylori, Whipple disease* Small bowel bacterial overgrowth *Giardiasis* *Strongyloides stercoralis*
Gastrointestinal inflammatory disorders	Gastric diseases Gastrointestinal disorders	Menetrier disease Eosinophilic gastroenteropathy Food induced enteropathy Celiac disease, Crohn disease, Ulcerative colitis, Tropical sprue Radiation enteritis GVHD, NEC
Gastrointestinal malignancies	Adenocarcinomas Lymphomas Kaposi sarcoma	Esophageal, gastric, colonic
Vasculitic disorders	Henoch Schönlein purpura Systemic lupus erythematosus	
Drugs	NSAIDs	
Metabolic/genetic	Congenital disorders of glycosylation (CDG) Mutations in *DGAT1* gene Mutations in CD55	CDG-Ib (*MPI)* Congenital enterocyte heparan sulphate deficiency (*ALG6)*
Intestinal lymphangiectasia	Congenital/ Primary IL • Syndromal/genetic/ metabolic	Turner, Noonan, Klippel–Trenaunay–Weber Hennekam syndrome *(CCBE1, FAT4)* PLE with skeletal dysplasia (*FGFR3*) Generalized lymphatic dysplasia (*PIEZO1)*
	Secondary • Infection • Inflammation • Radiotherapy • Neoplastic disorders • Cardiac disorders	Abdominal tuberculosis Crohn disease, sarcoidosis Retroperitoneal fibrosis Retroperitoneal malignancies, lymphoma Constrictive pericarditis, after Fontan operation, congestive heart failure

CDG , Carbohydrate deficient glycoprotein; *CMV* , cytomegalovirus; *GVHD* , graft versus host disease; *IL* , intestinal lymphangiectasia; *NEC* , *NSAIDs* , nonsteroidal anti-inflammatory drugs; *PLE* , protein-losing enteropathy.

IL is characterized by diffuse or local dilatation of the enteric lymphatics and is located in the mucosa, submucosa, or subserosa. Lymph rich in proteins, lipids, and lymphocytes leak into the bowel lumen, resulting in PLE, steatorrhea, and lymphocyte depletion. Hypoalbuminemia, hypogammaglobulinemia, edema, lymphopenia, malabsorption of fat and fat-soluble vitamins, and chylous ascites often occur. IL can also manifest with ascites, peripheral edema, and a low serum albumin. The etiology of *primary* IL is unknown. Several genes, including vascular endothelial growth factor receptor 3 *(VEGFR3)* , prospero-related homeobox-transcriptional factor *(PROX1)* , forkhead transcriptional factor *(FOXC2)* , and SRY (sex determining region Y)-Box 18 *(SOX18)* , are involved in the development of the lymphatic system and have been shown to have altered expression in the duodenal mucosa in patients with IL. Recently, mutation in CD55, a regulator of complement activation, was described as a cause for primary PLE. The diagnosis of PLE is suggested by the typical clinical and laboratory findings in association with an elevated fecal α_1 -antitrypsin clearance. Radiologic findings of uniform, symmetric thickening of mucosal folds throughout the small intestine are characteristic but nonspecific. Small bowel mucosal biopsy in patients with IL can show dilated lacteals with distortion of villi and no inflammatory infiltrate. A patchy distribution and deeper mucosal involvement on occasion causes false-negative results on small bowel histology. Video capsule endoscopy may reveal similar lesions (Figs. 364.8 and 364.9).

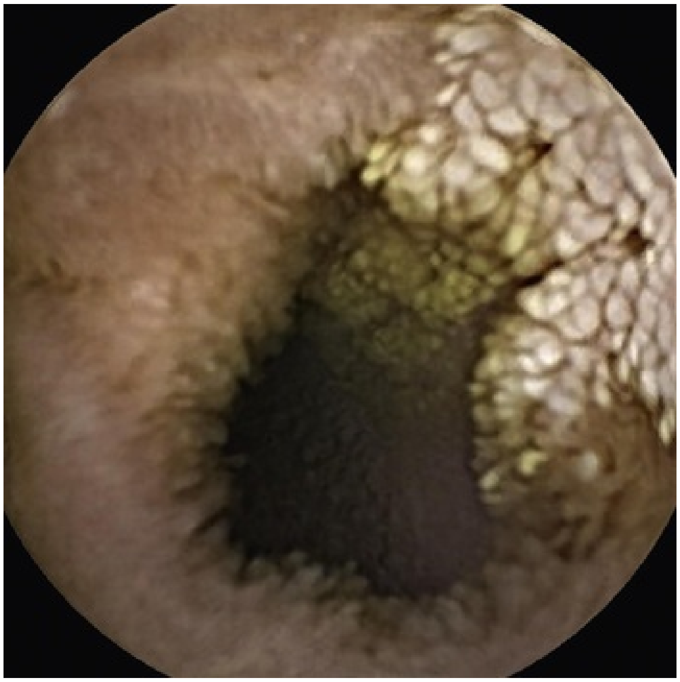

FIG. 364.8 Swollen villi detected by video capsule endoscopy in the proximal ileum. (From Gortani G, Maschio M, Ventura A: A child with edema, lower limb deformity, and recurrent diarrhea, *J Pediatr* 161:1177, 2012, Fig. 1.)

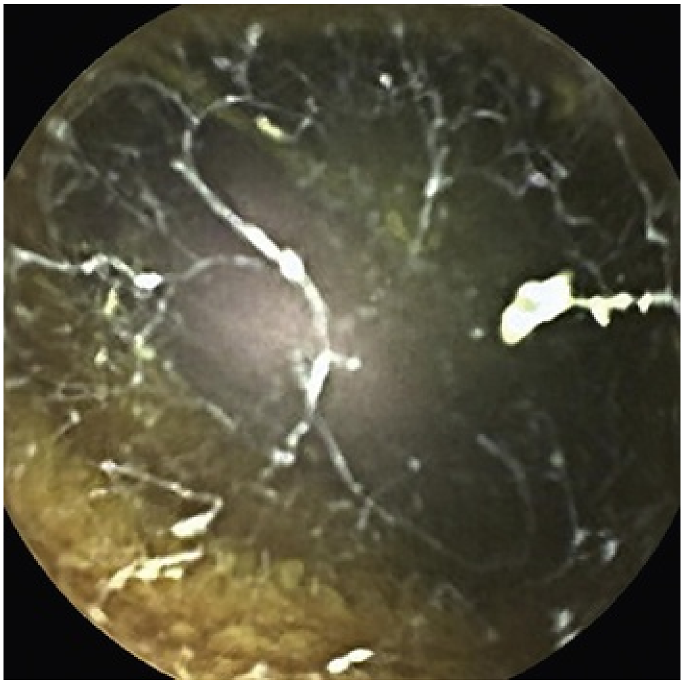

FIG. 364.9 Protein-rich lymphatic fluid aggregates detected by video capsule endoscopy in the intestinal lumen. (From Gortani G, Maschio M, Ventura A: A child with edema, lower limb deformity, and recurrent diarrhea, *J Pediatr* 161:1177, 2012, Fig. 2.)

Treatment of PLE is generally supportive and consists of a low fat and high-protein diet. In patients with IL, a low-fat and high-protein diet supplemented with MCTs is recommended. Besides dietary adjustments, appropriate treatment for the underlying etiology is necessary, as well as supportive care to avoid complications of edema. Rarely, parenteral nutrition is required. If only a portion of the intestine is involved, surgical resection may be considered. Few patients with lymphatic malformation and generalized lymphatic anomalies were successfully treated with propranolol. Successful use of mTOR inhibitor, everolimus, in a patient with primary IL has been reported. Prognosis depends upon the severity and treatment options of the underlying disease.

Intestinal Infections and Infestations Associated With Malabsorption

Alfredo Guarino, Raanan Shamir

Keywords

Postinfectious diarrhea
Environmental enteropathy
Tropical sprue
Proximal intestinal bacterial overgrowth
Whipple disease

Malabsorption is a rare consequence of primary intestinal infection and infestation in immunocompetent children, but is relatively common in malnourished children and is associated with significant mortality. Often malabsorption is associated with diarrhea and triggers a vicious circle with wasting and growth failure. For children living in developing countries, malabsorption is associated with long-term growth failure leading to stunting within a peculiar condition defined as environmental enteropathy, in which diarrhea is not always present. Generally, malabsorption is associated with a duration of an intestinal infection longer than expected. *Prolonged* diarrhea is an acute-onset diarrhea that lasts >7 days, whereas *chronic* diarrhea lasts >14 days (some use 30 days to define chronic).

Postinfectious Diarrhea

In infants and toddlers, chronic diarrhea can appear following infectious enteritis, regardless of the nature of the pathogen. The pathogenesis of the diarrhea is not always clear and may be related to persistent infection or re-infection, secondary lactase deficiency, food protein allergy, antibiotic-associated diarrhea or a combination of these. In some cases, postinfectious diarrhea may be the initial manifestation of functional diarrhea, in which case is not associated with malabsorption.

Treatment of postinfectious diarrhea is supportive and may include a lactose-free diet in the presence of secondary lactase deficiency; infants might require a semi-elemental diet. The beneficial effect of specific probiotic products may be indicated in selected conditions.

Proximal Intestinal Bacterial Overgrowth

Bacteria are normally present in large numbers in the colon (10^{11}-10^{13} colony-forming units [CFU]/g of feces) and have a symbiotic relationship with the host, providing nutrients and protecting the host from pathogenic organisms. Bacteria are usually present only in a small number in the stomach and small bowel; excessive numbers of bacteria in the stomach or small bowel are harmful. Bacterial overgrowth can result from clinical conditions that alter the gastric pH or small bowel motility, including disorders such as partial bowel obstruction, diverticula, intestinal failure, intestinal duplications, diabetes mellitus, idiopathic intestinal pseudoobstruction syndrome, and scleroderma, as well as proton pump inhibitor use. Prematurity, immunodeficiency, and malnutrition are other factors associated with bacterial overgrowth of the small bowel.

The diagnosis of bacterial overgrowth is often difficult and can be made by culturing small bowel aspirate ($>10^5$ CFU/mL) or by a lactulose hydrogen breath test. Lactulose is a synthetic disaccharide, which is not digested by mucosal brush border enzymes but can be fermented by bacteria. High baseline breath hydrogen and a quick rise in hydrogen in expired breath samples support the diagnosis of bacterial overgrowth; false-positive tests are common.

Bacterial overgrowth leads to inefficient intraluminal processing of dietary fat with steatorrhea due to bacterial deconjugation of bile salts, vitamin B_{12} malabsorption, and microvillus brush border injury with further malabsorption. Bacterial consumption of vitamin B_{12} and enhanced synthesis of folate result in decreased vitamin B_{12} and increased folate serum levels. Overproduction of *D-lactate* (the isomer of L-lactate) can cause stupor, neurologic dysfunction, and shock from D-lactic acidosis. Lactic acidosis should be suspected in children at risk of bacterial overgrowth, who show signs of neurologic deterioration and a high anion gap metabolic acidosis not explained by measurable acids such as L-lactate. Measurement of D-lactate is required because standard lactate assay only measures the L-isomer.

The treatment of bacterial overgrowth focuses on the correction of underlying causes such as partial obstruction. Oral metronidazole can provide relief for many months, but is not always effective. The cycling of antibiotics, including azithromycin, trimethoprim-sulfamethoxazole, ciprofloxacin, and metronidazole, may be required. Other alternatives are oral nonabsorbable antibiotics such as aminoglycosides, nitazoxanide, or rifaximin. Occasionally, antifungal therapy is required to control fungal overgrowth of the bowel.

Environmental Enteropathy (Tropical Sprue)

This is the result of the interactions between enteric pathogens, enteropathy, and malnutrition, and is associated with a peculiar intestinal histology (enteropathy) occurring in several developing countries. It is similar or overlaps with tropical sprue and is associated with evident or subclinical malabsorption. It is a frequent cause of death in childhood in endemic regions, particularly in Asian areas, such as south India, and in several African countries. In developing countries selected pathogens including rotavirus, shigella, cryptosporidium, and enterotoxigenic *Escherichia coli* cause the majority of intestinal infections leading to moderate to severe diarrhea and often trigger a vicious circle with malnutrition. This tends to progress to wasting and stunting with or without a clear association with diarrhea.

In addition to a high risk of death, environmental enteropathy impairs normal growth and brain development, and impacts productivity. The etiology of this disorder is unclear because it follows outbreaks of acute diarrheal disease and improves with antibiotic therapy; therefore an infectious etiology is suspected. Nevertheless, environmental enteropathy includes inter-related mechanisms such as intestinal malabsorption, increased permeability, loss of intestinal mass, inflammation, increased bacterial translocation, and impairment of immune response. The incidence is decreasing worldwide, largely because of an improvement in hygiene and access to nutrients. Clinical symptoms include fever and malaise followed by diarrhea. After about a week the acute features subside, and anorexia, intermittent diarrhea, and chronic malabsorption result in severe malnutrition characterized by glossitis, stomatitis, cheilosis, night blindness, hyperpigmentation, and edema, reflecting the various nutrient deficiencies. Muscle wasting is often marked, and the abdomen is often distended. Megaloblastic anemia results from folate and vitamin B_{12} deficiencies.

Diagnosis is made by small bowel biopsy, which shows villous flattening with crypt hyperplasia and mild intestinal inflammation, with lipid accumulation in the surface epithelium.

Treatment requires nutritional supplementation, including supplementation of folate and vitamin B_{12} . To prevent recurrence, 6 mo of therapy with oral folic acid (5 mg) and antibiotics are recommended. Relapses occur in 10–20% of patients who continue to reside in an endemic tropical region. The scale-up of infrastructure, particularly the improvement in hygiene conditions and access to food in association with people empowerment through educational interventions, are the key to prevention rather than medical interventions in individual cases.

Whipple Disease

Whipple disease is a chronic systemic infectious disorder. It is a rare disease, especially in childhood caused by *Tropheryma whipplei,* which can be cultured from a lymph node in the involved tissue.

The most common symptoms in Whipple disease are diarrhea, abdominal pain, weight loss, and joint pains. Malabsorption, lymphadenopathy, skin hyperpigmentation, and neurologic symptoms are also common. Involvement of other organs, such as eyes, heart, and kidneys, has been reported.

Diagnosis requires a high index of suspicion and is made upon demonstration of PAS-positive macrophage inclusions in the biopsy material, usually a duodenal biopsy. Positive identification using polymerase chain reaction for *T. whipplei confirms the diagnosis.*

Treatment requires antibiotics, such as trimethoprim sulfamethoxazole, for 1-2 yr. A 2-wk course of intravenous ceftriaxone or meropenem, followed by trimethoprim sulfamethoxazole for 1 yr, is recommended.

Immunodeficiency Disorders

Amit Assa, Raanan Shamir

Keywords

Diarrhea
hypogammaglobulinemia
immunoglobulins

GI disorders are present in 5–50% of patients with primary immune deficiencies driven by the fact that the gut is the largest lymphoid organ in the body. Malabsorption due to either intestinal inflammation or infection is common with primary immunodeficiency disorders; chronic diarrhea with failure to thrive is often the mode of presentation. Defects of humoral and or cellular immunity may be involved, including selective IgA deficiency, agammaglobulinemia, common variable immunodeficiency disease (CVID), severe combined immunodeficiency (SCID), hyper IgM syndrome, Wiskott-Aldrich syndrome, or chronic granulomatous disease. Although most patients with selective IgA deficiency are asymptomatic, malabsorption caused by giardiasis or nonspecific enteropathy with bacterial overgrowth can occur. Malabsorption syndrome or chronic noninfectious diarrhea manifesting as sprue-like enteropathy with villous atrophy has been reported in 60% of children with CVID. Malabsorption has also been reported in approximately 10% of patients with late-onset CVID, often secondary to giardiasis. Malabsorption as a result of infectious diarrhea—most commonly related to giardia, salmonella, campylobacter, cryptosporidium, and enteroviruses—is a well-recognized complication of X-linked agammaglobulinemia. Cryptosporidium is the most common pathogen causing diarrhea and malabsorption in hyper-IgM syndrome patients. SCID-affected children develop severe diarrhea and malabsorption early in life involving viral and opportunistic infections, especially chronic rotavirus infection, cytomegalovirus, and adenovirus. Malabsorption associated with immunodeficiency is exacerbated by villus atrophy and secondary disaccharidase deficiency. In chronic granulomatous disease, phagocytic function is impaired and granulomas develop throughout the GI tract, mimicking Crohn disease. In addition to failure to thrive, it is important to consider that malabsorption associated with immunodeficiency is often complicated by micronutrient deficiencies, including vitamins A, E, and B_{12} , and calcium, zinc, and iron.

Immunodeficiencies in children are more often secondary to other conditions such as cancer and chemotherapy. Malnutrition, diarrhea, and failure to thrive are common in untreated children with HIV infection. The risk of GI infection is related to the depression of the CD4 count. Opportunistic infections include *Cryptosporidium parvum*, cytomegalovirus, *Mycobacterium avium-intracellulare*, *Isospora belli*, *Enterocytozoon bieneusi*, *Candida albicans*, astrovirus, calicivirus, adenovirus, and the usual bacterial enteropathogens. In these patients, *Cryptosporidium* can cause a chronic secretory diarrhea.

Cancer chemotherapy can damage the bowel mucosa, leading to secondary malabsorption of disaccharides such as lactose. After bone marrow transplantation, mucosal damage from graft-versus-host disease can cause diarrhea and malabsorption. Small bowel biopsies show nonspecific villus atrophy, mixed inflammatory cell infiltrates, and increased apoptosis. Cancer chemotherapy and bone marrow transplantation are associated with pancreatic damage, which may lead to exocrine pancreatic insufficiency.

Immunoproliferative Small Intestinal Disease

Yael Mozer-Glassberg, Raanan Shamir

Keywords

IPSID (**immunoproliferative small intestinal disease**)
MALT (**mucosa associated lymphoid-tissue lymphoma**)
Antibiotic treatment

Lymphoma (Chapter 523) is the most common small bowel malignancy in the pediatric age group. Malignant lymphomas of the small intestine are categorized into 3 subtypes: Burkitt lymphoma, non-Hodgkin lymphomas, and Mediterranean lymphoma. Burkitt lymphoma, the most common form in children, characteristically involves the terminal ileum with extensive abdominal involvement. The relatively uncommon *Western* type of non-Hodgkin lymphomas (usually large B-cell type), can involve various regions of the small intestine. **Mediterranean lymphoma** (termed by The World Health Organization as *immunoproliferative small intestinal disease [IPSID]* or α-heavy chain disease) is a rare extra-nodal marginal zone B-cell lymphoma occurring primarily in the proximal small intestine. It is a variant of **mucosa-associated lymphoid-tissue lymphoma (MALT)** described in young adults from the developing world, and is characterized by lymphoplasmacytic intestinal infiltrates with monotypic α-heavy chain expression.

IPSID occurs most often in the proximal small intestine in older children and young adults in the Mediterranean basin, Middle East, Asia, and Africa. Poverty and frequent episodes of gastroenteritis during infancy are antecedent risk factors. The initial clinical presentation is intermittent diarrhea and abdominal pain. Later, chronic diarrhea with malabsorption, PLE, weight loss, digital clubbing, and growth failure ensue. Intestinal obstruction, abdominal masses, and ascites are common in advanced stages.

In contrast to primary nonimmunoproliferative small intestinal lymphomas, in which the pathology in the intestine is usually focal, involving specific segments of the intestine and leaving the segments between the involved areas free of disease, the pathology in IPSID is diffuse, with a mucosal cellular infiltrate involving large segments of the intestine and sometimes the entire length of the intestine, thus producing malabsorption. Molecular and immunohistochemical studies demonstrated an association with *Campylobacter jejuni* infection. The differential diagnosis includes chronic enteric infections (parasites, tropical sprue), CD, and other lymphomas. Radiologic findings include multiple filling defects, ulcerations, strictures, and enlarged mesenteric lymph nodes on CT scan.

The diagnosis is usually established by endoscopic biopsies and/or laparotomy. Upper endoscopy shows thickening, erythema, and nodularity of the mucosal folds in the duodenum and proximal jejunum. Capsule endoscopy may be helpful in the diagnosis. As the disease progresses, tumors usually appear in the proximal small intestine and rarely in the stomach. The diagnosis requires multiple duodenal and jejunal mucosal biopsies showing dense mucosal infiltrates, consisting of centrocyte-like and plasma cells. Progression to higher-grade large-cell lymphoplasmacytic and immunoblastic lymphoma is characterized by increased plasmocytic atypia with formation of aggregates and later sheets of dystrophic plasma cells and immunoblasts invading the submucosa and muscularis propria. A serum marker of IgA, a heavy-chain paraprotein, is present in most cases.

Treatment of early-stage IPSID with antibiotics results in complete remission in 30–70% of cases (tetracycline, ampicillin, or metronidazole) and some patients achieving durable remission that may last several years, but they should be monitored closely for relapse. However, the majority of untreated IPSID cases progress to lymphoplasmacytic and immunoblastic lymphoma invading the intestinal wall and mesenteric lymph nodes, which can metastasize to distant organs, requiring aggressive treatment with surgery and/or chemotherapy.

enteral nutrition

enteral autonomy
complications
central line infection
intestinal failure associated liver disease
small bowel bacterial overgrowth
lengthening procedure
intestinal transplantation

Short bowel (or short gut) syndrome results from congenital malformations or resection of the small bowel (Table 364.11). Its incidence increases with low birth weight and earlier gestational age and is estimated at 7/1,000 live births in U.S. infants with birth weight <1,500 mg. Loss of >50% of the small bowel, with or without a portion of the large intestine, can result in symptoms of generalized malabsorptive disorder or in specific nutrient deficiencies, depending on the region of the bowel resected. At birth, the length of small bowel is 200-250 cm; by adulthood, it grows to 300-800 cm. Bowel resection in an infant has a better prognosis than in an adult because of the potential for intestinal growth and adaptation. An infant with as little as 15 cm of bowel with an ileocecal valve, or 20 cm without, has the potential to survive and be eventually weaned from parenteral nutrition.

Table 364.11

Causes of Short Bowel Syndrome

CONGENITAL
Congenital short bowel syndrome Intestinal atresia Gastroschisis
BOWEL RESECTION
Necrotizing enterocolitis Volvulus with or without malrotation Long segment Hirschsprung disease Meconium peritonitis Crohn disease Trauma

In addition to the length of the bowel, the anatomic location of the resection is also important. The proximal 100-200 cm of jejunum is the main site for carbohydrate, protein, iron, and water-soluble vitamin absorption, whereas fat absorption occurs over a longer length of the small bowel. Depending on the region of the bowel resected, specific nutrient malabsorption can result. Vitamin B_{12} and bile salts are only absorbed in the distal ileum (Fig. 364.10). Jejunal resections are generally tolerated better than ileal resections because the ileum, unlike the jejunum, can adapt to absorb nutrients and fluids. Net sodium and water absorption is relatively much higher in the ileum. Ileal resection has a profound effect on fluid and electrolyte absorption due to malabsorption of sodium and water by the remaining ileum; ileal malabsorption of bile salts stimulates increased colonic secretion of fluid and electrolytes. The presence of a colon in continuity is better tolerated and improves absorption and enteral autonomy.

FIG. 364.10 **Absorption of nutrients in the small bowel varies with the region.**

Treatment

After bowel resection, treatment of short bowel syndrome is initially focused on repletion of the massive fluid and electrolyte losses while the bowel initially accommodates to absorb these losses. Proton pump inhibitors are usually added to reduce gastric secretions and to improve fluid balance. Nutritional support is often provided via parenteral nutrition. A central venous catheter should be inserted to provide parenteral fluid and nutrition support. The ostomy or stool output should be measured, and fluid and electrolyte losses adequately replaced. Measurement of urinary Na^+ to assess body Na^+ stores is useful to prevent Na^+ depletion. Maintaining urinary Na^+ higher than 20 mmol/L ensures that Na^+ intake is adequate. Early introduction of even a small amount of enteral feeding by mouth or tube feeding is essential and enhances bowel adaptation.

After the initial few weeks following resection, fluid and electrolyte losses stabilize, and the focus of therapy shifts to bowel rehabilitation with a gradual increase in the volume of enteral feeds. Continuous or bolus small-volume enteral feeding should be promoted with an extensively or partially hydrolyzed protein with MCT-enriched formula if the colon is in continuation. Breast milk is preferable over formula and its use should be encouraged as it stimulates gut hormones and promotes mucosal growth. Enteral feeding also increases pancreatobiliary flow and reduces parenteral nutrition-induced hepatotoxicity. Infant should be given a small amount of formula or mother's milk by mouth as early as possible to maintain an interest in oral feeding and to minimize or avoid the development of oral aversion. As intestinal adaptation occurs, enteral feeding increases, and parenteral supplementation decreases. The bowel mucosa proliferates, and the bowel lengthens with growth.

Approximately 60% of patients with short bowel syndrome achieve **enteral autonomy** within 5 yr of bowel resection and the majority achieve it in the first 2-3 yr after resection. In addition to bowel length, the presence of the ileocecal valve, a diagnosis of necrotizing enterocolitis, and care by an intestinal rehabilitation program increase the likelihood of achieving enteral autonomy.

Patients may require repeat surgeries for obstruction or bowel lengthening procedures (longitudinal lengthening, serial transverse enteroplasties or both) to optimize the bowel absorptive capacity. The bowel lengthening procedure is indicated in patients with dilated bowel who are unable to progress towards enteral autonomy or those with refractory bacterial overgrowth.

Vitamin and micronutrient deficiencies are common and worsen over time. The management of specific micronutrient and vitamin deficiencies and the treatment of transient problems, such as postinfectious mucosal malabsorption, are required. GI infections or small bowel bacterial overgrowth can cause setbacks in the progression to full enteral feeding in patients with marginal absorptive function. Marked increase in stool output or evidence of carbohydrate malabsorption (stool pH <5.5 and positive test for reducing substances) contraindicate further increases in enteral feeds. Slow advancement of continuous or bolus enteral feeding rates continues until all nutrients are provided enterally.

In patients with large stool output, the addition of soluble fiber and antidiarrheal agents, such as loperamide and anticholinergics, can be beneficial, although these drugs can increase the risk of bacterial overgrowth. Cholestyramine can be beneficial for patients with distal ileal resection, but its potential depletion of the BA pool can increase steatorrhea. Bacterial overgrowth is common in infants with a short bowel and can delay progression of enteral feedings. Empirical treatment with metronidazole or other antibiotics (nitazoxanide, rifaximin) is often useful. Diets high in fat and without simple sugars may be helpful in reducing bacterial overgrowth as well as enhancing adaptation.

Complications

Long-term complications of short bowel syndrome include those of parenteral nutrition: central catheter infection, thrombosis, intestinal failure associated liver disease (IFALD), and gallstones. Appropriate care of the central line to prevent infection and catheter-related thrombosis is extremely important. Sepsis is a leading cause of death, can occur any time after treatment is initiated (months to years later), and is most often bacterial (single organism more common than polymicrobial), although fungal infection may be noted in 20–25% of septic episodes. The use of an ethanol lock or Taurolidine lock can reduce the incidence of central catheter infections and prevent infections.

Some patients need long-term parenteral nutritional support, and lack of central line access is potentially life threatening; inappropriate removal or frequent changes of central lines in the neonatal period should be avoided. **IFALD** can lead to cholestasis, cirrhosis, and liver failure, and is a common reason for death or need the for transplantation. The incidence and severity of IFALD has significantly reduced over the last decade, probably due to the reduced use of soy-based lipid emulsions and the positive effect of omega–3-based lipid emulsions on cholestasis. Other complications of terminal ileal resection include vitamin B_{12} deficiency, which might not appear until 1-2 yr after parenteral nutrition is withdrawn. Long-term monitoring for deficiencies of vitamin B_{12} , folate, iron, fat-soluble vitamins, and trace minerals, such as zinc and copper, is important. Renal stones can occur as a result of hyperoxaluria secondary to steatorrhea (calcium binds to the excess fat and not to oxalate, so more oxalate is absorbed and excreted in the urine). Venous thrombosis and vitamin deficiency have been associated with hyperhomocysteinemia in short bowel syndrome. Bloody diarrhea secondary to patchy, mild colitis can rarely develop during the progression of enteral feedings. The pathogenesis of this *feeding colitis* is unknown, but it is usually benign and can improve with a hypoallergenic diet or treatment with mesalamine.

In some children with life-threatening complications of parenteral nutrition, especially progressive liver failure and loss of vascular access, small intestine and liver transplantation becomes the preferred therapy (see Chapter 365).

Chronic Malnutrition

Yaron Avitzur, Raanan Shamir

Keywords

Acute malnutrition
chronic malnutrition
severe malnutrition
anthropometry
diarrhea
refeeding syndrome

Primary malnutrition is very common in developing countries and is directly related to increased disease burden and mortality. In developed countries, the etiology, clinical course, and outcomes are different. The American Society for Parenteral and Enteral Nutrition (ASPEN) defined pediatric malnutrition in developed countries as an imbalance between nutrient requirements and intake that results in cumulative deficits of energy, protein, or micronutrients that may negatively affect growth, development, and other relevant outcomes. Malnutrition can be classified as *illness related* (caused by disease/trauma) or *non-illness–related* (caused by environmental/behavioral factors). It can be further classified into *acute* malnutrition (<3 mo; short duration, weight loss without stunting) or *chronic* malnutrition (>3 mo; weight loss and stunting) that may differ in their etiology, growth patterns, and outcome. Chronic malnutrition occurs mainly as a result of decreased food intake, malabsorption syndromes, and increased nutritional needs in children with chronic diseases. Malnutrition is diagnosed in 11–50% of hospitalized children and reports from Europe suggest a prevalence of close to 20% in chronically ill children. Child neglect and improper preparation of formula can result in severe malnutrition. Malnutrition can be identified by evaluating dietary intake, by medical history (anorexia, vomiting, dysphagia, mood and behavioral changes, abdominal pain, diarrhea), by anthropometric measurements (e.g., reduced weight per age and weight per height, body mass index <5th percentile, mid upper arm circumference <−1 z score), by clinical signs of nutrient deficiencies (atrophic tongue in iron deficiency; anemia or alopecia in zinc deficiency) and by laboratory tests assessing vitamin and micronutrient deficiencies. Screening tools for malnutrition are used in adults to provide a simple and fast way of diagnosing those patients at risk for malnutrition. Few such screening tools for the pediatric population were developed to assess children at risk, but their use in clinical practice is still questionable.

Malnourished children suffer from impaired immunity, chronic enteropathy, poor wound healing, muscle weakness, and diminished psychologic drive. Malnutrition has short-term consequences (increased disability, morbidity, and mortality) and long-term consequences (final adult size, developmental deficiencies, economic productivity). Undernutrition in hospitalized children is associated with increased infectious complications, delayed recovery, increased length of stay and costs, increased readmission rate, and increased mortality.

Nutritional rehabilitation in malnourished children is discussed in Chapter 58
.

Chronic malnutrition complicated by diarrheal dehydration is a commonly observed phenomenon. Infectious diarrhea is common in tropical and subtropical countries, in the setting of poor hygiene practices and water quality, in immunocompromised hosts (e.g., HIV, congenital immunodeficiency), and when impairment of the immune response is due to chronic malnutrition itself. In children with chronic disorders, diarrhea may be related to the underlying disease that should be sought for. Examples include noncompliance with a gluten-free diet in CD, noncompliance with pancreatic enzyme treatment in cystic fibrosis, and cholestatic liver disease with fat malabsorption. Malnutrition per se can lead to exocrine pancreatic insufficiency, which, in turn, aggravates malabsorption and diarrhea.

In infants and children with severe malnutrition, many of the signs normally used to assess the state of hydration or shock are unreliable. Severe malnutrition might be accompanied by sepsis; thus, children with septic shock might not have diarrhea, thirst, or sunken eyes but may be hypothermic, hypoglycemic, or febrile. Cardiac reserve is lowered, and heart failure is a common complication.

Despite clinical signs of dehydration, urinary osmolality may be low in the chronically malnourished child. Renal acidifying ability is also limited in patients with malnutrition.

Management of the diarrhea in chronically malnourished children is based on 3 principles: oral rehydration to correct dehydration, rapid resumption of feeds with avoidance of periods of nothing by mouth, and treating the etiology of the diarrhea.

When treating the dehydration, it must be remembered that in dehydrated and malnourished infants there appears to be overexpansion of the extracellular space accompanied by extracellular and presumably intracellular hypoosmolality. Thus reduced or hypotonic osmolarity oral rehydration solutions are indicated in this setting. When oral rehydration is not possible, the route of choice is nasogastric, and intravenous therapy should be avoided if possible.

Initial intravenous therapy in profound dehydration is designed to improve the circulation and expand extracellular volume. For patients with edema, the quality of fluid and the rate of administration might need to be readjusted from recommended levels to avoid overhydration and pulmonary edema. Blood should be given if the patient is in shock and severely anemic. Potassium salts can be given early if urine output is good. Clinical improvement may be more rapid with magnesium therapy.

Children with chronic malnutrition are at risk for the refeeding syndrome (see

Chapter 58). Therefore initial calorie provision should not exceed the previous daily intake and is usually begun at 50–75% of estimated resting energy expenditure, with rapid increase to caloric goals once there are no severe abnormalities in sodium, potassium, phosphorus, calcium, or magnesium. Correction of malnutrition and catch-up growth are not part of the primary treatment of these children, but a nutrition rehabilitation plan is necessary.

Carbohydrate Malabsorption

Symptoms of carbohydrate malabsorption include loose watery diarrhea, flatulence, abdominal distention, and pain. Some children are asymptomatic unless the mal-absorbed carbohydrate is consumed in large amounts. Disaccharidases are present on the brush border membrane of the small bowel. **Disaccharidase deficiency** can be caused by a genetic defect or secondary to damage to the small bowel epithelium, as occurs with infection or inflammatory disorders.

Unabsorbed carbohydrates enter the large bowel and are fermented by intestinal bacteria, producing organic acids and gases such as methane and hydrogen. The gases can cause discomfort and the unabsorbed carbohydrates and the organic acids cause osmotic diarrhea characterized by an acidic pH and the presence of either reducing or nonreducing sugars in the stool. Hydrogen gas can be detected in the breath as a sign of fermentation of unabsorbed **carbohydrates (H_2 -breath test).**

Lactase Deficiency

Congenital lactase deficiency is rare and is associated with symptoms occurring on exposure to lactose in milk. Fewer than 50 cases have been reported worldwide. In patients with congenital lactase deficiency, 5 distinct mutations in the coding region of the *LCT* gene were found. In most patients (84%), homozygosity for a nonsense mutation, 4170T-A (Y1390X; OMIM 223000), designated Fin (major), was found.

Primary adult type-hypolactasia is caused by a physiologic decline in lactase actively that occurs following weaning in most mammals. The brush-border lactase is expressed at low levels during fetal life; activity increases in late fetal life and peaks from term to 3 yr, after which levels gradually decrease with age. This decline in lactase levels varies between ethnic groups. Lactase deficiency occurs in approximately 15% of white adults, 40% of Asian adults, and 85% of African-American adults in the United States. Lactase is encoded by a single gene *(LCT)* of approximately 50 kb located on chromosome 2q21. C/T (−13910) polymorphisms of the *MCM6* gene were found to be related to adult-type hypolactasia in most European populations. In 3 African populations—Tanzanians, Kenyans, and Sudanese—3 single-nucleotide polymorphisms, G/C(−14010), T/G(−13915), and C/G(−13907), were identified with lactase persistence and have derived alleles that significantly enhance transcription from the lactase gene promoter in vitro.

Secondary lactose intolerance follows small bowel mucosal damage (CD, acute severe gastroenteritis) and is usually transient, improving with mucosal healing. Lactase deficiency can be diagnosed by H_2 -breath test (2 g/kg up to 25 g) or by measurement of lactase activity in mucosal tissue retrieved by small bowel biopsy. Diagnostic testing is not mandatory, and often simple dietary changes that reduce or eliminate lactose from the diet relieve symptoms.

Treatment of lactase deficiency consists of a milk-free diet. A lactose-free formula (based on either soy or cow's milk) can be used in infants. In older children, low-lactose milk can be consumed. The addition of lactase to dairy products usually abbreviates the symptoms.

Live-culture yogurt contains bacteria that produce lactase enzymes and is therefore tolerated in most patients with lactase deficiency. Hard cheeses and cottage cheeses have a small amount of lactose and are generally well tolerated.

Fructose Malabsorption

Children consuming a large quantity of juice rich in fructose, corn syrup, or natural fructose in fruit juices can present with diarrhea, abdominal distention, and slow weight gain. Restricting the amount of juice in the diet resolves the symptoms and helps avoid unnecessary investigations. A fructose H_2 breath test can be helpful in the diagnosis of fructose malabsorption. The reason for fructose malabsorption is the reduced abundance of GLUT-5 transporter on the surface of the intestinal brush-border membrane, which occurs in approximately 5% of the population.

Sucrase-Isomaltase Deficiency

Sucrase-isomaltase (SI) deficiency is a rare autosomal recessive disorder with a complete absence of sucrase and reduced maltase digestive activity. The SI complex is composed of 1,927 amino acids encoded by a 3,364 bp messenger RNA. The gene locus on chromosome 3 has 30 exons spanning 106.6 kb. The majority of SI mutations result in a lack of enzyme protein synthesis (null mutation). Posttranslational processing defects are also identified.

Approximately 2% of Europeans and Americans are mutant heterozygote. Sucrase deficiency is especially common in indigenous Greenlanders (estimated 5%) in whom it is often accompanied by lactase deficiency. Gene variants of the SI are found to have some implications in IBS, because they were found more often in patients with IBS than in controls.

Symptoms of SI deficiency usually begin when the infant is exposed to sucrose or a glucose polymer diet. This can occur with ingestion of non–lactose-based infant formula or on the introduction of pureed food, especially fruits and sweets. Diarrhea, abdominal pain, and poor growth are observed. Occasionally, patients present with symptoms in late childhood or even adult life, but careful history often indicates that symptoms appeared earlier. Diagnosis of sucrase-isomaltase malabsorption requires acid hydrolysis of stool for reducing substances because sucrase is a nonreducing sugar. Alternatively, a diagnosis can be achieved with a hydrogen breath test, a direct enzyme assay of small bowel biopsy, or genetic testing.

The mainstay of treatment is lifelong dietary restriction of sucrose-containing foods, although symptoms may diminish with age. Enzyme replacement with a purified yeast enzyme, sacrosidase (Sucraid), is a highly effective adjunct to dietary restriction.

Glucose-Galactose Malabsorption

More than 30 different mutations of the sodium/glucose cotransporter gene *(SGLT1)* are identified. These mutations cause a rare autosomal recessive disorder of intestinal glucose and galactose/Na^+ cotransport system that leads to osmotic diarrhea. Because most dietary sugars are polysaccharides or disaccharides with glucose or galactose moieties, diarrhea follows the ingestion of glucose, breast milk, or conventional lactose-containing formulas. Dehydration and acidosis can be severe, resulting in death.

The stools are acidic and contain sugar. Patients with the defect have normal absorption of fructose, and their small bowel function and structure are normal in all other aspects. Intermittent or permanent glycosuria after fasting, or after a glucose load, is a common finding because of the transport defect also being present in the kidney. The presence of reducing substances in watery stools and slight glycosuria despite low blood sugar levels is highly suggestive of glucose-galactose malabsorption. Malabsorption of glucose and galactose is easily identified using the breath hydrogen test. It is safe to perform the 1st test with a dose of 0.5 g/kg of glucose; if necessary, a 2nd test can be performed using 2 g/kg. Breath H_2 will rise more than 20 ppm. The small intestinal biopsy is useful to document a normal villous architecture and normal disaccharidase activities. The identification of mutations of *SGLT1* makes it possible to perform prenatal screening in families at risk for the disease.

Treatment consists of rigorous restriction of glucose and galactose. Fructose, the only carbohydrate that can be given safely, should be added to a carbohydrate-free formula at a concentration of 6–8%. Diarrhea immediately ceases when infants are given such a formula. Although the defect is permanent, later in life, limited amounts of glucose, such as starches or sucrose, may be tolerated.

Exocrine Pancreatic Insufficiency

Chapter 376 discusses disorders of exocrine pancreatic insufficiency. Cystic fibrosis is the most common congenital disorder associated with exocrine pancreatic insufficiency. Although rare, the next most common cause of pancreatic insufficiency in children is Shwachman-Diamond syndrome. Other rare disorders causing exocrine pancreatic insufficiency are Johanson-Blizzard syndrome (severe steatorrhea, aplasia of alae nasi, deafness, hypothyroidism, scalp defects) Pearson bone marrow syndrome (sideroblastic anemia, variable degree of neutropenia, thrombocytopenia), and isolated pancreatic enzyme deficiency (lipase, colipase and lipase-colipase, trypsinogen, amylase). Deficiency of enterokinase—a key enzyme that is produced in the proximal small bowel and is responsible for the activation of trypsinogen to trypsin—manifests clinically as exocrine pancreatic insufficiency.

Autoimmune polyendocrinopathy syndrome type 1 , a rare autosomal recessive disorder, is caused by mutation in the autoimmune regulator gene (AIRE). Chronic mucocutaneous candidiasis is associated with failure of the parathyroid gland, adrenal cortex, pancreatic β cells, gonads, gastric parietal cells, and thyroid gland. Pancreatic insufficiency and steatorrhea are associated with this condition.

Enterokinase (Enteropeptidase) Deficiency

Enterokinase (enteropeptidase) is a brush-border enzyme of the small intestine. It is responsible for the activation of trypsinogen into trypsin. Deficiency of this enzyme results in severe diarrhea, malabsorption, failure to thrive, and hypoproteinemic edema after birth.

The diagnosis can be established by measuring the enzyme level in intestinal tissue or by genetic testing, as enterokinase deficiency is caused by mutation in the serine protease-7 gene *(PRSS7)* on chromosome 21q21. Treatment of this rare autosomal recessive disorder consists of replacement with pancreatic enzymes and administration of a protein hydrolyzed formula with added MCT oil in infancy.

Trehalase Deficiency

The disaccharide trehalose is mainly present in mushrooms and has been approved to add to dried food. It is hydrolyzed by the intestinal trehalase into 2 molecules of glucose. Trehalase deficiency has been reported in 8% of Greenlanders, otherwise only 3 cases of this deficiency have been reported elsewhere. In untreated celiac disease the intestinal trehalase activity is reduced as those of other disaccharidases and recovers after introduction of a gluten-free diet.

Trypsinogen Deficiency

Trypsinogen deficiency is a rare syndrome with symptomatology similar to that of enterokinase deficiency. Enterokinase catalyzes the conversion of trypsinogen to trypsin, which, in turn, activates the various pancreatic proenzymes, such as chymotrypsin, procarboxypeptidase, and proelastase, for their active forms. Deficiency of trypsinogen results in severe diarrhea, malabsorption, failure to thrive, and hypoproteinemic edema soon after birth.

The trypsinogen gene is encoded on chromosome 7q35. Treatment is the same as for enterokinase deficiency, with pancreatic enzymes and protein hydrolysate formula with added MCT oil in infancy.

Liver and Biliary Disorders Causing Malabsorption

Anil Dhawan, Raanan Shamir

Keywords

Cholestasis
Nutrition

Liver disease
malabsorption
vitamin deficiency

Absorption of lipids and lipid-soluble vitamins depend to a great extent on adequate bile flow delivering BA to the small intestine that help mixed micelle formation of lipid droplets. Most of the liver and biliary disorders lead to impairment of the bile flow, contributing to malabsorption of long-chain fatty acids and vitamins such as A, D, E, and K. Liver disorders that are associated with significant malabsorption and failure to thrive are mainly due to these categories:

PFIC syndromes and BA synthesis defects. PFIC type 1 is also associated with chronic diarrhea caused by bile transport defect in the gut. It is not uncommon for these children to have symptomatic fat-soluble vitamin deficiencies and suffer from pathologic fractures and peripheral neuropathy.

Children with storage disorders (e.g., **Wolman disease**) also manifest with severe failure to thrive and multiple vitamin deficiencies.

Children with biliary disorders such as biliary atresia after porto-enterostomy surgery (Kasai portoenterostomy), cystic fibrosis, neonatal sclerosing cholangitis, Alagille syndrome, and sclerosing cholangitis constitute another major group of disorders with reduced bile flow where malabsorption could be a significant challenge

Chronic liver disease of any etiology could also lead to lipid malabsorption from the above described mechanisms. In addition, severe portal hypertension can lead to portal hypertensive enteropathy, resulting in poor absorption of the nutrients.

Decompensated liver disease leads to anorexia and increased energy expenditures, further widening the gap between calorie intake and net absorption, leading to severe malnutrition. Adequate management of nutrition is essential to improve the outcome with or without liver transplantation. This is usually achieved by using MCT-rich milk formula, supplemental vitamins, and continuous or bolus enteral feed where oral intake is poor.

Vitamin D deficiency is commonly observed on biochemical tests, and children can present with pathologic fractures. Simultaneous administration of vitamin D with the water-soluble vitamin E preparation (TPGS 1,000 succinate) enhances absorption of vitamin D as well. In young infants with **cholestasis** , **oral vitamin D_3 is given** at a dose of 1,000 IU/kg/24 hr. After 1 mo, if the serum

25-hydroxyvitamin D level is low, intramuscular administration of 10,000 units/kg or maximum of 60,000 is recommend. Three 6 mo, 25-hydroxy vitamin D blood level monitoring is suggested in children with severe cholestasis.

Vitamin E deficiency in patients with chronic cholestasis is not usually symptomatic, but it can manifest as a progressive neurologic syndrome, which includes peripheral neuropathy (manifesting as loss of deep tendon reflexes and ophthalmoplegia), cerebellar ataxia, and posterior column dysfunction. Early in the course, findings are partially reversible with treatment; late features might not be reversible. It may be difficult to identify vitamin E deficiency because the elevated blood lipid levels in cholestatic liver disease can falsely elevate the serum vitamin E level. Therefore it is important to measure the ratio of serum vitamin E to total serum lipids; the normal level for patients younger than 12 yr of age is >0.6, and for patients older than 12 yr it is >0.8. The neurologic disease can be prevented with the use of an oral water-soluble vitamin E preparation (TPGS, Liqui-E) at a dose of 25-50 IU/day in neonates and 15-25 IU/kg/day in children.

Vitamin K deficiency can occur as a result of cholestasis and poor fat absorption. In children with liver disease it is very important to differentiate between the coagulopathy related to vitamin K malabsorption and one secondary to the synthetic failure of the liver. A single dose of vitamin K administered intravenously does not correct the prolonged prothrombin time in liver failure, but the deficiency state responds within a few hours. Easy bruising may be the first sign. In neonatal cholestasis, coagulopathy as a result of vitamin K deficiency can manifest with intracranial bleeds with devastating consequences, and prothrombin time should be routinely measured to monitor for deficiency in children with cholestasis. All children with cholestasis should receive regular vitamin K supplementation.

Vitamin A deficiency is rare and is associated with night blindness, xerophthalmia, and increased mortality if patients contract measles. Serum vitamin A levels should be monitored and adequate supplementation considered; caution should be observed as high levels of vitamin A can cause liver damage.

Congenital (primary) malabsorption disorders originate from multitude types of defects including structural or functional defects of enterocytes or disorders involving other cellular lineages of the GI tract such as enteroendocrine or immune cells (see Chapter 364.3 and 367). Integral membrane proteins, which fulfill a transport function as receptor or channel across the apical or basolateral membrane of enterocytes for nutritional components, are another class of disorders associated with primary disorders of malabsorption. Histologic examination of the small and large bowel is typically normal. Most of these disorders are inherited in an autosomal recessive pattern. Most are rare, and patients present with a broad phenotypic heterogeneity as a result of modifier genes and nutritional and other secondary factors.

Disorders of Carbohydrate Absorption

These are described in Chapter 364.9 .

Patients with **Fanconi-Bickel syndrome** present with tubular nephropathy; rickets; hepatomegaly; glycogen accumulation in liver, kidney, and small bowel; failure to thrive; fasting hypoglycemia and postprandial hyperglycemia. The disorder is caused by homozygous mutations of GLUT2 *(SLC2A2),* the facilitative monosaccharides transporter at the basolateral membrane of enterocytes, hepatocytes, renal tubules, pancreatic islet cells, and cerebral neurons. The patients exhibit postprandial hyperglycemia secondary to low insulin secretion (impaired glucose-sensing mechanisms in beta-cells) and fasting hypoglycemia due to altered glucose transport out of the liver. The increased intracellular glucose level inhibits glycogen degradation leading to glycogen accumulation and hepatomegaly. Similarly, altered monosaccharides transport out of enterocytes may be responsible for the putative glycogen accumulation and as a consequence, for diarrhea and malabsorption observed in some patients. Therapy includes the substitution of electrolyte losses and vitamin D, and supplying uncooked cornstarch to prevent hypoglycemia. Patients who present in the neonatal period need frequent small meals and galactose-free milk.

Disorders of Amino Acid and Peptide Absorption

Protein digestion and absorption in the intestine is accomplished by a combination of proteases, peptidases, and peptide and amino acid transporters. Amino acid transporters are essential for the absorption of amino acids from nutrients, mediate the inter-organ, intercellular transfer of amino acids and the transport of amino acids between cellular compartments. Owing to their ontogenic origins, enterocytes and renal tubules share similar amino acid transporters. Their highest intestinal transporter activity is found in the jejunum. The transporters causing Hartnup disease, cystinuria, iminoglycinuria, and dicarboxylic aminoaciduria are located in the apical membrane, and those causing lysinuric protein intolerance (LPI) and blue diaper syndrome are anchored in the basolateral membrane of the intestinal epithelium.

Dibasic amino acids, including cystine, ornithine, lysine, and arginine are taken up by the Na-independent SLC3A1/SLC7A9, which is defective in cystinuria. Cystinuria is the most common primary inherited aminoaciduria. This disorder is not associated with any GI or nutritional consequences because of compensation by an alternative transporter. However, hypersecretion of cystine in the urine leads to recurrent cystine stones, which account for up to 6–8% of all urinary tract stones in children. Ample hydration, urine alkalinization, and cystine-binding thiol drugs can increase the solubility of cystine. Cystinuria type I *(SLC3A1)* is inherited as an autosomal recessive trait, whether the transmission of non-type I cystinuria *(SLC7A9)* is autosomal dominant with incomplete penetrance. Cystinuria type I has been described in association with 2p21 deletion syndrome and hypotonia-cystinuria syndrome.

LPI is the second most common disorder of amino acids transport (see Chapter 103.14). LPI is caused by y^+ LAT-1 (SLC7A7) carrier at the basolateral membrane of the intestinal and renal epithelium and the failure to deliver cytosolic dibasic cationic amino acids into the paracellular space. This defect is not compensated by the SLC3A1/SLC7A9 transporter at the apical membrane. The symptoms of LPI, which appear after weaning, include diarrhea, failure to thrive, hepatosplenomegaly, nephritis, respiratory insufficiency, alveolar proteinosis, pulmonary fibrosis, and osteoporosis. Abnormalities of bone marrow have also been described in a subgroup of LPI patients. The disorder is characterized by low plasma concentrations of dibasic amino acids (in contrast to high levels of citrulline, glutamine, and alanine) and massive excretion of lysine (as well as orotic acid, ornithine, and arginine in moderate excess) in the urine. Hyperammonemia and coma usually develop after episodic attacks of vomiting, after fasting, or following the administration of large amounts of protein (or alanine load), possibly because of a deficiency of intramitochondrial ornithine. Some patients show moderate retardation. Cutaneous manifestations can include alopecia, perianal dermatitis, and sparse hair. Some patients avoid protein-containing food. Immune dysfunction potentially attributable to nitric oxide overproduction secondary to arginine intracellular trapping might be the pathophysiological route explaining many LPI complications, including hemophagocytic lymphohistiocytosis, various autoimmune disorders, and an incompletely characterized immune deficiency. Treatment includes dietary protein restriction (<1.5 g/kg/day), orally administered citrulline (100 mg/kg/day), which is well absorbed from the intestine and carnitine supplementation.

Hartnup disease is characterized by the malabsorption of all neutral amino acids (except proline), including the essential amino acid tryptophan. It is characterized by aminoaciduria, photosensitive pellagra-like rash, headaches, cerebellar ataxia, delayed intellectual development, and diarrhea. The clinical spectrum ranges from asymptomatic patients to severely affected patients with progressive neurodegeneration leading to death by adolescence. SLC6A19, which is the major luminal sodium-dependent neutral amino acid transporter of small intestine and renal tubules, has been identified as the defective protein. Its association with collectrin and angiotensin-converting enzyme II is likely to be involved in the phenotypic heterogeneity of Hartnup disorder. Tryptophan is a precursor of nicotinamide adenine dinucleotide phosphate biosynthesis; therefore, the disorder can be treated by nicotinamide in addition to a diet of 4 g protein/kg. The use of lipid-soluble esters of amino acids and tryptophan ethyl ester has also been reported.

Defects in specific, basolateral tryptophan transporter (SLC16A10) are the cause of **blue diaper syndrome** (indicanuria, Drummond syndrome). Intestinal bacteria convert the unabsorbed tryptophan to indican, which is responsible for the bluish discoloration of the urine after its hydrolysis and oxidation. Symptoms can include digestive disturbances such as vomiting, constipation, poor appetite, failure to thrive, hypercalcemia, nephrocalcinosis, fever, irritability, and ocular abnormalities.

The underlying defect of **iminoglycinuria** is the malabsorption of proline, hydroxyproline, and glycine as a consequence of the proton amino acid transporter SLC36A2 defect, with a possible participation of modifier genes, one of which (SLC6A20) is present in the intestinal epithelium. This disorder is usually benign, but sporadic cases with encephalopathy, mental retardation, deafness, blindness, kidney stones, hypertension, and gyrate atrophy have been described.

The neuronal glutamate transporter EAAT3 (SLC1A1) is affected in **dicarboxylic aminoaciduria** . This carrier is present in the small intestine, kidney, and brain, and transports the anionic acids L -glutamate, L - and D -aspartate, and L -cysteine. There are single case reports indicating that this disorder could be associated with hyperprolinemia and neurologic symptoms such as POLIP (polyneuropathy, ophthalmoplegia, leukoencephalopathy, intestinal pseudoobstruction) syndrome.

Disorders of Fat Transport

These are described in Chapter 104.3 and 364.3 .

Disorders of Vitamin Absorption

Transporters and receptors of the intestinal epithelium have been described for water-soluble but not fat-soluble vitamins, the latter being absorbed primarily into enterocytes by passive diffusion after the emulsification of fats by bile salts. Transfer proteins (retinol-binding protein, RBP4, and α-tocopherol transfer protein, TTP1) have been involved in deficiency states of vitamins E (spinocerebellar ataxia) and A (ophthalmologic signs), respectively.

Vitamin B_{12} (cobalamin) is synthesized exclusively by microorganisms and is acquired mostly from meat and milk (see Chapter 481.2). Its absorption starts with the removal of cobalamin from dietary protein by gastric acidity and its binding to haptocorrin. In the duodenum, pancreatic proteases hydrolyze the cobalamin-haptocorrin complex, allowing the binding of cobalamin to intrinsic factor (IF), which originates from parietal cells. The receptor of the cobalamin-IF complex (Cbl-IF) is located at the apical membrane of the ileal enterocytes, and represents a heterodimer consisting of cubilin (CUBN) and amnionless (AMN). After endocytic uptake into endosomes, the Cbl-IF and its receptor binds to megalin and forms a cobalamin–transcobalamin-2 complex (after cleavage of IF) for further transcytosis. Vitamin B_{12} exits the lysosome via LMBD1 and ABCD4, and is released to the blood stream most likely through the basolateral transporter multifunctional multidrug resistance protein 1 (MRP1). Biologically available circulating vitamin B_{12} is bound to transcobalamin (TC), a nonglycosylated protein that carries 10–30% of the total vitamin B_{12} . TC-vitamin B_{12} complexes enter the cells via 2 members of the LDL receptor gene family, CD320 and renal Lrp2/Megalin. As a cofactor for methionine synthase, cobalamin converts homocysteine to methionine. Cobalamin deficiency can be caused by inadequate intake of the vitamin (e.g., breastfeeding by mothers on a vegan diet), primary or secondary achlorhydria including autoimmune gastritis, exocrine pancreatic insufficiency, bacterial overgrowth (see Chapter 364.4), ileal disease (Crohn disease, see Chapter 362.2), ileal (or gastric) resection, infections (fish tapeworm), and Whipple disease (see Chapter 367).

Clinical signs of congenital cobalamin malabsorption, which usually appear from a few months to more than 10 yr, are pancytopenia including **megaloblastic anemia** , fatigue, failure to thrive, and neurologic symptoms, including developmental delay. Recurrent infections and bruising may be present. Laboratory evaluation indicates low serum cobalamin, hyperhomocysteinemia, methylmalonic acidemia, and mild proteinuria. The Schilling test is useful to differentiate between a lack of IF and the malabsorption of cobalamin. Several rare autosomal recessive disorders of congenital cobalamin deficiency affect absorption and transport of cobalamin (in addition to 7 other inherited defects of cobalamin metabolism). These include mutations of the gastric IF *(GIF)* gene with absence of IF (but normal acid secretion and lack of autoantibodies against IF or parietal cells), mutations of the *AMN* and *CUBN* genes subunits of the Cbl-IF receptor in ileum (**Imerslund-Grasbeck syndrome**), and mutations in the TC 2 cDNA. Two new inborn defects were identified recently in the genes encoding LMBD1 and ABCD4 transporters, and are responsible for the rare Cbl-lF inborn defect resulting in the trapping of free vitamin B_{12} in lysosomes. These disorders require long-term parenteral cobalamin treatment: intramuscular injections of cobalamin. High-dose substitution with oral cyanocobalamin (1 mg biweekly) does not seem to be sufficient for all patients with congenital cobalamin deficiency.

Folate is an essential vitamin required to synthesize methionine from homocysteine. It is found mainly in green leafy vegetables, legumes, and oranges. After its uptake by enterocytes, folate is converted to 5-methyltetrahydrofolate. Secondary folate deficiency is caused by insufficient folate intake, villous atrophy (e.g., CD, IBD), treatment with phenytoin, and trimethoprim, among others (see Chapter 481.1). Several inherited disorders of folate metabolism and transport have been described.

Three mammalian folate transporter systems have been described to date in a variety of tissues: (1) the bidirectional reduced folate carrier 1 (RFC1, SLC19A1), (2) the glycosyl-phosphatidylinositol-anchored folate receptors (FOLR1, FOLR2, and FOLR4) responsible for folate-receptor mediated endocytosis, and (3) the human proton-coupled folate transporter (PCFT). Hereditary **folate malabsorption** is characterized by a defect of the PCFT of the brush-border, leading to impaired absorption of folate in the upper small intestine as well as impaired transport of folate into the central nervous system. Symptoms of congenital folate malabsorption are diarrhea, failure to thrive, megaloblastic anemia (in the first few mo of life), glossitis, infections *(Pneumocystis jiroveci)* with hypoimmunoglobulinemia, and neurologic abnormalities (seizures, intellectual impairment, and basal ganglia calcifications). Macrocytosis, with or without neutropenia, multilobulated polymorphonuclear cells, increased lactate dehydrogenase and bilirubin, increased saturation of transferrin, and decreased cholesterol can be found. Low levels of folate are present in serum and cerebrospinal fluid. Plasma homocysteine concentrations as well as urine excretion of formiminoglutamic acid and orotic acid are elevated. Long-lasting deficiency is best documented using red cell folate. Therapy involves large doses of oral (up to 100 mg/day) or systemic (intrathecal) folate. Sulfasalazine and methotrexate are potent inhibitors of PCFT. Therefore, folate deficiency may develop during treatment with these drugs. Although the RFC1 is ubiquitously expressed, including the brush-border membrane in the small intestine, involvement of RFC1 in intestinal folate uptake has not been confirmed.

The molecular basis of intestinal transport of other water-soluble vitamins such as vitamin C (Na^+ -dependent vitamin C transporters 1 and 2), pyridoxine/vitamin B_6 , and biotin/vitamin B_5 (Na^+ -dependent multivitamin transporter) have been described; congenital defects of these transporter systems have not yet been found in humans. A **thiamine/vitamin B_1 -responsive megaloblastic anemia** syndrome, which is associated with early-onset type 1 diabetes mellitus and sensorineural deafness, is caused by mutations of the thiamine transporter protein, THTR-1 (SLC19A2), present in the brush-border.

Disorders of Electrolyte and Mineral Absorption

Congenital chloride diarrhea (CCD) belongs to the more common causes of severe congenital diarrhea, with prevalence in Finland of 1 : 20,000. It is caused by a defect of the *SLC26A3* gene, which encodes a Na^+ -independent Cl^- /HCO_3

$^-$ exchanger within the apical membrane of ileal and colonic epithelium. Founder mutations have been described in Finnish, Polish, and Arab patients: V317del, I675-676ins, and G187X, respectively. The Cl^- /HCO_3 $^-$ exchanger absorbs chloride originating from gastric acid and the cystic fibrosis transmembrane conductance regulator and secretes bicarbonate into the lumen, neutralizing the acidity of gastric secretion.

Prenatally, CCD is characterized by maternal polyhydramnios, dilated fetal bowel loops and preterm birth. Newborns with CCD present with severe life-threatening *secretory diarrhea* during the first few weeks of life. Volvulus has been reported in few patients with CCD. Laboratory findings are metabolic alkalosis, hypochloremia, hypokalemia, and hyponatremia (with high plasma renin and aldosterone activities). Fecal chloride concentrations are >90 mmol/L and exceed the sum of fecal sodium and potassium. Early diagnosis and aggressive lifelong enteral substitution of KCl in combination with NaCl (chloride doses of 6-8 mmol/kg/day for infants and 3-4 mmol/kg/day for older patients) prevent mortality and long-term complications (such as urinary infections, hyperuricemia with renal calcifications, renal insufficiency, and hypertension) and allow normal growth and development. Orally administered proton pump inhibitors, cholestyramine, and butyrate can reduce the severity of diarrhea. The diarrheal symptoms usually tend to regress with age. However, febrile diseases are likely to exacerbate symptoms as a consequence of severe dehydration and electrolyte imbalances. (See Chapter 71 for fluid and electrolyte management.)

The classic form of **congenital sodium diarrhea** (CSD) manifests with polyhydramnios, massive *secretory diarrhea* , severe metabolic acidosis, alkaline stools (fecal $pH > 7.5$) and hyponatremia because of fecal losses of Na^+ (fecal $Na^+ > 70$ mmol/L). Urinary secretion of sodium is low to normal. CSD is clinically and genetically heterogeneous. A syndromic form of CSD with superficial punctate keratitis, choanal or anal atresia, hypertelorism, and corneal erosions has been related to mutations of *SPINT2,* encoding a serine–protease inhibitor, whose pathophysiologic action on intestinal Na^+ absorption is unclear. This form of CSD is also referred to as **CTE** (intestinal epithelial dysplasia), as it often shows clustered enterocytes that form “tufts” with branching crypts on histology (described in Chapter 364.3). Two genetic defects have been identified so far in several patients with the non-syndromic form of CSD. Dominant activating mutations in receptor guanylate cyclase C *(GUCY2C)* were found to cause a spectrum of secretory diarrheas including nonsyndromic CSD in 4 patients. These mutations were associated with elevated intracellular cyclic guanosine monophosphate (cGMP) levels that induced inhibition of NHE3 exchanger via its phosphorylation by cGMP kinase II. Mutations in *SLC9A3* , the gene encoding the Na^+ /H^+ antiporter 3 (NHE3), the major intestinal brush-border Na^+ /H^+ exchanger, were identified in 9 patients with non-syndromic CSD. IBD developed in a number of patients with dominant GC-C mutations, and also in 2 of 9 patients with recessive SLC9A3 mutations, implicating NHE3 in the pathogenesis of IBD in a subset of patients. The congenital form of **acrodermatitis enteropathica** manifests with severe deficiency of body zinc soon after birth in bottle-fed children, or after weaning from breastfeeding. Clinical signs of this disorder are anorexia, diarrhea, failure to thrive, humoral and cell-mediated immunodeficiency (poor wound healing, recurrent infections), male hypogonadism, skin lesions (vesicobullous dermatitis on the extremities and perirectal, perigenital, and perioral regions, and alopecia), and neurologic abnormalities (tremor, apathy, depression, irritability, nystagmus, photophobia, night blindness, and hypogeusia). The genetic defect of acrodermatitis enteropathica is caused by a mutation in the Zrt-Irt-like protein 4 (ZIP4, SLC39A4), normally expressed on the apical membrane, which enables the uptake of zinc into the cytosol of enterocytes. The zinc-dependent alkaline phosphatase and plasma zinc levels are low. Paneth cells in the crypt of the small intestinal mucosa show inclusion bodies. Acrodermatitis enteropathica requires long-term treatment with elemental zinc at 1 mg/kg/day. Maternal zinc deficiency impairs embryonic, fetal, and postnatal development. Chapter 67 describes the *acquired* forms of zinc deficiency. Transient neonatal zinc deficiency is an autosomal dominant disorder with similar manifestations as AE. The disease is caused by mutations in ZnT2, the transporter responsible for supplying human milk with zinc.

Menkes disease and **occipital horn syndrome** are both caused by mutations in the gene encoding Cu^{2+} transporting adenosine triphosphatase (ATPase), α-polypeptide (ATP7A), also called Menkes or MNK protein. ATP7A is mainly expressed by enterocytes, placental cells, and the central nervous system, and is localized in the *trans* -Golgi network for copper transfer to enzymes in the secretory pathway or to endosomes to facilitate copper efflux. Copper values in liver and brain are low in contrast to an increase in mucosal cells, including enterocytes and fibroblasts. Plasma copper and ceruloplasmin levels decline postnatally. Clinical features of Menkes disease are progressive cerebral degeneration (convulsions), feeding difficulties, failure to thrive, hypothermia, apnea, infections (urinary tract), peculiar facies, hair abnormalities (kinky hair), hypopigmentation, bone changes, and cutis laxa. Patients with the classic form of Menkes disease usually die before the age of 3 yr. A therapeutic trial with copper-histidinase should start before the age of 6 wk. In contrast to Menkes disease, occipital horn syndrome usually manifests during adolescence with borderline intelligence, craniofacial abnormalities, skeletal dysplasia (short clavicles, pectus excavatum, genu valgum), connective tissue abnormalities, chronic diarrhea, orthostatic hypotension, obstructive uropathy, and osteoporosis. It should be differentiated from Ehlers-Danlos syndrome type V.

Active calcium absorption is mediated by the transient receptor potential channel 6 (TRPV6) at the brush border membrane, calbindin, and the Ca-ATPase, or the Na^+ -Ca^{++} exchanger for calcium efflux at the basolateral membrane within the proximal small bowel. A congenital defect of these transporters has not yet been described.

Intestinal absorption of dietary magnesium, which occurs via the transient receptor potential channel TRPM6 at the apical membrane, is impaired in familial **hypomagnesemia with secondary hypocalcemia** , which manifests with neonatal seizures and tetany.

Intestinal iron absorption consists of several complex regulated processes starting with the uptake of heme-containing iron by heme carrier protein 1 (HCP1) and Fe^{2+} (after luminal reduction of oxidized Fe^{3+}) by the divalent metal transporter 1 (DMT1) at the apical membrane, followed by the efflux of Fe^{2+} by ferroportin 1 (also called the iron-regulated transporter) at the basolateral membrane of duodenal enterocytes. Hepatic hormone hepcidin has a key role in iron homeostasis by interacting with ferroportin. When it binds to ferroportin, hepcidin induces phosphorylation of the iron exporter, causing its internalization and degradation. A decrease in the ferroportin protein level on the cell surface inhibits iron export from intracellular pools. Thus, hepcidin controls plasma iron levels by reducing iron absorption in the gut, lowering iron release from hepatocytes, and preventing iron recycling by macrophages Hepcidin deficiency causes iron overload in hereditary hemochromatosis and iron-loading anemias, whereas hepcidin excess causes or contributes to the development of iron-restricted anemia in inflammatory diseases, infections, some cancers, and chronic kidney disease. Mutations of the ferroportin 1 gene have been found in the autosomal dominant form of **hemochromatosis** type 4. Mutations within the hemochromatosis (HFE) gene (Cys282 Tyr, His63Asn, Ser65Cys) of classic hemochromatosis reduce the endocytic uptake of diferric transferrin by the transferrin receptor-1 at the basolateral membrane of the intestinal epithelium. Hepcidin is the defective gene of juvenile hemochromatosis (type 2, subtype B). Elevated hepcidin results in hypoferremia and insufficient supply of iron for erythropoiesis, leading to different types of anemia. The underlying causes of hepcidin elevation in iron-restricted anemias are varied. An example of a genetic cause of hepcidin increase is the familial **iron-refractory iron deficiency anemia** (IRIDA), an autosomal recessive disorder caused by a mutation in matriptase-2 *(TMPRSS6)* , a negative regulator of hepcidin expression. This anemia is characterized by very low plasma iron levels, unresponsiveness to oral iron therapy and partial correction by parenteral iron. Mutations in DMT1 transporter *(SLC11A2)* are another cause of **IRIDA** . The development of severe microcytic, hypochromic anemia typifies these patients; however, surprisingly, some of them load iron in the liver.

CHAPTER 365

Intestinal Transplantation in Children With Intestinal Failure

Jorge D. Reyes, André A.S. Dick

The introduction of tacrolimus and the development of the abdominal multiorgan procurement techniques allowed the tailoring of various types of intestine grafts that can contain other intraabdominal organs, such as the liver, pancreas, and stomach. The understanding that the liver protects the intestine against rejection demonstrates the interaction between recipient and donor immunocytes (host-versus-graft and graft-versus-host) which under the cover of immunosuppression allows varying degrees of graft acceptance and eventual minimization of drug therapy. Over the past several years the number of patients placed on the list for and those undergoing intestinal transplantation has decreased, which may be a result of (1) improvements in the care of patients with intestinal failure under a multidisciplinary intestinal care team management, (2) the introduction of new lipid management strategies for the treatment of cholestatic liver disease, and (3) corrective surgery enhancing absorptive surface and motility, which has led to increased survival and decreased morbidity.

Indications for Intestinal Transplant

Intestinal failure describes a patient who has lost the ability to maintain nutritional support and adequate fluid requirements, needed to sustain growth, with their own intestine and is permanently dependent on total parenteral nutrition (TPN). The majority of these patients have short bowels as a result of a congenital deficiency or acquired condition (see Chapter 364.07). In others, the cause of intestinal failure is a functional disorder of motility or absorption (Table 365.1). Rarely do patients receive intestinal transplants for benign neoplasms.

The complications of intestinal failure include loss of venous access, life-threatening infections, and TPN-induced cholestatic liver disease.

Table 365.1

Causes of Intestinal Failure in Children Requiring Transplantation

SHORT BOWEL
• Congenital disorders • Volvulus • Gastroschisis • Necrotizing enterocolitis • Intestinal atresia • Trauma
INTESTINAL DYSMOTILITY
• Intestinal pseudoobstruction • Intestinal aganglionosis (Hirschsprung disease)
ENTEROCYTE DYSFUNCTION
• Microvillus inclusion disease • Tufting enteropathy • Autoimmune disorders • Crohn disease
TUMORS
• Familial polyposis • Inflammatory pseudotumor

Paucity of Venous Access

Administration of TPN requires the insertion of a centrally placed venous catheter, there being only 6 readily accessible sites (bilateral internal jugulars, subclavians, iliac veins). The loss of venous access generally occurs in the setting of recurrent catheter sepsis and thrombosis; clinical convention suggests that loss of 50% of these venous access sites places the patient at risk of not being able to be treated with TPN.

Life-Threatening Infections

Life-threatening infections are usually catheter-related; the absence of significant lengths of intestine may be associated with abnormal motility of the residual bowel (producing both delayed or rapid emptying), with varying degrees of bacterial overgrowth and possible bacterial or fungal translocation as a consequence of loss of intestinal barrier function and/or loss of gut immunity.

This situation can produce cholestatic liver disease, multisystem organ failure, and metastatic infectious foci in lungs, kidneys, liver, and the brain.

Liver Disease

The development of cholestatic liver disease is the most serious complication of intestinal failure and may be a consequence of the toxic drug effects of TPN on hepatocytes, a disruption of bile flow and bile acid metabolism, and the frequent occurrence of bacterial translocation and sepsis with endotoxin release into the portal circulation. This complication varies in frequency depending on the patient's age and the etiology of the intestinal failure; it is most common in neonates with extreme short gut. The effects on the liver include fatty transformation, steatohepatitis and necrosis, fibrosis, and then cholestasis. The development of clinical jaundice (total bilirubin > 3 mg/dL) and thrombocytopenia are significant risk factors for poor outcome, because these changes portend the development of portal hypertensive gastroenteropathy, hypersplenism, coagulopathy, and uncontrollable bleeding.

Transplantation Operation

Donor Selection

Intestinal grafts are usually procured from hemodynamically stable, ABO-identical brain-dead donors who have minimal clinical or laboratory evidence suggesting intraabdominal ischemia; size matching varies according to age of the recipients; present surgical techniques allow for significant reductions of the graft in order to achieve abdominal closure. Human leukocyte antigen has been random, and cross matching has not been a determinant of graft acceptance. Exclusion criteria include a history of malignancy and intraabdominal evidence of infection; systemic viral or bacterial infections are not excluded. Donor preparation has been limited to the administration of systemic and enteral antibiotics. Prophylaxis for graft-versus-host disease with graft pretreatment using irradiation or a monoclonal antilymphocyte antibody has varied over time. Grafts have been preserved with the University of Wisconsin solution, as is the case with other types of abdominal organs.

Types of Intestinal Grafts

Intestinal allografts are used in various forms, either alone (as an **isolated intestine graft**) or as a composite graft, which can include the liver, duodenum, and pancreas (**liver–intestine graft**); when this composite graft includes the stomach, and the recipient operation requires the removal of all of the patient's gastrointestinal tract (as with intestinal pseudoobstruction) and liver, then this replacement graft is known as a **multivisceral graft** .

The procurement of these various types of grafts focuses on the preservation of the arterial vessels of celiac and/or superior mesenteric arteries, as well as appropriate venous outflow, which would include the superior mesenteric vein or the hepatic veins in the composite grafts. The larger composite grafts inherently retain the celiac and superior mesenteric arteries; this includes multivisceral grafts, liver plus small bowel grafts, and *modified multivisceral grafts* in which the liver is excluded but the entire gastrointestinal tract is replaced, including the stomach. The isolated intestine graft retains the superior mesenteric artery and vein; this graft can be accomplished with preservation of the vessels going to the pancreas, when that organ has been allocated to another recipient. The graft that is to be used in a particular recipient is dissected out in situ and then removed after cardiac arrest of the donor, with core cooling of the organs, using an infusion of preservation solution (Fig. 365.1).

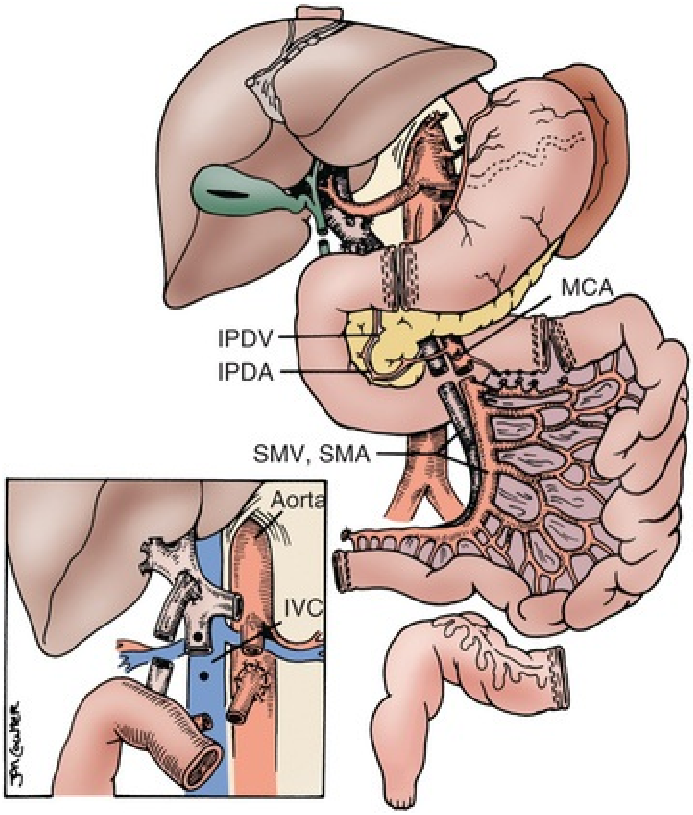

FIG. 365.1 The various abdominal organs can be dissected in situ, providing isolated or composite grafts to fit the individual patient's needs. Separation of intestine and pancreas is feasible, with preservation of the inferior pancreaticoduodenal artery *(IPDA)* and vein *(IPDV).* The use of vascular grafts from the donor allow connections to the superior mesenteric pedicle (artery *[SMA]* and vein *[SMV]*) to aorta and inferior vena cava *(IVC)* or portal vein *(inset). MCA,* Major coronary artery. (From Abu-Elmagd K, Fung J, Bueno J, et al: Logistics and technique for procurement of intestinal, pancreatic and hepatic grafts from the same donor, *Ann Surg* 232:680–697, 2000.)

Various modifications in these grafts have included the preservation of visceral ganglia at the base of the arteries, the inclusion of donor duodenum and pancreas for the liver and intestine graft, the inclusion of colon, the reduction of the liver graft (into left or right side) and variable reduction of the intestine graft, and the development of living donor intestine grafts.

The Recipient Operation

Because many children have had multiple previous abdominal operations, intestinal transplantation can be a formidable technical challenge; most children require replacement of the liver because of TPN-induced disease and often present with advanced liver failure. Transplantation of an isolated intestinal allograft involves exposure of the lower abdomen, infrarenal aorta, and inferior vena cava. Placement of vascular homografts using donor iliac artery and vein to these vessels allows arterialization and venous drainage of the intestinal graft. In patients who have retained their intestine and then undergo an enterectomy at the time of transplantation, use of the native superior mesenteric vessels is feasible.

Transplantation of a larger composite graft requires the removal and replacement of the native liver in the liver with intestine transplant, and complete abdominal exenteration in the multivisceral transplant. In a similar fashion, the infrarenal aorta is exposed for placement of an arterial conduit graft (donor thoracic aorta) for arterialization of the graft. The venous drainage is achieved to the retained hepatic veins, which are fashioned to a single conduit for anastomosis to the allograft liver.

The intestinal anastomosis to native proximal and distal bowel is performed, leaving an enterostomy of distal allograft ileum; this will be used for routine posttransplantation surveillance endoscopy and biopsy. This ostomy is closed 3-6 mo after transplantation (Fig. 365.2).

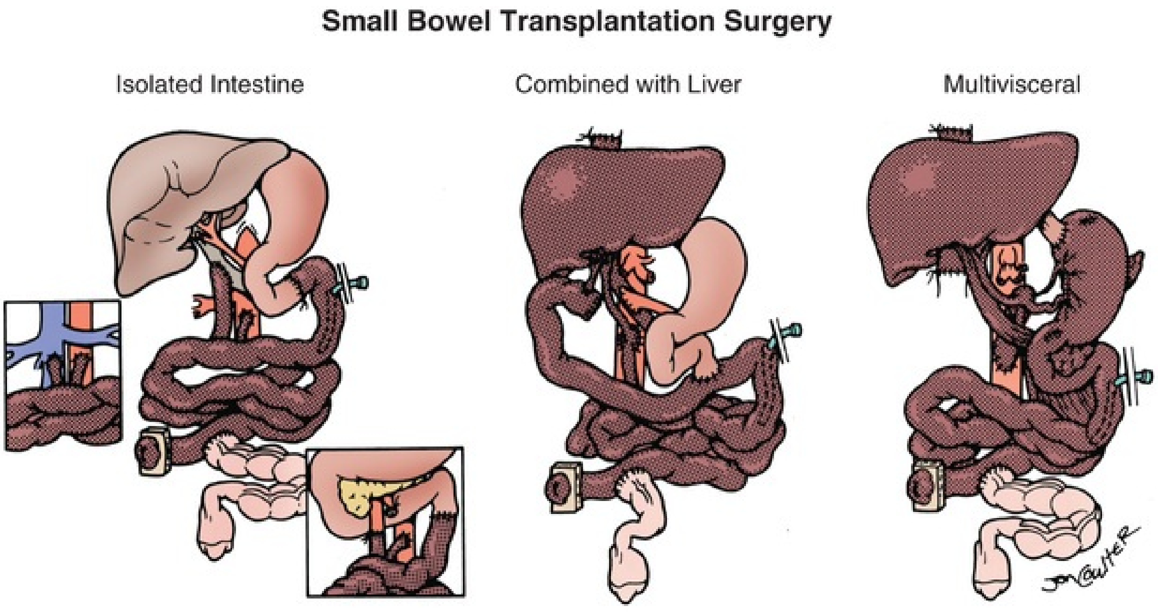

FIG. 365.2 **The three basic intestinal transplant procedures (the graft is *shaded*). With the isolated intestine, the venous outflow may be to the recipient portal vein *(main figure),* inferior vena cava *(inset left),* or superior mesenteric vein *(inset right).* With the composite grafts, which include the liver, the arterialization is from the aorta with venous drainage out from the liver graft to the recipient inferior vena cava.**

Postoperative Management

Immunosuppression

Successful immunosuppression for intestinal transplantation is initiated with tacrolimus and corticosteroids. This required high levels of tacrolimus (in the nephrotoxic range), and although initial success rates were high they were followed by rejection rates of > 80%, infection, and late drug toxicities, resulting in a gradual loss of grafts and patients. The next generation of protocols incorporated the addition of other agents, such as azathioprine, cyclophosphamide, induction with an interleukin-2 antibody antagonist, mycophenolate mofetil, and rapamycin. This modification resulted in a decreased incidence in the severity of initial rejection; the ability to decrease immunosuppression later did not allow for stabilization of long-term survival. The introduction of *recipient pretreatment* using antilymphocyte antibodies and the elimination of recipient therapy with steroids have resulted in improved transplant survival as a result of a significant decrease in the incidence of rejection and infection, permitting the gradual decrease of immunosuppressive drug therapy within 3 mo, and a decline in drug toxicity events. The most common induction regimen used is T cell depleting agents followed by -2 receptor antagonists (Fig. 365.3). A mainstay of maintenance immunosuppression is tacrolimus and prednisone dual therapy. By 1 yr the majority of patients are on tacrolimus monotherapy (Fig. 365.4).

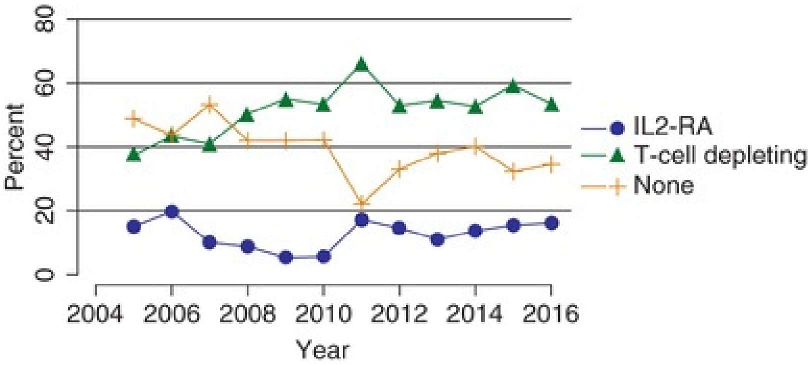

FIG. 365.3 **Induction agents used in intestinal transplant recipients. Immunosuppression at transplant reported to the OPTN. *IL2-RA* , interleukin-2 receptor antagonist. Allograft Assessment

There are no simple laboratory tools that allow assessment of the intestinal allograft. The gold standard for diagnosis of intestinal allograft rejection has been serial endoscopic surveillance and biopsies through the allograft ileostomy. Clinical signs and symptoms of rejection or infection of the allograft can overlap and mimic each other, producing either rapid diarrhea or complete ileus with pseudoobstruction syndromes, or gastrointestinal bleeding. Any changes in clinical status should warrant thorough evaluation for rejection with endoscopic biopsies and an evaluation for opportunistic infection, malabsorption, and other enteral infections.

The diagnosis of *acute rejection* is based on seeing destruction of crypt epithelial cells from apoptosis, in association with a mixed lymphocytic infiltrate. These histologic findings may or may not correlate with endoscopic evidence of injury, which varies from diffuse erythema and friability to ulcers and, in cases of severe rejection, exfoliation of the intestinal mucosa. *Chronic rejection* of the allograft can be diagnosed only through full-thickness sampling of the intestine, which shows the typical vasculopathy that can result in progressive ischemia of the allograft.

Rejection and Graft-Versus-Host Disease

Acute rejection rates for the intestinal allograft are significantly higher than with any other organ, in the range of 80–90%, and severe rejection requiring the use of antilymphocyte antibody preparations may be as high as 30%. Triple-drug regimens and the use of interleukin-2 antibody inhibitors have resulted in significant decreases in rejection rates; nonetheless, the amount of immunosuppression was incompatible with improvements in long-term patient and graft survival. Rejection rates of 40% are achievable with the use of antilymphocyte globulin. These protocols induce varying degrees of *proper tolerance* , which can eventually allow for minimization of immunosuppression, thus reducing the risk of drug toxicity and infection. Vascular rejection has been an uncommon occurrence, and chronic rejection has been seen in approximately 15% of cases.

Graft-versus-host disease is infrequent but potentially life-threatening; the mortality rate exceeds 80% and most recipients die from infectious complications from bone marrow failure. The incidence seen in intestinal transplantation is 5–6%. Although no standard treatment is available, early diagnosis, prevention of infection, and initiation of treatment as soon as possible may improve outcomes.

Infections

Infectious complications are the most significant cause of morbidity and mortality after intestinal transplantation. The most common infections (bacterial, fungal, polymicrobial) occur as a result of the continuing need for venous catheter placement for as long as 1 yr posttransplantation. Infections as a consequence of immunosuppressive drug management are from cytomegalovirus (CMV) infection (22% incidence), Epstein-Barr virus (EBV)–induced infections (21% incidence), and adenovirus enteritis (40% incidence). Despite improvements in monitoring and preventative measures, CMV remains the most common viral infection postintestinal transplantation. CMV may be acquired from blood transfusions, reactivation of endogenous viruses, or the donated allograft. The highest-risk recipients for CMV infection are those who are immunologically naïve and receive an allograft from a donor who is seropositive. The 2 CMV prevention strategies commonly employed are universal prophylaxis and preemptive therapy. Consensus guidelines recommend prophylaxis treatment for high-risk patients (donor+/recipient−). The preferred drugs for CMV prophylaxis are ganciclovir and oral valganciclovir.

Patients at the highest risk for EBV infection are those who are seronegative at the time of transplantation and those requiring a high-burden immunosuppressive therapy to maintain their graft. EBV disease varies from asymptomatic viremia to posttransplant lymphoproliferative disorder (PTLD). The incidence of EBV-related PTLD is highest in patients receiving intestinal allografts compared to liver, heart, or kidney. Children have a higher incidence of PTLD compared to adults, and are most likely to have EBV+PTLD. Early diagnosis and prevention of PTLD is essential and the mainstay of therapy is to reduce immunosuppression, although some patients have required chemotherapy. The use of anti–B-cell monoclonal antibodies, such as the anti-CD20 antibody rituximab, in PTLD has been successful as noted in anecdotal reports. Successful management of these viral infections is achieved through early detection and preemptive therapy, for both CMV and EBV, before the development of a serious life-threatening infection. This approach has improved outcomes for CMV, eliminating the mortality in the pediatric patient population (see Chapters 205 , 281 , and 282).

Outcomes

Intestinal transplantation is the standard of care for children with intestinal failure who have significant complications of TPN and can no longer tolerate such therapy. Data from the Organ Procurement and Transplantation Network (OPTN)/Scientific Registry of Transplant Recipients (SRTR) Annual Report 2015, and center-specific data reports have documented significant improvements with short- and long-term survivals for transplantations occurring principally in the last 10 yr; isolated intestinal transplantation graft failure rates for deceased donor transplants in 2013-2014 were 24.5% at 1 yr, 42.4% at 3 yr for transplants in 2011-2012, and 54% at 5 yr for transplants in 2009-2010 (Fig. 365.5). For liver-intestine recipients during the same time period graft failure rates were 27% at 1 yr, 33.3% at 3 yr, 48.7% at 5 yr, and 51% at 10 yr for transplants 2003-2004 (Fig. 365.6). It is hoped that with the minimization strategies currently used the long-term survival will plateau as occurs with other organ transplants; rehabilitation and quality-of-life studies have shown that more than 80% of survivors reach total independence from TPN and have meaningful life activities. Consequently, there has been a shift in efforts to improve long-term outcomes and quality of life.

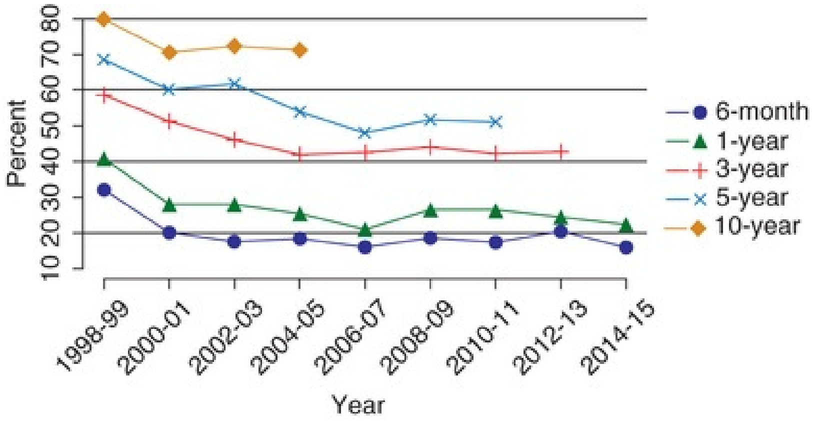

FIG. 365.5 Graft failure among transplant recipients of intestine without liver. All recipients of deceased donor intestines, including multiorgan transplants. Patients are followed until the earliest of retransplant, graft failure, death, or December 31, 2016. Estimates computed with Cox proportional hazards models adjusted for age, sex, and race. CHAPTER 366

Acute Gastroenteritis in Children

Karen L. Kotloff

The term *gastroenteritis* denotes inflammation of the gastrointestinal tract, most commonly the result of infections with bacterial, viral, or parasitic pathogens (Tables 366.1 to 366.3). Many of these infections are foodborne illnesses (Table 366.4). Several clinical syndromes are often described because they have different (albeit overlapping) etiologies, outcomes, and treatments. **Acute gastroenteritis** (AGE) captures the bulk of infectious cases of diarrhea. The most common manifestations are diarrhea and vomiting, which can also be associated with systemic features such as abdominal pain and fever. **Dysentery** refers to a syndrome characterized by frequent small stools containing visible blood, often accompanied by fever, tenesmus, and abdominal pain. This should be distinguished from bloody diarrhea (larger volume bloody stools with less systemic illness) because the etiologies may differ. **Prolonged** (lasting 7-13 days) and **persistent diarrhea** (lasting 14 days or longer) are important because of their impact on growth and nutrition.

Table 366.1

Etiologies of Viral Gastroenteritis

ETIOLOGY	INCUBATION PERIOD	ACUTE SIGNS AND SYMPTOMS	DURATION OF ILLNESS	PRINCIPAL VEHICLE AND TRANSMISSION	RISK FACTORS	COMMERCIA AVAILABLE DIAGNOSTIC TEST
Caliciviruses (including noroviruses and sapoviruses)	12-48 hr	Nausea, vomiting, abdominal cramping, diarrhea, fever, myalgia, and some	1-3 days	Person-to-person (fecal-oral and aerosolized vomit), and food, water, and fomites contaminated with human feces.	Very contagious (chlorine and heat resistant); produces large outbreaks in	No. Testing stool or vom using real ti reverse transcriptas (RT)- quantitative PCR is the

		headache			closed settings such as cruise ships, and restaurants.	preferred method, available in public healt laboratories Immunoass for norovir have poor sensitivity. FDA-clear multiplex P assays are available to detect these organisms. Norovirus genotyping and GII) is performed CDC.
Rotavirus (groups A-C), astrovirus, and enteric adenovirus (serotypes 40 and 41)	2-4 days	Often begins with vomiting, followed by watery diarrhea, low-grade fever	3-8 days	Person-to-person (fecal-oral), fomites. Aerosol transmission of rotavirus may be possible.	Nearly all infants and children worldwide were infected by 2 yr of age before vaccine introduction.	Yes. Rotavirus: immunoassay (preferred), late agglutination, a immune-chromatography stool. Enteric adenovirus: immunoassay. cleared multipl PCR assays are available to det these organisms

Table 366.2

Etiologies of Bacterial Gastroenteritis

ETIOLOGY	INCUBATION PERIOD	ACUTE SIGNS AND SYMPTOMS	DURATION OF ILLNESS	PRINCIPAL VEHICLE AND TRANSMISSION	RISK FACTOR
Bacillus cereus (preformed emetic toxin)	1-6 hr	Sudden onset of severe nausea and vomiting; diarrhea may be present	24 hr	Soil and water	Improperly refrigerated coo or fried rice, me
Bacillus cereus (enterotoxins formed in vivo)	8-16 hr	Abdominal cramps, watery diarrhea; nausea and vomiting	1-2 days	Soil and water	Meats, stews, gravies, vanilla sauce

		may be present			
Campylobacter jejuni	1-5 days	Diarrhea, (10–20% of episodes are prolonged), cramps, fever, and vomiting; bloody diarrhea, bacteremia, extraintestinal infections, severe disease in immunocompromised	5-7 days (sometimes >10 days) usually self-limiting	Wild and domestic animals and animal products, including pets	Raw and undercooked poultry, unpasteurized m untreated surfac water
Clostridium difficile toxin	Unknown—can appear weeks after antibiotic cessation	Mild to moderate watery diarrhea that can progress to severe, pseudomembranous colitis with systemic toxicity.	Variable	Person-person (fecal-oral), mostly within healthcare facilities	Immunosuppres intestinal diseas surgery, prolong hospitalization, antibiotics
Clostridium perfringens toxin	8-16 hr	Watery diarrhea, nausea, abdominal cramps; fever is rare	1-2 days	Environment, human and animal intestines	Meats, poultry, gravy, dried or precooked foods with poor temperature cont
Enterohemorrhagic *Escherichia coli* (EHEC) including *E. coli* O157:H7 and other *Shiga* toxin–producing *E. coli* (STEC)	1-9 days (usually 3-4 days)	Watery diarrhea that becomes bloody in 1-4 days in ~40% of infections; in contrast to dysentery, bloody stools are large volume and fever/toxicity are minimal. More common in children <4 yr old.	4-7 days	Food and water contaminated with feces from ruminants; infected people and animals (fecal-oral); predominantly high-resource countries	Undercooked be especially hamburger, unpasteurized m and juice, raw fr and petting zoos recreational swimming, dayc Antimotility age and antibiotics increase risk of hemolytic uremi syndrome
Enterotoxigenic *E. coli* (ETEC)	1-5 days	Watery diarrhea, abdominal cramps, some vomiting	3-7 days	Water or food contaminated with human feces	Infants and youn children in LMI and travelers
Salmonella , nontyphoidal	1-5 days	Diarrhea, (10–20% prolonged), cramps, fever, and vomiting; bloody diarrhea, bacteremia, extraintestinal infections, severe disease in immunocompromised	5-7 days (sometimes >10 days) usually self-limiting	Domestic poultry, cattle, reptiles, amphibians, birds	Ingestion of raw undercooked foo improper food handling, travele immunosuppres hemolytic anemi achlorhydria, contact with infected animal
Shigella spp.	1-5 days (up to 10 days for *S. dysenteriae* type 1)	Abdominal cramps, fever, diarrhea Begins with watery stools that can be the only	5-7 days	Infected people or fecally contaminated surfaces (fecal-oral)	Poor hygiene an sanitation, crowding, travel daycare, MSM, prisoners

		manifestation or proceed to dysentery.			
Staphylococcus aureus (preformed enterotoxin)	1-6 hr	Sudden onset of severe nausea and vomiting Abdominal cramps Diarrhea and fever may be present	1-3 days	Birds, mammals, dairy, and environment	Unrefrigerated o improperly refrigerated mea potato and egg salads, cream pastries
Vibrio cholerae O1 and O139	1-5 days	Watery diarrhea and vomiting, that can be profuse and lead to severe dehydration and death within hours.	3-7 days	Food and water contaminated with human feces	Contaminated w fish, shellfish, street-vended fo from endemic or epidemic setting blood group O, vitamin A deficiency
Vibrio parahaemolyticus	2-48 hr	Watery diarrhea, abdominal cramps, nausea, vomiting. Bacteremia and wound infections occur uncommonly, especially in high-risk patients, e.g., with liver disease and diabetes.	2-5 days	Estuaries and marine environments; currently undergoing pandemic spread	Undercooked or seafood, such as fish, shellfish
Vibrio vulnificus	1-7 days	Vomiting, diarrhea, abdominal pain. Bacteremia and wound infections, particularly in patients with chronic liver disease (presents with septic shock and hemorrhagic bullous skin lesions)	2-8 days	Estuaries and marine environments	Undercooked or shellfish, especia oysters, other contaminated seafood, and ope wounds exposed seawater
Yersinia enterocolitica and *Yersinia pseudotuberculosis*	1-5 days	Diarrhea, (10–20% prolonged), cramps, fever, and vomiting; bloody diarrhea, bacteremia, extraintestinal infections, severe disease in immunocompromised; pseudoappendicitis occurs primarily in older children.	5-7 days (sometimes >10 days) usually self-limiting	Swine products, occasionally person-to-person and animal-to-humans, water-borne, bloodborne (can multiply during refrigeration)	Undercooked po improper food handling, unpasteurized m tofu, contaminat water, transfusio from a bacterem person, cirrhosis chelation therap

[†] FDA-cleared multiplex PCR assays are available but generally not recommended for diagnosis in individual patients because of inability to determine antimicrobial susceptibility to guide treatment or speciate the organism for outbreak investigation.

Table 366.4

Incidence of Bacterial and Parasitic Food-Borne Infections in 2017 and Percentage Change Compared With 2014-2016 Average Annual Incidence by Pathogen FoodNet Sites,[*] 2014-2017 [†]

PATHOGEN	**2017**		**2017 VERSUS 2014-2016**	
	NO. OF CASES	**INCIDENCE RATE** [§]	**% CHANGE** [¶]	**(95% CI)**
Bacteria				
Campylobacter	9,421	19.1	10	(2 to 18)
Salmonella	7,895	16.0	−5	(−11 to 1)
Shigella	2,132	4.3	−3	(−25 to 25)
Shiga toxin–producing *E. coli* [**]	2,050	4.2	28	(9 to 50)
Yersinia	489	1.0	166	(113 to 234)
Vibrio	340	0.7	54	(26 to 87)
Listeria	158	0.3	26	(2 to 55)
Parasites				
Cryptosporidium	1,836	3.7	10	(−16 to 42)
Cyclospora	163	0.3	489	(253 to 883)

[*] Connecticut, Georgia, Maryland, Minnesota, New Mexico, Oregon, Tennessee, and selected counties in California, Colorado, and New York.

[†] Data for 2017 are preliminary.

[§] Per 100,000 population.

[¶] Percentage change reported as increase or decrease.

[**] For Shiga toxin–producing *E. coli* , all serogroups were combined because it is not possible to distinguish between serogroups using culture-independent diagnostic tests. Reports that were only Shiga toxin–positive from clinical laboratories and were Shiga toxin–negative at a public health laboratory were excluded (n = 518). When these were included, the incidence rate was 5.2, which was a 57% increase (CI = 33–85%).

CI, confidence interval; *FoodNet,* CDC's Foodborne Diseases Active Surveillance Network.

From Marder EP, Griffin PM, Cieslak PR, et al: Preliminary incidence and trends of infections with pathogens transmitted commonly through food—foodborne diseases active surveillance network, 10 U.S. sites, 2006-2017, *MMWR* 67(11):324–328, 2018 (Table 1, p. 325).

Burden of Childhood Diarrhea

Although global mortality due to diarrheal diseases has declined substantially (39%) during the past 2 decades, it remains unacceptably high. In 2015, diarrheal disease caused an estimated 499,000, or 8.6% of all childhood deaths, making it the 4th most common cause of child mortality worldwide. Over the same period, a smaller decline (10%) was observed in the incidence of diarrhea disease among children younger than 5 yr. Almost 1.0 billion episodes occurred in 2015 worldwide, resulting in an estimated 45 million childhood disability-adjusted life years. Approximately 86% of the episodes occurred in Africa and South Asia (63% and 23%, respectively). The decline in diarrheal mortality, despite the lack of significant changes in incidence, is the result of preventive rotavirus vaccination and improved case management of diarrhea, as well as improved nutrition of infants and children. These interventions have included widespread home- and hospital-based oral rehydration solution (ORS) therapy and improved nutritional management of children with diarrhea.

In addition to the risk of mortality, high rates of diarrhea can be associated with long-term adverse outcomes. Diarrheal illnesses, especially episodes among young children that are recurrent, prolonged, or persistent, can be associated with malnutrition, stunting, micronutrient deficiencies, and significant deficits in psychomotor and cognitive development.

Pathogens

Rotavirus is the most common cause of AGE among children throughout the world. Several other viruses occur less frequently. Norovirus and sapovirus are the 2 genera of *Caliciviruses* that cause AGE. Norovirus genogroup II, genotype

4 (GII.4) has predominated globally during the past decade. Among the more than 50 serotypes of adenovirus, 40 and 41 are most often associated with diarrhea. Astroviruses are identified less often (see Table 366.1).

The major bacterial pathogens that cause AGE are nontyphoidal *Salmonella* (NTS), *Shigella, Campylobacter* , and *Yersinia* (see Table 366.2). Five pathotypes of *Escherichia coli* infect humans: Shiga toxin–producing (STEC), also known as enterohemorrhagic (EHEC), enterotoxigenic (ETEC), enteropathogenic (EPEC), enteroaggregative (EAEC), and enteroinvasive (EIEC). Two serogroups of *Vibrio cholerae* (O1 and O139) produce epidemic cholera and cause nearly all sporadic cases. *Clostridium difficile* disease can be both nosocomial and community acquired in children. Bacterial pathogens that cause foodborne illness due to their ability to produce emetic and/or enterotoxins include *Bacillus cereus* , *Clostridium perfringens* , and *Staphylococcus aureus.* The significance of isolating *Aeromonas* and *Plesiomonas* in a diarrheal stool remains uncertain.

Giardia intestinalis, Cryptosporidium spp., *Cyclospora cayetanensis* , and *Entamoeba histolytica* are the most common parasites that cause diarrhea in the United States (see Table 366.3). At least 13 species of *Cryptosporidium* are associated with human disease, but *C. hominis* and to a less extent *C. parvum* are most common. The genus *Entamoeba* comprises 6 species that colonize humans, but only *E. histolytica* is considered a human pathogen. *G. intestinalis* (formerly *G. lamblia* and *G. duodenalis*) is a flagellate protozoan that infects the small intestine and biliary tract. Other protozoa that uncommonly cause AGE are *Isospora belli* (now designated *Cystoisospora belli*) and *Blastocystic hominis.*

Epidemiology in the United States and Other Middle- and High-Income Countries

Risk Factors Related to Economic Development. Insufficient access to adequate hygiene, sanitation, and clean drinking water are the main factors leading to the heavy burden of AGE in developing countries. Nonetheless, infectious AGE remains ubiquitous in middle- and high- income countries, although the severe consequences have become uncommon. In fact, economic development poses its own risks for transmission of enteric pathogens. The ability to mass-produce and widely distribute food has led to large multistate outbreaks of AGE due to NTS, STEC, and other agents. Globalization has cultivated a taste for tropical fruits and vegetables, creating a mechanism for importation of novel pathogens. The increasing frequency of antimicrobial resistance among bacteria that causes AGE has been linked to the use of antibiotics as growth-promotors for animals bred for food. Recreational swimming facilities and water treatment systems have provided a vehicle for massive outbreaks of *Cryptosporidium* , a chlorine-resistant organism. Venues serving catered food to large groups of people, such as hotels and cruise ships, are conducive to outbreaks, as are institutions where hygiene is compromised, such as daycare centers, prisons, and nursing homes. Hospitalization and modern medical therapy have created a niche for nosocomial *C. difficile* toxin infection (Table 366.5).

Table 366.5

Exposure or Condition Associated With Pathogens Causing Diarrhea

---

EXPOSURE OR CONDITION	**PATHOGEN(S)**
FoodBorne	
Foodborne outbreaks in hotels, cruise ships, resorts, restaurants, catered events	Norovirus, nontyphoidal *Salmonella* , *Clostridium perfringens* , *Bacillus cereus* , *Staphylococcus aureus* , *Campylobacter* spp., ETEC, STEC, *Listeria* , *Shigella* , *Cyclospora cayetanensis* , *Cryptosporidium* spp.
Consumption of unpasteurized milk or dairy products	*Salmonella* , *Campylobacter* , *Yersinia enterocolitica* , *S. aureus* toxin, *Cryptosporidium* , and STEC. *Listeria* is infrequently associated with diarrhea, *Brucella* (goat milk cheese), *Mycobacterium bovis* , *Coxiella burnetii*
Consumption of raw or undercooked meat or poultry	STEC (beef), *C. perfringens* (beef, poultry), *Salmonella* (poultry), *Campylobacter* (poultry), *Yersinia* (pork, chitterlings), *S. aureus* (poultry), and *Trichinella* spp. (pork, wild game meat)
Consumption of fruits or unpasteurized fruit juices, vegetables, leafy greens, and sprouts	STEC, nontyphoidal *Salmonella* , *Cyclospora* , *Cryptosporidium* , norovirus, hepatitis A, and *Listeria monocytogenes*
Consumption of undercooked eggs	*Salmonella* , *Shigella* (egg salad)
Consumption of raw shellfish	*Vibrio* species, norovirus, hepatitis A, *Plesiomonas*
Exposure or Contact	
Swimming in or drinking untreated fresh water	*Campylobacter* , *Cryptosporidium* , *Giardia* , *Shigella* , *Salmonella* , STEC, *Plesiomonas shigelloides*
Swimming in recreational water facility with treated water	*Cryptosporidium* and other potentially waterborne pathogens when disinfectant concentrations are inadequately maintained
Healthcare, long-term care,	Norovirus, *Clostridium difficile* , *Shigella* , *Cryptosporidium* , *Giardia* , STEC,

prison exposure, or employment	rotavirus
Childcare center attendance or employment	Rotavirus, *Cryptosporidium* , *Giardia* , *Shigella* , STEC
Recent antimicrobial therapy	*C. difficile* , multidrug-resistant *Salmonella*
Travel to resource-challenged countries	*Escherichia coli* (enteroaggregative, enterotoxigenic, enteroinvasive), *Shigella* , typhi and nontyphoidal *Salmonella* , *Campylobacter* , *Vibrio cholerae* , *Entamoeba histolytica* , *Giardia* , *Blastocystis* , *Cyclospora* , *Cystoisospora* , *Cryptosporidium*
Exposure to house pets with diarrhea	*Campylobacter* , *Yersinia*
Exposure to pig feces in certain parts of the world	*Balantidium coli*
Contact with young poultry or reptiles	Nontyphoidal *Salmonella*
Visiting a farm or petting zoo	STEC, *Cryptosporidium* , *Campylobacter*
Exposure or Condition	
Age group	Rotavirus (6-18 mo of age), nontyphoidal *Salmonella* (infants from birth to 3 mo of age and adults >50 yr with a history of atherosclerosis), *Shigella* (1-7 yr of age), *Campylobacter* (young adults)
Underlying immunocompromising condition	Nontyphoidal *Salmonella* , *Cryptosporidium* , *Campylobacter* , *Shigella* , *Yersinia*
Hemochromatosis or hemoglobinopathy	*Y. enterocolitica* , *Salmonella*
AIDS, immunosuppressive therapies	*Cryptosporidium* , *Cyclospora* , *Cystoisospora* , microsporidia, *Mycobacterium avium* –intercellulare complex, cytomegalovirus
Anal-genital, oral-anal, or digital-anal contact	*Shigella* , *Salmonella* , *Campylobacter* , *E. histolytica* , *Giardia lamblia* , *Cryptosporidium*

ETEC, enterotoxigenic *Escherichia coli* ; *STEC,* Shiga toxin–producing *Escherichia coli* .

From Shane AL, Mody RK, Crump JA, et al: 2017 Infectious Diseases Society for America clinical practice guidelines for the diagnosis and management of infectious diarrhea, *Clin Infect Dis* 65(12):e45–80, 2017 (Table 2, p. e48).

Endemic Diarrhea. In the United States, rotavirus was the most common cause of medically attended AGE among children younger than 5 yr until the introduction of rotavirus vaccine for routine immunization of infants. Annual epidemics swept across the country beginning in the southwest in November and reaching the northeast by May, affecting nearly every child by the age of 2 yr. Since vaccine introduction, healthcare utilization for AGE has decreased markedly. Norovirus is the leading cause of AGE among children in the United States seeking healthcare, followed by sapovirus, adenovirus 40 and 41, and astrovirus (see Table 366.1).

Foodborne Transmission. The most comprehensive resource for describing the burden of bacterial and protozoal diarrhea in the United States is the Foodborne Diseases Active Surveillance Network (FoodNet) maintained by the Centers for Disease Control and Prevention (CDC) (see Table 366.4). FoodNet performs active laboratory-based surveillance of 9 bacterial and protozoal enteric infections commonly transmitted by food. Among children 0-19 yr of age in 2015, NTS was most common, followed by *Campylobacter* and *Shigella* , then STEC and *Cryptosporidium* . *Vibrio, Yersinia, and Cyclospora* were the least common (see Table 366.5). Children younger than 5 yr have the highest incidence of disease, and the elderly have the highest frequency of hospitalization and death. Only 5% of these infections are associated with recognized outbreaks.

Noninfectious agents may also cause foodborne gastrointestinal symptoms due to a direct toxic effect of the food (mushrooms) or contamination (heavy metals) (Table 366.6).

Table 366.6

Foodborne Noninfectious Illnesses

ETIOLOGY	INCUBATION PERIOD	SIGNS AND SYMPTOMS	DURATION OF ILLNESS	ASSOCIATED FOODS	LABORATORY TESTING	TREAT
Antimony	5 min-8 hr usually <1 hr	Vomiting, metallic taste	Usually self-limited	Metallic container	Identification of metal in beverage or food	Support
Arsenic	Few hours	Vomiting, colic, diarrhea	Several days	Contaminated food	Urine Can cause eosinophilia	Gastric BAL (dimerc
Cadmium	5 min-8 hr usually <1 hr	Nausea, vomiting, myalgia, increase in salivation, stomach pain	Usually self-limited	Seafood, oysters, clams, lobster, grains, peanuts	Identification of metal in food	Support
Ciguatera fish poisoning (ciguatera toxin)	2-6 hr	GI: abdominal pain, nausea, vomiting, diarrhea	Days to weeks to months	A variety of large reef fish: grouper, red snapper, amberjack, and barracuda (most common)	Radioassay for toxin in fish or a consistent history	Sup care mar Chil mor vulr
	3 hr	Neurologic: paresthesias, reversal of hot or cold, pain, weakness				
	2-5 days	Cardiovascular: bradycardia, hypotension, increase in T-wave				

		abnormalities				
Copper	5 min-8 hr usually <1 hr	Nausea, vomiting, blue or green vomitus	Usually self-limited	Metallic container	Identification of metal in beverage or food	Support
Mercury	1 wk or longer	Numbness, weakness of legs, spastic paralysis, impaired vision, blindness, coma Pregnant women and the developing fetus are especially vulnerable	May be protracted	Fish exposed to organic mercury, grains treated with mercury fungicides	Analysis of blood, hair	Support
Mushroom toxins, short-acting (muscimol, muscarine, psilocybin, *Coprinus atramentaria* , ibotenic acid)	<2 hr	Vomiting, diarrhea, confusion, visual disturbance, salivation, diaphoresis, hallucinations, disulfiram-like reaction, confusion, visual disturbance	Self-limited	Wild mushrooms (cooking might not destroy these toxins)	Typical syndrome and mushroom identified or demonstration of the toxin	Support
Mushroom toxins, long-acting (amanitin)	4-8 hr diarrhea; 24-48 hr liver failure	Diarrhea, abdominal cramps, leading to hepatic and renal failure	Often fatal	Mushrooms	Typical syndrome and mushroom identified and/or demonstration of the toxin	Support care, lif threaten may ne support
Nitrite poisoning	1-2 hr	Nausea, vomiting, cyanosis, headache, dizziness, weakness, loss of consciousness, chocolate-brown blood	Usually self-limited	Cured meats, any contaminated foods, spinach exposed to excessive nitrification	Analysis of the food, blood	Support care, m blue
Pesticides (organophosphates or carbamates)	Few minutes to few hours	Nausea, vomiting, abdominal cramps, diarrhea,	Usually self-limited	Any contaminated food	Analysis of the food, blood	Atropin PAM (pralido used w atropine

		headache, nervousness, blurred vision, twitching, convulsions, salivation, meiosis				able to sympto rarely necessa carbama poisoni
Puffer fish (tetrodotoxin)	<30 min	Paresthesias, vomiting, diarrhea, abdominal pain, ascending paralysis, respiratory failure	Death usually in 4-6 hr	Puffer fish	Detection of tetrodotoxin in fish	Life-threaten may ne respirat support
Scombroid (histamine)	1 min-3 hr	Flushing, rash, burning sensation of skin, mouth and throat, dizziness, urticaria, paresthesias	3-6 hr	Fish: bluefin, tuna, skipjack, mackerel, marlin, escolar, and mahi	Demonstration of histamine in food or clinical diagnosis	Support care, antihist
Shellfish toxins (diarrheic, neurotoxic, amnesic)	Diarrheic shellfish poisoning: 30 min-2 hr	Nausea, vomiting, diarrhea, and abdominal pain accompanied by chills, headache, and fever	Hours to 2-3 days	A variety of shellfish, primarily mussels, oysters, scallops, and shellfish from the Florida coast and the Gulf of Mexico	Detection of the toxin in shellfish; high-pressure liquid chromatography	Support care, ge self-lim
	Neurotoxic shellfish poisoning: few minutes to hours	Tingling and numbness of lips, tongue, and throat, muscular aches, dizziness, reversal of the sensations of hot and cold, diarrhea, and vomiting				
	Amnesic shellfish poisoning: 24-48 hr	Vomiting, diarrhea, abdominal pain and neurologic problems such as confusion, memory loss, disorientation, seizure, coma				Elderly especial sensitiv amnesi shellfis poisoni
Shellfish toxins (paralytic shellfish	30 min-3 hr	Diarrhea, nausea,	Days	Scallops, mussels, clams,	Detection of toxin in food or	Life-threaten

poisoning)		vomiting leading to paresthesias of mouth and lips, weakness, dysphasia, dysphonia, respiratory paralysis		cockles	water where fish are located; high-pressure liquid chromatography	may nee respirat support
Sodium fluoride	Few minutes to 2 hr	Salty or soapy taste, numbness of mouth, vomiting, diarrhea, dilated pupils, spasms, pallor, shock, collapse	Usually self-limited	Dry foods (e.g., dry milk, flour, baking powder, cake mixes) contaminated with NaF-containing insecticides and rodenticides	Testing of vomitus or gastric washings Analysis of the food	Support
Thallium	Few hours	Nausea, vomiting, diarrhea, painful paresthesias, motor polyneuropathy, hair loss	Several days	Contaminated food	Urine, hair	Support
Tin	5 min-8 hr usually <1 hr	Nausea, vomiting, diarrhea	Usually self-limited	Metallic container	Analysis of the food	Support
Vomitoxin	Few minutes to 3 hr	Nausea, headache, abdominal pain, vomiting	Usually self-limited	Grains such as wheat, corn, barley	Analysis of the food	Support
Zinc	Few hours	Stomach cramps, nausea, vomiting, diarrhea, myalgias	Usually self-limited	Metallic container	Analysis of the food, blood and feces, saliva or urine	Support

BAL, bronchoalveolar lavage; *GI,* gastrointestinal.

Diarrhea Outbreaks. The U.S. Foodborne Disease Outbreak Surveillance System quantifies enteric infections associated with foodborne outbreaks. In 2015, among all age groups, norovirus was the most common agent (46%), followed by NTS (23%). Less common are *C* . *perfringens* (6%), STEC (5%), *Campylobacter* (5%), and *S* . *aureus* (2%), followed much less often (each 1%) by *B* . *cereus* , *Clostridium botulinum, Shigella, Cryptosporidium, Yersinia, Listeria, Vibrio parahaemolyticus,* and *Shigella* . Outbreaks of enteric pathogens propagated by direct person-to-person contact are most often caused by norovirus and *Shigella* species; other pathogens include NTS, rotavirus, *Giardia* , *Cryptosporidium* , *C . difficile*, and *C. jejuni.*

Nosocomial Diarrhea. *C. difficile* is the most common cause of healthcare-associated infection in the United States. Severe disease occurs most often in those with predisposing conditions (e.g., recent antibiotics, gastric acid suppression, immunosuppression, gastrointestinal comorbidities). In contrast to adults, rates of colostomy and in-hospital mortality have not increased in children despite increasing rates of community and hospital-acquired *C. difficile* infection, suggesting that *C. difficile* may be less pathogenic in children. Moreover, high rates of asymptomatic carriage (and presence of toxin) among children younger than 2 yr creates diagnostic uncertainty, so testing and treatment should be reserved for those with supporting clinical evidence (see Table 366.2).

Zoonotic Transmission. Many diarrheal pathogens are acquired from animal reservoirs (see Tables 366.1 to 366.3 , 366.5). The ability of NTS to undergo transovarian passage in hens allows infection of intact grade A pasteurized eggs, a source of multiple large outbreaks. Although *Campylobacter* is prevalent in poultry, its lower outbreak potential has been attributed to its lack of transovarian spread in hens and stringent growth requirements, which limit its ability to replicate in foods. On the other hand, *Campylobacter* has an extensive reservoir in domestic and wild animals and remains a major cause of sporadic bacterial foodborne disease in industrialized countries, usually from consumption of contaminated chicken, meat, beef, and milk. Its ubiquitous animal reservoir also has resulted in widespread contamination of surface waters, resulting in diarrhea among hikers and campers who drink from streams, ponds, and lakes in wilderness areas. The predilection for STEC to asymptomatically colonize the intestines of ruminant animals explains why unpasteurized dairy products, fruits harvested from fields where cattle graze, and undercooked hamburger are common vehicles. The major animal reservoir for *Yersinia* is pigs, so ingestion of raw or undercooked pork products is an important risk factor. Pets can be the source of NTS (asymptomatic young birds, amphibians, and reptiles), *Campylobacter* , and *Yersinia* (puppies and kittens that are usually ill with diarrhea).

Seasonality. Seasonality provides a clue to implicate specific pathogens, although patterns may differ in tropical and temperate climates. Rotavirus and norovirus peak in cool seasons, whereas enteric adenovirus infections occur throughout the year, with some increase in summer. *Salmonella, Shigella,* and

Campylobacter favor warm weather, whereas the tendency for *Yersinia* to tolerate cold manifests as a winter seasonality, with higher prevalence in northern countries, and ability to survive in contaminated blood products during refrigeration.

Epidemiology in Low- and Middle-Income Countries

The Global Enteric Multicenter Study (GEMS) evaluated children younger than 5 yr living in 7 low-income countries in sub-Saharan Africa and South Asia and seeking healthcare for moderate-to-severe diarrhea (Fig. 366.1). Although a broad array of pathogens were identified, most episodes of moderate-to-severe diarrhea were attributed to 4 pathogens: rotavirus, *Cryptosporidium, Shigella* , and ETEC producing heat-stable toxin (ST) either alone or in combination with heat-labile toxin (LT), herein termed ST-ETEC, and, to less extent, adenovirus 40 and 41. On the other hand, several etiologic agents that are common causes of AGE in high-resource settings are notable for their low frequency in resource-limited settings: NTS, STEC, norovirus, and *C. difficile* toxin. The 3 agents associated with most deaths among children under 5 yr are rotavirus (29%), *Cryptosporidium* (12%), and *Shigella* (11%). The Etiology, Risk Factors, and Interactions of Enteric Infections and Malnutrition and the Consequences for Child Health and Development Project (MAL-ED) was a study of less severe, community-based diarrhea. Viral causes predominated (36.4% of the overall incidence), but *Shigella* had the single highest attributable incidence (26.1 attributable episodes per 100 child-years).

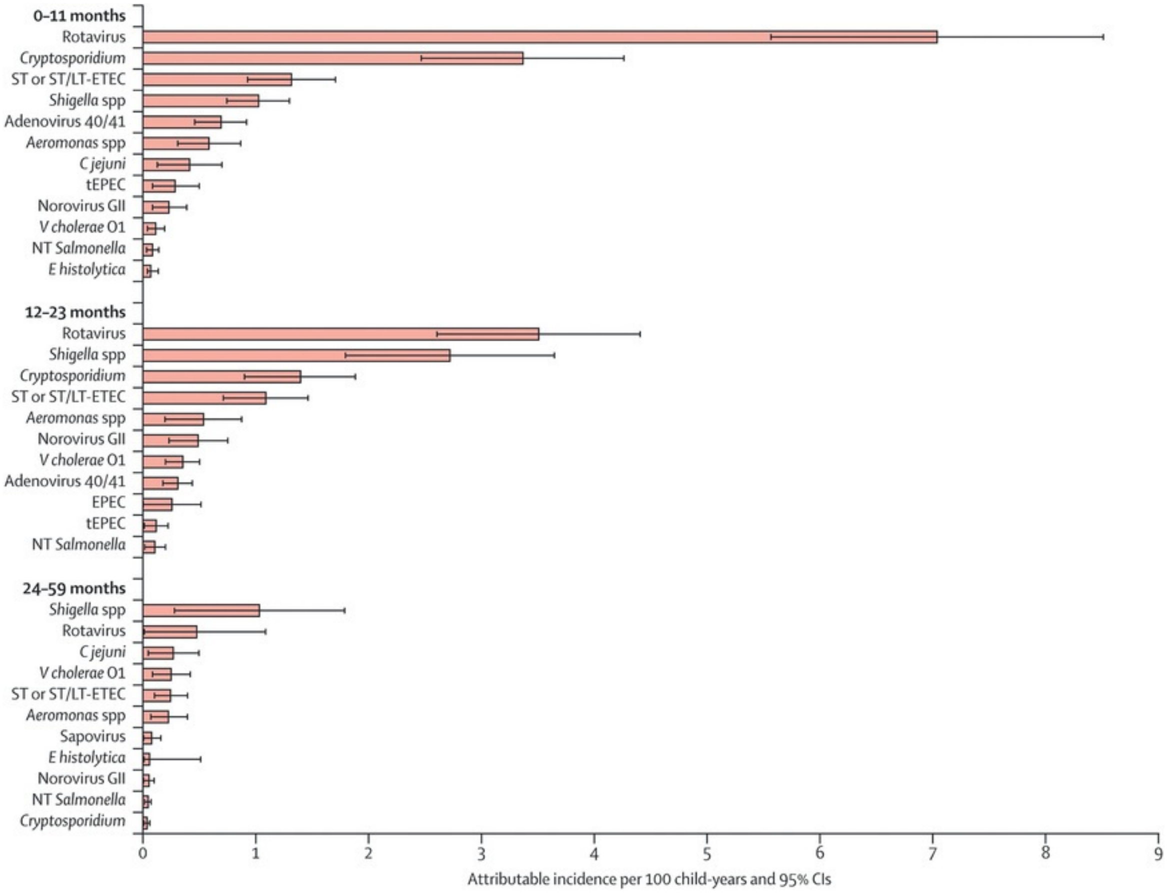

FIG. 366.1 Attributable incidence of pathogen-specific moderate-to-severe diarrhea per 100 child-yr by age stratum, all sites combined. The *bars* show the incidence rates, and the *error bars* show the 95% confidence intervals. *EPEC* , enteropathogenic; *ETEC* , enterotoxigenic; *LT* , labile toxin; *NT* , Nontyphoidal; *ST* , stable toxin. (Modified from Kotloff KL, Nataro JP, Blackwelder WC, et al: Burden and aetiology of diarrhoeal disease in infants and young children in developing countries [the Global Enteric Multicenter Study, GEMS]: a prospective, case-control study, *Lancet* 382[9888]:209–222, 2013, Fig. 4.)

Host Risk Factors

Most pathogens show an age predilection. The incidence of rotavirus and NTS are highest in infancy. Endemic shigellosis peaks in 1-4 yr olds, whereas *Campylobacter* and *Cryptosporidium* show a bimodal distribution with the greatest number of reported cases in infants and young children a secondary peak in adolescents and young adults. Pandemic *V. cholerae* and *S. dysenteriae* type 1 produce high attack rates and mortality in all age groups and often afflict displaced persons in emergency settings. Some agents (e.g., NTS, *Shigella*, *Campylobacter, Yersinia* , and *Cryptosporidium*) are more frequent and more severe when the host is immunocompromised or malnourished.

Additional risks factors for AGE include immunodeficiency, measles, malnutrition, and lack of exclusive or predominant breastfeeding. Malnutrition increases the risk of diarrhea and associated mortality, and moderate to severe stunting increases the odds of diarrhea-associated mortality. The fraction of such infectious diarrhea deaths that are attributable to nutritional deficiencies varies with the prevalence of deficiencies; the highest attributable fractions are in sub-Saharan Africa, South Asia, and Andean Latin America. The risks are particularly high with malnutrition, particularly when associated with micronutrient deficiency. Vitamin A deficiency accounts for 157,000 deaths from diarrhea, measles, and malaria. Zinc deficiency is estimated to cause 116,000 deaths from diarrhea and pneumonia. Table 366.7 summarizes some of the key risk factors associated with childhood diarrhea globally, especially in the presence of micronutrient deficiency.

Table 366.7

Proven Risk Factors With Direct Biologic Links to Diarrhea: Relative Risks or Odds Ratios and 95% Confidence Intervals

	DIARRHEAL MORBIDITY	**DIARRHEAL MORTALITY**
No breastfeeding (0-5 mo)	RR = 2.7 (1.7-4.1) compared with exclusive breastfeeding	RR = 10.5 (2.8-39.6) compared with exclusive breastfeeding
No breastfeeding (6-23 mo)	RR = 1.3 (1.1-1.6) compared with any breastfeeding	RR = 2.2 (1.1-4.2) compared with any breastfeeding
Underweight	(compared with ≥2 WAZ)	(compared with ≥1 WAZ)
−2 to ≤1 WAZ		OR = 2.1 (1.6-2.7)
−3 to ≤2 WAZ	RR = 1.2 (1.1-1.4)	OR = 3.4 (2.7-4.4)
≤3 WAZ		OR = 9.5 (5.5-16.5)
Stunted		
−2 to ≤1 HAZ		OR = 1.2 (0.9-1.7)

Pathogenesis of Infectious Diarrhea

Intrinsic properties of the organism help to define the mode of transmission and incubation period (Table 366.8). Enteropathogens that are infectious in small inocula (*Shigella,* STEC, norovirus, rotavirus, *G. intestinalis, Cryptosporidium* spp., *C. difficile, E. histolytica*) are readily transmitted by person-to-person contact via the fecal-oral route. Pathogens with larger infectious doses, such as cholera, NTS, ETEC, and *Campylobacter* , generally require food or water vehicles (see Tables 366.1 to 366.3). Pathogens that produce preformed toxins (*S. aureus, B. cereus* emetic toxin) have shorter incubation periods (1-6 hr) compared with 8-16 hr for those that must elaborate enterotoxins in situ (e.g., *C. perfringens* and *B. cereus enterotoxin*). Incubation periods of 1-5 days are seen with pathogens that attach to the epithelium and elaborate enterotoxins (e.g., *V. cholerae* , ETEC) or cytotoxins (e.g., *S* . *dysenteriae* type 1 and STEC) or those that invade and disrupt the intestinal epithelium (*Shigella* , NTS, *Campylobacter* , and *Yersinia*). The requirement for protozoa to progress through a life cycle to trigger pathogenic processes results in a more extended incubation period. Other properties affecting transmissibility are bioavailability as conferred by a copious and/or prolonged fecal shedding, extended infectivity in the environment, and resistance to disinfection (all exhibited by norovirus and *Cryptosporidium*), or a large environmental or animal reservoir (e.g., *Campylobacter*). The ability to circumvent immune surveillance by frequent antigenic changes resulting from recombinational events (e.g., norovirus) or a large serotype diversity (e.g., *Shigella*) maintains a susceptible host population.

Table 366.8

Comparison of 3 General Pathogenic Mechanisms of Enteric Infection

TYPE OF INFECTION

PARAMETER	**I**	**II**	**III**
Mechanism	Noninflammatory (enterotoxin or adherence/superficial invasion)	Inflammatory, epithelial destruction (invasion, cytotoxin)	Penetrating
Location	Proximal small bowel	Colon	Distal small bowel
Illness	Watery diarrhea	Dysentery	Enteric fever
Stool examination	No fecal leukocytes Mild or no ↑ lactoferrin	Fecal polymorphonuclear leukocytes ↑↑ Lactoferrin	Fecal mononuclear leukocytes
Examples	*Vibrio cholerae* ETEC *Clostridium perfringens* *Bacillus cereus* *Staphylococcus aureus* Also [†] : *Giardia intestinalis* *Rotavirus* Noroviruses *Cryptosporidium* spp. EPEC, EAEC *Cyclospora cayetanensis*	*Shigella* EIEC STEC NTS *Vibrio parahaemolyticus* *Clostridium difficile* *Campylobacter jejuni* *Entamoeba histolytica* [*]	*Yersinia enterocolitica* *Salmonella* Typhi, *S.* Paratyhpi, and occasionally NTS, *Campylobacter*, and *Yersinia*

[*] Although amebic dysentery involves tissue inflammation, the leukocytes are characteristically pyknotic or absent, having been destroyed by the virulent amebae.

[†] Although not typically enterotoxic, these pathogens alter bowel physiology via adherence, superficial cell entry, cytokine induction, or toxins that inhibit cell function.

EAEC, enteroaggregative *E. coli;* EIEC, enteroinvasive *E. coli;* EPEC, enteropathogenic *Escherichia coli;* ETEC, enterotoxigenic *Escherichia coli* ; *NTS,* nontyphoidal *Salmonella; STEC,* Shiga toxin–producing *Escherichia coli* .

Modified from Mandell GL, Bennett JE, Dolin R, editors: *Principles and practices of infectious diseases* , ed 7, Philadelphia, 2010, Churchill Livingstone.

Viral AGE causes a cytolytic infection of the small intestinal villus tips resulting in decreased absorption of water, disaccharide malabsorption, inflammation, and cytokine activation. The rotavirus protein NSP4 acts as a viral enterotoxin that produces secretory diarrhea. In addition, rotavirus activates the enteric nervous system causing decreased gastric emptying and increased intestinal mobility. There is a genetic susceptibility to both rotavirus and norovirus infection that is mediated by histo-blood group antigens on the epithelial cell surface and in mucus secretions (Fig. 366.2).

Pathogens primarily manifesting as secretory diarrhea attach to the surface of the epithelium and stimulate secretion of water and electrolytes by activating adenylate cyclase and raising intracellular cAMP (*V. cholerae* and heat- LT–producing ETEC) and/or cGMP (ETEC producing heat-ST) (Figs. 366.3 and 366.4). The diarrheagenic phenotype of *C. difficile* is attributed to production of toxins A (an enterotoxin) and B (an enterotoxin and cytotoxin). The epidemic hypervirulent NAP1 *C. difficile* also makes binary toxin, which may enhance colonization and augment toxin production.

FIG. 366.4 Movement of Na^+ and Cl^- in the small intestine. A, Movement in normal subjects. Na^+ is absorbed by 2 different mechanisms in absorptive cells from villi: glucose-stimulated absorption and electroneutral absorption (which represents the coupling of Na^+/H^+ and Cl^-/HCO_3^- exchanges). B, Movement during diarrhea caused by a toxin and inflammation. (From Petri WA, Miller M, Binder HJ, et al: Enteric infections, diarrhea and their impact on function and development, *J Clin Invest* 118:1277–1290, 2008.)

Shigella , NTS, *Campylobacter* , and *Yersinia* all possess an invasive phenotype and elicit diarrhea by a variety of mechanisms that generally involves elicitation of inflammatory cytokines with or without associated toxin production (Fig. 366.5). The pathogenesis of *Shigella* , the most common cause of bacillary dysentery, has been characterized in greatest detail. Following invasion, *Shigella* induces extensive destruction and inflammation of the intestinal epithelium producing ulcers and microabscesses that manifest with diarrheal stools containing blood and pus. Production of enterotoxins contributes to secretory diarrhea, which can be seen early in shigellosis or as the sole manifestation. A single serotype of *Shigella* , *S* . *dysenteriae* type 1, elaborates the Shiga toxin which increases the severity of illness and is responsible for development of hemolytic uremic syndrome (HUS).

Cryptosporidia sporozoites released from ingested cysts penetrate intestinal epithelial cells and develop into trophozoites within the intracellular, but extracytoplasmic, environment. After undergoing asexual multiplication and sexual development, they are released in the colon as infectious oocysts capable of causing autoinfection. Host factors, in particular T-cell function, play a critical role in disease severity. *Cyclospora* cysts are not infectious in freshly passed stools but must sporulate in the environment for 1-2 wk to become infectious; they are usually transmitted in contaminated produce and water (see Table 366.4).

Clinical Manifestation of Diarrhea

General Findings. Diarrhea is usually defined as the passage of 3 or more abnormally loose or liquid stools per day. Frequent passage of formed stools is not diarrhea, nor is the passing of loose, pasty stools by breastfed babies. Clinical clues to the possible etiology of gastroenteritis are noted in Table 366.9 .

Table 366.9

Clinical Presentations Suggestive of Infectious Diarrhea Etiologies

FINDING	LIKELY PATHOGENS
Persistent or chronic diarrhea	*Cryptosporidium* spp., *Giardia lamblia* , *Cyclospora cayetanensis* , *Entamoeba histolytica* , non-typhoidal *Salmonella*, *Yersinia,* and *Campylobacter* spp.
Visible blood in stool	STEC, *Shigella* , *Salmonella* , *Campylobacter* , *Entamoeba histolytica* , noncholera *Vibrio parahaemolyticus* , *Yersinia* , *Balantidium coli* , and *Aeromonas*
Fever	Not highly discriminatory—viral, bacterial, and parasitic infections can cause fever. In general, higher temperatures are suggestive of bacterial etiology or *E. histolytica* . Patients infected with STEC usually are not febrile at time of presentation
Abdominal pain	STEC, *Salmonella* , *Shigella* , *Campylobacter* , *Yersinia* , noncholera *Vibrio* species, *Clostridium difficile*
Severe abdominal pain, often grossly bloody stools (occasionally nonbloody), and minimal or no fever	STEC, *Salmonella* , *Shigella* , *Campylobacter* , and *Yersinia enterocolitica*
Persistent abdominal pain and fever	*Y. enterocolitica and Y. pseudotuberculosis* ; may mimic appendicitis
Nausea and vomiting lasting ≤24 hr	Ingestion of *Staphylococcus aureus* enterotoxin or *Bacillus cereus* (short-incubation emetic syndrome)
Diarrhea and abdominal cramping lasting 1-2 days	Ingestion of *Clostridium perfringens* or *Bacillus cereus* (long-incubation emetic syndrome)
Vomiting and nonbloody diarrhea	Norovirus (low-grade fever usually present during the first 24 hr in 40% of infections); diarrhea usually lasts 2-3 days or less; other viral diarrheas (e.g., rotavirus, enteric adenovirus, sapovirus, astrovirus) usually last 3-8 days.
Chronic watery diarrhea, often lasting a year or more	Brainerd diarrhea (epidemic secretory diarrhea, etiologic agent has not been identified); postinfectious irritable bowel syndrome

STEC, Shiga toxin–producing *Escherichia coli* .

From Shane AL, Mody RK, Crump JA, et al: 2017 Infectious Diseases Society for America clinical practice guidelines for the diagnosis and management of infectious diarrhea, *Clin Infect Dis* 65(12):e45–80, 2017 (Table 3, p. e54).

In the past, many guidelines divided patients into subgroups for mild (3–5%), moderate (6–9%), and severe (≥10%) dehydration. However, it is difficult to distinguish between mild and moderate dehydration based on clinical signs alone. Therefore most guidelines now combine mild and moderate dehydration and simply use none, some, and severe dehydration. The individual signs that best predict dehydration are prolonged capillary refill time >2 sec, abnormal skin turgor, hyperpnea (deep, rapid breathing suggesting acidosis), dry mucous membranes, absent tears, and general appearance (including activity level and thirst). As the number of signs increases, so does the likelihood of dehydration. Tachycardia, altered level of consciousness, and cold extremities with or without hypotension suggest severe dehydration.

Viral Diarrhea. Symptoms of rotavirus AGE usually begin with vomiting followed by frequent passage of watery nonbloody stools, associated with fever in about half the cases (see Table 366.1). The diarrhea lacks fecal leukocytes, but stools from 20% of cases contain mucus. Recovery with complete resolution of symptoms generally occurs within 7 days. Although disaccharide malabsorption is found in 10–20% of episodes, it is rarely clinically significant.

Other viral agents elicit similar symptoms and cannot be distinguished from rotavirus based on clinical findings. In an outbreak setting, the pattern of a brief incubation period (12-48 hr), short duration of illness, and clustering of cases is shared by caliciviruses and preformed bacterial toxin. However, unlike preformed toxins, caliciviruses cause secondary infections, which confirm the contagious nature of the outbreak. Diarrheal illnesses caused by enteric adenovirus infections tend to be more prolonged than rotavirus (7 to 10 days), whereas astroviruses cause a shorter course (~5 days) usually without significant vomiting.

Bacterial Diarrhea. Although there is considerable overlap, fever >40°C, overt fecal blood, abdominal pain, no vomiting before diarrhea onset, and high stool frequency (>10 per day) are more common with bacterial pathogens (see Tables 366.2 and 366.9). Although high fever and overt fecal blood are often absent in bacterial enteritis, when present, there is a high probability of a bacterial etiology. The classical bacterial agents, NTS, *Shigella, Campylobacter,* and *Yersinia*, present with 1 of 5 syndromes.

1. Acute diarrhea, the most common presentation, may be accompanied by fever and vomiting. Clinically silent bacteremia associated with uncomplicated NTS AGE can be seen among otherwise healthy children younger than 2 yr living in industrialized countries.
2. Bloody diarrhea or frank dysentery is classically caused by *Shigella* . Watery diarrhea typically precedes dysentery and is often the sole clinical manifestation of mild infection. Progression to dysentery indicates colitis and may occur within hours to days. Patients with severe infection may pass more than 20 dysenteric stools in 1 day. Dysenteric illnesses due to *Campylobacter* have been confused with inflammatory bowel disease.
3. Invasive, nonfocal disease (**enteric fever**) is a febrile illness associated with bacteremia without localized infection. Diarrhea may be minimal or absent. Although classically the result of *S.* Typhi or Paratyphi A and B, enteric fever can result from systemic spread of the classical bacterial enteropathogens. Although enteric fever caused by *S.* Typhi or Paratyphi

A and B primarily affect preschool and school-age children in endemic countries, other bacterial enteropathogens most often cause disease in infants (particularly <3 mo), the immunocompromised, and children with malnutrition. Additional risk factors include hemolytic anemia and intravascular lesions for NTS, and iron overload, cirrhosis, and chelation therapy for *Yersinia* sepsis. The distinct clones of NTS that have arisen in sub-Saharan Africa described earlier are causing enteric fever–type illnesses often in the absence of AGE. *Shigella* sepsis is rare and is seen most often in malnourished and immunocompromised hosts.

4. Extraintestinal invasive infections can result from either local invasion or bacteremic spread (Table 366.10). Examples of local invasion include mesenteric adenitis, appendicitis, and rarely cholecystitis, mesenteric venous thrombosis, pancreatitis, hepatic, or splenic abscess. Bacteremic spread may result in pneumonia, osteomyelitis, meningitis (3 conditions seen most commonly with NTS), abscesses, cellulitis, septic arthritis, and endocarditis. *Shigella* can cause noninvasive contiguous infections such as vaginitis and urinary tract infections.

Table 366.10

Intestinal and Extraintestinal Complications of Enteric Infections

COMPLICATION	ASSOCIATED ENTERIC PATHOGEN(S)
Intestinal Complications	
Persistent diarrhea	All causes
Recurrent diarrhea (usually immunocompromised persons)	*Salmonella, Shigella* , *Yersinia* , *Campylobacter, Clostridium difficile* , *Entamoeba histolytica* , *Cryptosporidium, Giardia*
Toxic megacolon	*Shigella* , *C. difficile* , *E. histolytica*
Intestinal perforation	*Shigella* , *Yersinia, C. difficile* , *E. histolytica*
Rectal prolapse	*Shigella* , STEC, *C. difficile*
Enteritis necroticans–jejunal hemorrhagic necrosis	*Clostridium perfringens* type C beta toxin
Extraintestinal Complications	
Dehydration, metabolic abnormalities, malnutrition, micronutrient deficiency	All causes
Bacteremia with systemic spread of bacterial pathogens, including endocarditis, osteomyelitis, meningitis, pneumonia, hepatitis, peritonitis,	Nontyphoidal *Salmonella, Shigella, Yersinia, Campylobacter*

chorioamnionitis, soft tissue infection, and septic thrombophlebitis	
Local spread (e.g., vulvovaginitis and urinary tract infection) Pseudoappendicitis Exudative pharyngitis, cervical adenopathy Rhabdomyolysis and hepatic necrosis	*Shigella* *Yersinia, Campylobacter* (occasionally) *Yersinia* *Bacillus cereus* emetic toxin
Postinfectious Complications	
Reactive arthritis	*Salmonella, Shigella, Yersinia, Campylobacter, Cryptosporidium, C. difficile*
Guillain-Barré syndrome	*Campylobacter*
Hemolytic uremic syndrome	STEC, *Shigella dysenteriae* 1
Glomerulonephritis, myocarditis, pericarditis	*Shigella, Campylobacter, Yersinia*
Immunoglobulin A (IgA) nephropathy	*Campylobacter*
Erythema nodosum	*Yersinia, Campylobacter, Salmonella*
Hemolytic anemia	*Campylobacter, Yersinia*
Intestinal perforation	*Salmonella, Shigella, Campylobacter, Yersinia, Entamoeba histolytica*
Osteomyelitis, meningitis, aortitis	*Salmonella, Yersinia, Listeria*

STEC, Shiga toxin–producing *Escherichia coli.*

From Centers for Disease Control and Prevention: Managing acute gastroenteritis among children, *MMWR Recomm Rep* 53:1–33, 2004.

5. Vertical transmission of *Shigella* , NTS, and *Campylobacter* can produce perinatal infection resulting in a spectrum of illness from isolated diarrhea or hematochezia to fulminant neonatal sepsis. One species of *Campylobacter, C. fetus,* is particularly virulent in pregnant women and can result in chorioamnionitis, abortion, and neonatal sepsis and meningitis.

Crampy abdominal pain and nonbloody diarrhea are the first symptoms of STEC infection, sometimes with vomiting. Within several days, diarrhea becomes bloody and abdominal pain worsens. Bloody diarrhea lasts between 1 and 22 days (median 4 days). In contrast to dysentery, the stools associated with STEC hemorrhagic colitis are large volume and rarely accompanied by high fever. ETEC produce a secretory watery diarrhea that affects infants and young children in developing countries and is the major causative agents of travelers' diarrhea, accounting for about half of all episodes in some studies. EPEC remains a leading cause of persistent diarrhea associated with malnutrition among infants from developing countries. EIEC, which are genetically, biochemically, and clinically nearly identical to *Shigella* , causes rare foodborne outbreaks in industrialized countries. EAEC has been associated with persistent diarrhea in immunocompromised persons and sporadic diarrhea in infants in countries with varying levels of economic development; however, some other studies have not found an association with disease.

C. difficile toxin is associated with several clinical syndromes. The most common is mild to moderate watery diarrhea, low-grade fever, and mild abdominal pain. Occasionally, the illness will progress to full-blown *pseudomembranous colitis* characterized by diarrhea, abdominal cramps, and fever. The colonic mucosa contains 2-5 mm raised, yellowish plaques. Fatal cases are associated with toxic megacolon, systemic toxicity, and multisystem organ failure, possibly related to systemic absorption of toxin. A vomiting illness is associated with *S. aureus* and *B. cereus* emetic toxin, while diarrhea is the major manifestation of *C. perfringens* and *B. cereus* enterotoxins.

Protozoal Diarrhea. Illnesses due to intestinal protozoa tend to be more prolonged, sometimes for 2 wk or more, but usually self-limited in the otherwise healthy host (see Table 366.3). In general, the duration and severity of *Cryptosporidium* diarrhea is strongly influenced by the immune and nutritional status of the host. A protozoal etiology should be suspected when there is a prolonged diarrheal illness characterized by episodes of sometimes-explosive diarrhea with nausea, abdominal cramps, and abdominal bloating. The stools are usually watery but can be greasy and foul smelling due to concomitant malabsorption of fats, which is more likely to occur if the parasite load is high. Occasionally diarrhea may alternate with constipation.

In addition to diarrhea, *E. histolytica* causes a range of other syndromes. Amebic dysentery is characterized by bloody or mucoid diarrhea, which may be profuse and lead to dehydration or electrolyte imbalances. Hepatic amebiasis is limited to abscess formation in the liver, which may occur with or without intestinal disease.

Intestinal and Extraintestinal Complications

The major complications from diarrhea from any cause are dehydration, electrolyte, or acid-base derangements, which can be life-threatening (see Table 366.10). Avoiding delays in diagnosis and treatment, and appropriate supportive care using either oral, enteral, or intravenous hydration can prevent or treat most of these conditions. Children who experience frequent episodes of acute diarrhea or prolonged or persistent episodes (seen especially in low resource settings) are at risk for poor growth and nutrition and complications such as secondary infections and micronutrient deficiencies (iron, zinc, vitamin A). Ensuring continued nutritional support during diarrheal episodes is important because prolonged limitation of the diet may extend diarrheal symptoms. Reestablishing a normal diet generally restores villous anatomy and function with resolution of loose stools.

Viral AGE illnesses are usually self-limited and resolve after several days. Rarely, **intussusception** is triggered by lymphoid hyperplasia associated with viral AGE. Complications of bacterial AGE may be the result of local or systemic spread of the organism; in malnourished children and HIV-infected populations, associated **bacteremia** is well-recognized. Toxic megacolon, intestinal perforation, and rectal prolapse can occur, particularly in association with *Shigella* in developing countries and *C. difficile* . The most dreaded complication of pediatric diarrhea in the United States is **HUS** , the leading cause of acquired renal failure in children, developing in 5–10% of patients infected with STEC. It is usually diagnosed 2-14 days after the onset of diarrhea. HUS is unlikely to occur once diarrhea has remained resolved for 2 or 3 days with no evidence of hemolysis. Risk factors include age 6 mo to 4 yr, bloody diarrhea, fever, elevated leukocyte count, and treatment with antibiotics and antimotility agents. Two-thirds of patients no longer excrete the organism at the time they develop HUS (Chapter 538.5).

Pseudoappendicitis secondary to mesenteric adenitis is a notable complication of *Yersinia* , and sometimes *Campylobacter* . Older children and adolescents are most often affected. It typically presents with fever and abdominal pain with tenderness localized to the right lower quadrant, with or without diarrhea, and can be confused with appendicitis. CT scan or sonogram may be helpful to distinguish true appendicitis.

Immune-mediated complications that are thought to result from immunologic cross reactivity between bacterial antigens and host tissues are more often seen in adults than children. These include reactive arthritis following infection with the classical bacterial enteropathogens and Guillain-Barré syndrome following *Campylobacter* infection.

Protozoan illnesses, when persistent, can lead to poor weight gain in the young and immunocompromised individuals, weight loss, malnutrition, or vitamin deficiencies. Infection with *Entamoeba* can cause severe ulcerating colitis, colonic dilation, and perforation. The parasite may spread systemically, most commonly causing liver abscesses. In high-risk settings, it is critical to exclude *Entamoeba* infection and tuberculosis before initiating corticosteroids for presumed ulcerative colitis.

Differential Diagnosis

The physician should also consider noninfectious diseases that can present with bright red blood per rectum or hematochezia (Table 366.11). In an infant or young child without systemic symptoms, these may include anal fissures, intermittent intussusception, juvenile polyps, and Meckel diverticulum. Necrotizing enterocolitis can cause lower gastrointestinal bleeding in infants, especially premature neonates. Inflammatory bowel disease should be considered in older children. Examples of noninfectious causes of nonbloody diarrhea include congenital secretory diarrheas, endocrine disorders (hyperthyroidism), neoplasms, food intolerance, and medications (particularly antibiotics). Noninfectious causes of chronic or relapsing diarrhea include cystic fibrosis, celiac disease, milk protein intolerance, and congenital or acquired disaccharidase deficiency. Significant abdominal pain should raise suspicion of other infectious processes in the abdomen such as appendicitis and pelvic inflammatory disease. Prominent vomiting with or without abdominal pain can be a manifestation of pyloric stenosis, intestinal obstruction, pancreatitis, appendicitis, and cholecystitis.

Table 366.11

Differential Diagnosis of Acute Dysentery and Inflammatory Enterocolitis

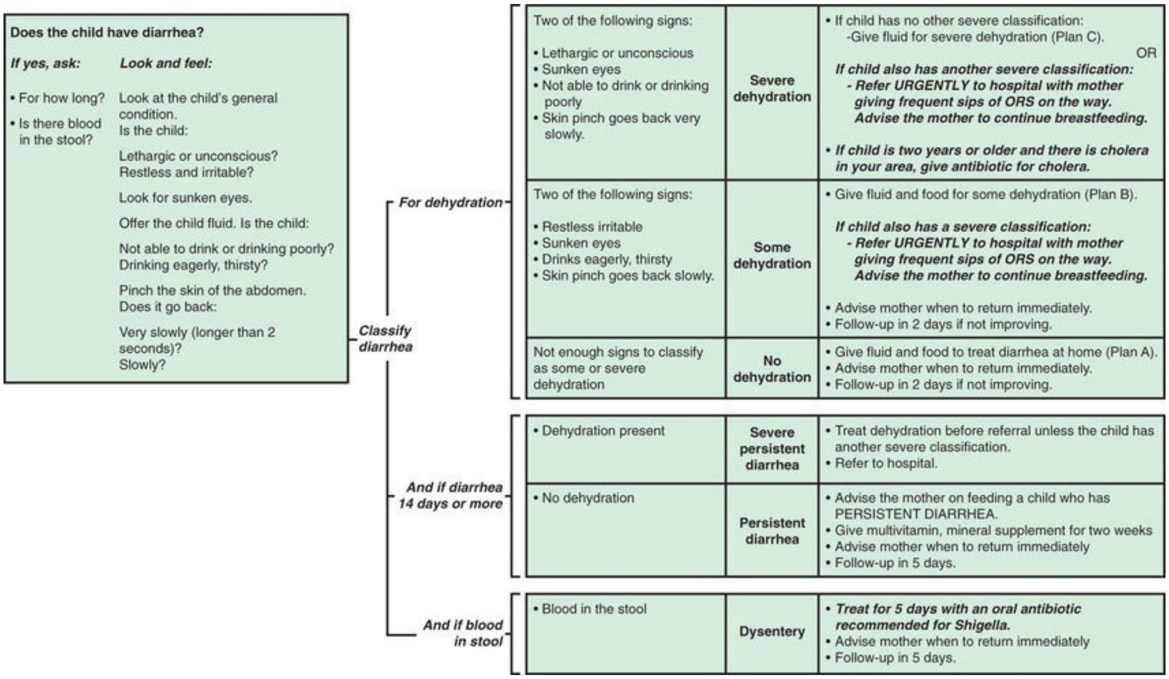
Specific Infectious Processes
• Bacillary dysentery *(Shigella dysenteriae, Shigella flexneri, Shigella sonnei, Shigella boydii; invasive Escherichia coli)* • Campylobacteriosis *(Campylobacter jejuni)* • Amebic dysentery *(Entamoeba histolytica)* • Ciliary dysentery *(Balantidium coli)* • Bilharzial dysentery *(Schistosoma japonicum, Schistosoma mansoni)* • Other parasitic infections *(Trichinella spiralis)* • Vibriosis *(Vibrio parahaemolyticus)* • Salmonellosis *(Salmonella typhimurium)*

• Typhoid fever *(Salmonella typhi)* • Enteric fever *(Salmonella choleraesuis, Salmonella paratyphi)* • Yersiniosis *(Yersinia enterocolitica)* • Spirillar dysentery *(Spirillum spp.)*
Proctitis
• Gonococcal *(Neisseria gonorrhoeae)* • Herpetic (herpes simplex virus) • Chlamydial *(Chlamydia trachomatis)* • Syphilitic *(Treponema pallidum)*
Other Syndromes
• Necrotizing enterocolitis of the newborn • Enteritis necroticans • Pseudomembranous enterocolitis *(Clostridium difficile)* • Typhlitis
Chronic Inflammatory Processes
• Enteropathogenic and enteroaggregative *E. coli* • Gastrointestinal tuberculosis • Gastrointestinal mycosis • Parasitic enteritis
Syndromes Without Known Infectious Cause
• Idiopathic ulcerative colitis • Celiac disease • Crohn disease • Radiation enteritis • Ischemic colitis • Immune deficiency including HIV infection • Allergic enteritis

From Mandell GL, Bennett JE, Dolin R, editors: *Principles and practices of infectious diseases* , ed 7, Philadelphia, 2010, Churchill Livingstone.

Clinical Evaluation of Diarrhea

In the initial evaluation of all patients with AGE, the physician should focus on the patient's hydration status and electrolyte balance, as well as evidence of sepsis or invasive bacterial infection, which could complicate bacterial AGE (Fig. 366.6). Once the patient is stabilized, the history and physical examination can focus on detecting risk factors and exposures, as well as the clinical features that may suggest specific etiologic agents (see Tables 366.5 and 366.6).



Does the child have diarrhea?
If yes, ask:
Look and feel:
• For how long?
• Is there blood in the stool?
Look at the child's general condition.
Is the child:
Lethargic or unconscious?
Restless and irritable?
Look for sunken eyes.
Offer the child fluid. Is the child:
Not able to drink or drinking poorly?
Drinking eagerly, thirsty?
Pinch the skin of the abdomen.
Does it go back:
Very slowly (longer than 2 seconds)?
Slowly?
Classify diarrhea
For dehydration
Two of the following signs:
• Lethargic or unconscious
• Sunken eyes
• Not able to drink or drinking poorly
• Skin pinch goes back very slowly.
Severe dehydration
• If child has no other severe classification:
-Give fluid for severe dehydration (Plan C).
OR
If child also has another severe classification:
- Refer URGENTLY to hospital with mother giving frequent sips of ORS on the way.
Advise the mother to continue breastfeeding.
• If child is two years or older and there is cholera in your area, give antibiotic for cholera.
Two of the following signs:
• Restless irritable
• Sunken eyes
• Drinks eagerly, thirsty
• Skin pinch goes back slowly.
Some dehydration
• Give fluid and food for some dehydration (Plan B).
If child also has a severe classification:
- Refer URGENTLY to hospital with mother giving frequent sips of ORS on the way.
Advise the mother to continue breastfeeding.
• Advise mother when to return immediately.
• Follow-up in 2 days if not improving.
Not enough signs to classify as some or severe dehydration
No dehydration
• Give fluid and food to treat diarrhea at home (Plan A).
• Advise mother when to return immediately.
• Follow-up in 2 days if not improving.
And if diarrhea 14 days or more
• Dehydration present
Severe persistent diarrhea
• Treat dehydration before referral unless the child has another severe classification.
• Refer to hospital.
• No dehydration
Persistent diarrhea
• Advise the mother on feeding a child who has PERSISTENT DIARRHEA.
• Give multivitamin, mineral supplement for two weeks
• Advise mother when to return immediately
• Follow-up in 5 days.
And if blood in stool
• Blood in the stool
Dysentery
• Treat for 5 days with an oral antibiotic recommended for Shigella.
• Advise mother when to return immediately
• Follow-up in 5 days.

FIG. 366.6 Integrated Management of Childhood Illnesses protocol for the recognition and management of diarrhea in developing countries. *ORS,* oral rehydration solution.

Important elements of the medical history include the duration of diarrhea and a description of stools (frequency, amount, presence of blood or mucus), fever (duration, magnitude), vomiting (onset, amount and frequency), and the amount and type of solid and liquid oral intake. Clinical signs of dehydration should be evaluated (Table 366.12): urine output (number of wet diapers per day and time since the last urination), whether eyes appear sunken, whether the child is active, whether the child drinks vigorously, and the date and value of the most recent weight measurement. A documented weight loss can be used to calculate the fluid deficit. The past medical history should identify comorbidities that might increase the risk or severity of AGE.

Table 366.12

Clinical Signs Associated With Dehydration

SYMPTOM	MINIMAL OR NO DEHYDRATION	SOME DEHYDRATION	SEVERE DEHYDRATION
Mental status	Well; alert	Normal, fatigued or restless, irritable	Apathetic, lethargic, unconscious
Thirst	Drinks normally; might refuse liquids	Thirsty; eager to drink	Drinks poorly; unable to drink
Heart rate	Normal	Normal to increased	Tachycardia, with bradycardia in most

			severe cases
Quality of pulses	Normal	Normal to decreased	Weak, thready, or impalpable
Breathing	Normal	Normal; fast	Deep
Eyes	Normal	Slightly sunken	Deeply sunken
Tears	Present	Decreased	Absent
Mouth and tongue	Moist	Dry	Parched
Skinfold	Instant recoil	Recoil in <2 sec	Recoil in >2 sec
Capillary refill	Normal	Prolonged	Prolonged; minimal
Extremities	Warm	Cool	Cold; mottled; cyanotic
Urine output	Normal to decreased	Decreased	Minimal

Modified from Duggan C, Santosham M, Glass RI: The management of acute diarrhea in children: oral rehydration, maintenance, and nutritional therapy, *MMWR Recomm Rep* 41(RR-16):1–20, 1992; and World Health Organization: *The treatment of diarrhoea: a manual for physicians and other senior health workers,* Geneva, 1995, World Health Organization; and Centers for Disease Control and Prevention: Diagnosis and management of foodborne illnesses, *MMWR* 53(RR-4):1–33, 2004.

Certain physical signs are best assessed before approaching the child directly, so he/she remains calm, including general appearance (activity, response to stimulation) and respiratory patterns. Skin turgor is assessed by pinching a small skin fold on the lateral abdominal wall at the level of the umbilicus. If the fold does not promptly return to normal after release, the recoil time is quantified as delayed slightly or ≥2 sec. Excess subcutaneous tissue and hypernatremia may produce a false negative test and malnutrition can prolong the recoil time. To measure capillary refill time, the palmar surface of the child's distal fingertip is pressed until blanching occurs, with the child's arm at heart level. The time elapsed until restoration of normal color after release usually exceeds 2 sec in the presence of dehydration. Mucous membrane moisture level, presence of tears, and extremity temperature should be assessed.

Laboratory Diagnosis

Most cases of AGE do not require diagnostic laboratory testing. Stool specimens could be examined for mucus, blood, neutrophils or fecal lactoferrin, a neutrophil product. The finding of more than 5 leukocytes per high-power field or a positive lactoferrin assay in an infant not breastfeeding suggests an infection with a classical bacterial enteropathogen; patients infected with STEC and *E. histolytica* usually have negative tests.

Laboratory diagnosis of viral AGE may be helpful when an outbreak is suspected, cases are linked to a suspected outbreak, or when cohorting of patients is considered to limit the spread of infection. The preferred method of testing norovirus is real-time reverse transcription quantitative polymerase chain reaction (RT-qPCR), available at most public health and virology laboratories. Commercial tests are available for the diagnosis of rotavirus and enteric adenoviruses but not for astrovirus in the United States (see Table 366.1).

Stool cultures for detection of bacterial agents are costly, so requests should be restricted to patients with clinical features predictive of bacterial AGE, have moderate or severe disease, are immunocompromised, in outbreaks with suspected hemolytic-uremic syndrome, or have a highly suggestive epidemiologic history. To optimize recovery of pathogens, stool specimens for culture need to be transported and plated quickly; if the latter is not quickly available, specimens might need to be transported in special transport media. If the child has not passed a stool and antibiotics will be administered, a rectal swab should be collected promptly. After dipping the cotton tip into the medium that will be used for transport, it is gently inserted into the child's rectum and rotated 360 degrees. A properly collected rectal swab is stained or covered with fecal material. Standard stool culture methods performed in clinical microbiology laboratories recover *Shigella* and *Salmonella* species. If *Campylobacter* , *Yersinia* , or *Vibrio* species are suspected, the laboratory should be notified unless media are routinely used for their detection. All bloody stools should also be inoculated into media specific for detection of *E. coli* 0157:H7 or directly tested for the presence of Shiga-like toxin (or both). Except for *C. difficile* , nosocomial acquisition of a bacterial enteric pathogen is very unlikely. Hence stool microbiologic assays are generally not indicated for patients in whom diarrhea develops more than 3 days after admission unless the patient is immunocompromised or to investigate a hospital outbreak (see Table 366.2). Stool can also be tested for bacterial pathogens by nucleic acid amplification test (NAAT); if the NAAT is positive, the sample should automatically be cultured to determine antimicrobial sensitivities.

For children older than 2 yr who have recently received antibiotics or have other risk factors, evaluation for *C. difficile* infection may be appropriate. The cytotoxin assay detects toxin B, but testing for toxin A is also available in some laboratories; however, this test is laborious. Several tests are commercially available to detect toxin-producing *C. difficile* in stool, including enzyme immunoassays for toxins A and B, cell culture cytotoxicity assay, and PCR. The sensitivities of cell culture and PCR are superior to that of immunoassay. Testing for *C . difficile* toxin in children younger than 2 yr is discouraged because the organism and its toxins are commonly detected in asymptomatic infants (see Table 366.2).

Evaluation for intestinal protozoa that cause diarrhea is usually indicated in patients who recently traveled to an endemic area, have contact with untreated water, and manifest suggestive symptoms. The most commonly used method is direct microscopy of stool for cysts and trophozoites. However, this approach is time consuming and lacks sensitivity, in part because shedding can be intermittent. Analyzing 3 specimens from separate days is optimal, and fecal concentration techniques provide some benefit. The sensitivity and specificity of microscopy are substantially improved using immunofluorescence antibodies that are commercially available for visualization of *Cryptosporidium* and *Giardia* cysts. In addition, enzyme immunoassays are available for *Cryptosporidium, Giardia*, and *Entamoeba* that are more sensitive and specific than direct microscopy and provide a useful diagnostic tool (not all commercial kits distinguish between pathogenic *E. histolytica* and nonpathogenic *E. dispar*). Molecular methods (NAAT) are also available.

Several culture-independent *rapid multiplex molecular panels* for detection of viral, bacterial, and protozoal gastrointestinal pathogens directly from stool samples are FDA approved, including xTag GPP (14 pathogens), Verigene EP (9 pathogens), and the FirmArray GI (22 pathogens). These methods offer several advantages over conventional diagnostics, including reduced sample volume requirements, broad coverage without the need to select specific tests, enhanced ability to detect coinfections, increased sensitivity, and rapid turnaround. However, their use is controversial because the available tests do not provide strain specificity or antimicrobial susceptibility testing to assist with outbreak detection and treatment decisions.

Most episodes of diarrheal dehydration are isonatremic and do not warrant serum electrolyte measurements. Electrolyte measurements are most useful in children with severe dehydration, when intravenous fluids are administered, when there is a history of frequent watery stools, yet the skin pinch feels doughy without delayed recoil, which suggests hypernatremia, or when inappropriate rehydration fluids have been administered at home. A suspicion for HUS prompts a complete blood count with review of the peripheral smear, platelets, serum electrolytes, and renal function tests. Patients with shigellosis can demonstrate bandemia or even a leukemoid reaction. Blood culture should be obtained if there is concern for systemic bacterial infection. This includes infants and children with fever and/or blood in the stool who are younger than 3 mo, are immunocompromised, or have hemolytic anemia or other risk factors. If diarrhea persists with no cause identified, endoscopic evaluation may be indicated. Biopsy specimens help in diagnosing inflammatory bowel disease or identifying infecting agents that may mimic it. A sweat test is warranted if cystic fibrosis is suspected.

Treatment

The broad principles of management of AGE in children include rehydration and maintenance ORS plus replacement of continued losses in diarrheal stools and vomitus after rehydration, continued breastfeeding, and refeeding with an age-appropriate, unrestricted diet as soon as dehydration is corrected. Zinc supplementation is recommended for children in developing countries.

Hydration

Children, especially infants, are more susceptible than adults to dehydration because of the greater basal fluid and electrolyte requirements per kilogram and because they are dependent on others to meet these demands (Table 366.13). *Dehydration must be evaluated rapidly and corrected in 4-6 hr according to the degree of dehydration and estimated daily requirements*. When there is emesis, small volumes of ORS can be given initially by a dropper, teaspoon, or syringe, beginning with as little as 5 mL at a time. The volume is increased as tolerated. The low-osmolality World Health Organization (WHO) ORS containing 75 mEq of sodium, 64 mEq of chloride, 20 mEq of potassium, and 75 mmol of glucose per liter, with total osmolarity of 245 mOsm/L, is now the global standard of care and more effective than home fluids. Soda beverages, fruit juices, tea, and other home fluids are not suitable for rehydration or maintenance therapy because they have inappropriately high glucose concentration and osmolalities and low sodium concentrations. Tables 366.12 and 366.13 outline a clinical evaluation plan and management strategy for children with moderate to severe diarrhea. Replacement for emesis or stool losses is noted in Table 366.13 . Oral rehydration can also be given by a nasogastric tube if needed; this is not the usual route.

Table 366.13

Fluid and Nutritional Management of Diarrhea

DEGREE OF DEHYDRATION[*]	REHYDRATION THERAPY	REPLACEMENT OF LOSSES DURING MAINTENANCE [†]
Some dehydration	Infants [‡] and children: ORS, 50-100 mL/kg over 3-4 hr. Continue breast feeding. After 4 hr, give food every 3-4 hr for children who normally receive solid foods.	Infants and children: <10 kg body weight: 50-100 mL ORS for each diarrheal stool or vomiting episode, up to ~500 mL/day >10 kg body weight: 100-200 mL ORS for each diarrheal stool or vomiting episode; up to ~1 L/day Replace losses as above as long as diarrhea or vomiting continues
Severe dehydration	Malnourished infants may benefit from smaller-volume, frequent boluses of 10 mL/kg body weight due to reduced capacity to increase cardiac output with larger volume resuscitation. Infants (<12 months) and children (12 mo to 5 yr) without malnutrition: Give 20-30 mL/kg boluses of intravenous isotonic crystalloid solution (e.g., normal saline solution) over 30-60 min. Repeat boluses as necessary to restore adequate perfusion. Then give 70 mL/kg over 2.5-5 hr. (Note the slower infusion times are for infants.) Reassess the infant or child frequently and adjust infusion rate if needed. Switch to ORS, breast milk, and feed as described for some dehydration, when the child can drink, perfusion is adequate, and mental status is normal. Adjust electrolytes and administer dextrose based on chemistry values.	Infants and children: <10 kg body weight: 50-100 mL ORS for each diarrheal stool or vomiting episode, up to ~500 mL/day >10 kg body weight: 100-200 mL ORS for each diarrheal stool or vomiting episode; up to ~1 L/day Adolescents and adults: Ad libitum, up to ~2 L/day Replace losses as above as long as

		diarrhea or vomiting continue. If unable to drink, administer either through a nasogastric tube or give 5% dextrose 0.25 normal saline solution with 20 mEq/L potassium chloride intravenously.

[*] A variety of scales are available to grade the severity of dehydration in young children, but no single, standard, validated method exists. Note that signs of dehydration may be masked when a child is hypernatremic. The World Health Organization defines some dehydration as the presence of two or more of the following signs: restlessness/irritability, sunken eyes, drinks eagerly, thirsty, and skin pinch goes back slowly. Severe dehydration is defined as two or more of the following signs: lethargy/unconsciousness, sunken eyes, unable to drink/drinks poorly, and skin pinch goes back very slowly (>2 sec).

[†] After rehydration is complete, maintenance fluids should be resumed along with an age-appropriate normal diet offered every 3-4 hr. Children previously receiving a lactose-containing formula can tolerate the same product in most instances. Diluted formula does not appear to confer any benefit.

[‡] Breastfed infants should continue nursing throughout the illness.

Low-osmolarity ORS can be given to all age groups, with any cause of diarrhea. It is safe in the presence of hypernatremia, as well as hyponatremia (except when edema is present). Some commercially available formulations that can be used as ORS include Pedialyte Liters (Abbott Nutrition), CeraLyte (Cero Products), and Enfalac Lytren (Mead Johnson). Popular beverages that should not be used for rehydration include apple juice, Gatorade, and commercial soft drinks.

ORS, oral rehydration solution.

Modified from Centers for Disease Control and Prevention: Managing acute gastroenteritis among children: oral rehydration, maintenance, and nutritional therapy. *MMWR Recomm Rep* 52(RR-16):1–16, 2003; and World Health Organization. Pocket book of hospital care for children: Guidelines for the management of common childhood illnesses, ed 2 (http://www.who.int/maternal_child_adolescent/documents/child_hospital_care/en/).

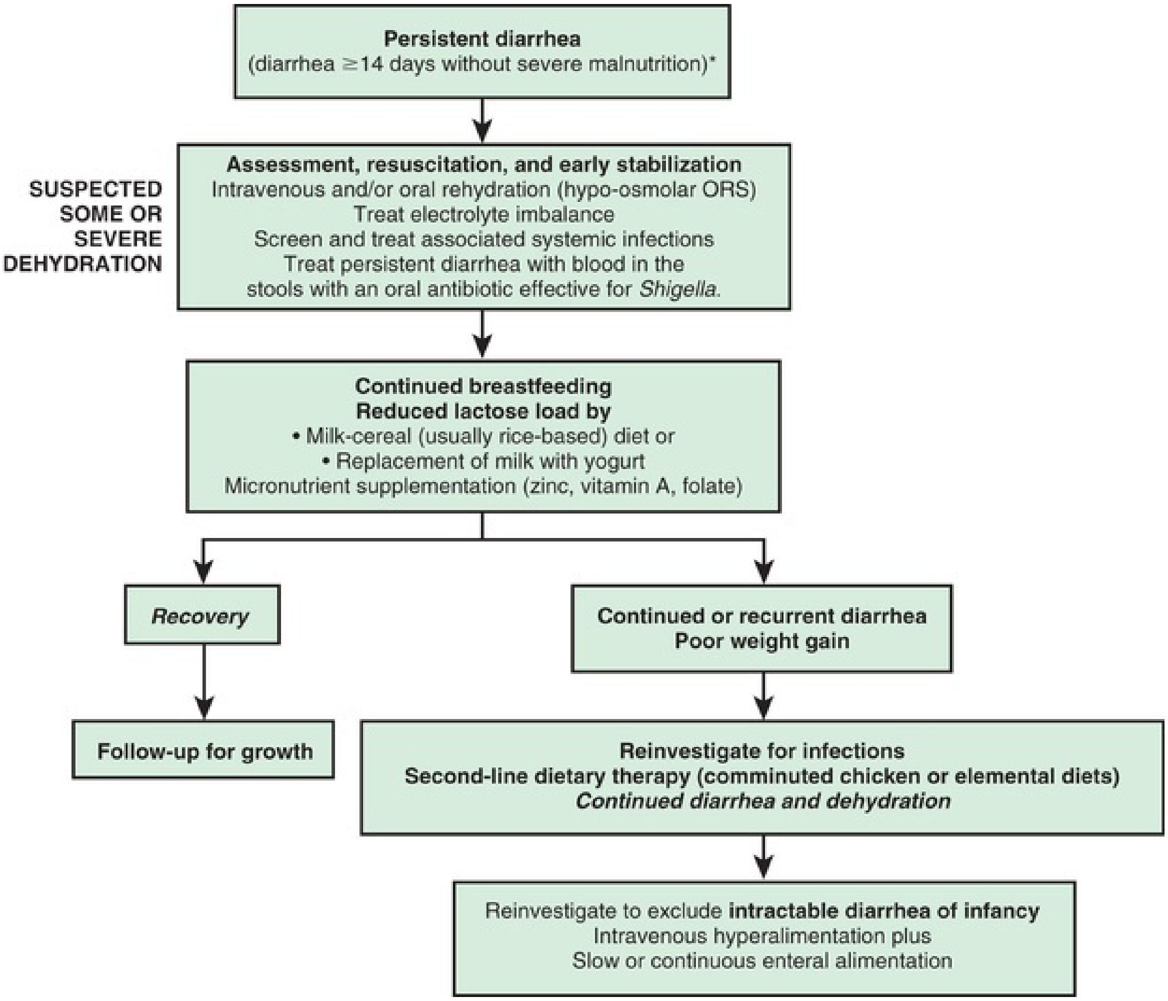
A small minority of children, including those with severe dehydration or unable to tolerate oral fluids, require initial intravenous rehydration, but oral rehydration is the preferred mode of rehydration and replacement of ongoing losses. Signs of severe dehydration that might necessitate intravenous resuscitation are shown in Table 366.13 . Limitations to ORS include shock, decreased level of consciousness, an ileus, intussusception, carbohydrate intolerance (rare), severe emesis, and high stool output (>10 mL/kg/hr).

Enteral Feeding and Diet Selection

Continued breastfeeding and refeeding with an age-appropriate, unrestricted diet as soon as dehydration is improving or resolved aids in recovery from the episode. Foods with complex carbohydrates (rice, wheat, potatoes, bread, and cereals), fresh fruits, lean meats, yogurt, and vegetables should be reintroduced while ORS is given to replace ongoing losses from emesis or stools and for maintenance. Fatty foods or foods high in simple sugars (juices, carbonated sodas) should be avoided. The usual energy density of any diet used for the therapy of diarrhea should be around 1 kcal/g, aiming to provide an energy intake of a minimum of 100 kcal/kg/day and a protein intake of 2-3 g/kg/day. In selected circumstances when adequate intake of energy-dense food is problematic, the addition of amylase to the diet through germination techniques can also be helpful.

If the normal diet includes infant formula, it should not be diluted, or changed to a lactose-free preparation unless lactose malabsorption is evident. With the exception of acute lactose intolerance in a small subgroup, most children with diarrhea are able to tolerate milk and lactose-containing diets. *Withdrawal of milk and replacement with specialized lactose-free formulations are unnecessary.* Although children with persistent diarrhea are not lactose intolerant, administration of a lactose load exceeding 5 g/kg/day may be associated with higher purging rates and treatment failure. Alternative strategies for reducing the lactose load while feeding malnourished children who have prolonged diarrhea include addition of milk to cereals and replacement of milk with fermented milk products such as yogurt.

Rarely, when dietary intolerance precludes the administration of cow's milk–based formulations or whole milk, it may be necessary to administer specialized milk-free diets such as a comminuted or blenderized chicken-based diet or an elemental formulation. Although effective in some settings, the latter are unaffordable in most developing countries. In addition to rice-lentil formulations, the addition of green banana or pectin to the diet has also been shown to be effective in the treatment of persistent diarrhea. Fig. 366.7 gives an algorithm for managing children with prolonged diarrhea in developing countries.



Persistent diarrhea
(diarrhea ≥14 days without severe malnutrition)*
SUSPECTED SOME OR SEVERE DEHYDRATION
Assessment, resuscitation, and early stabilization
Intravenous and/or oral rehydration (hypo-osmolar ORS)
Treat electrolyte imbalance
Screen and treat associated systemic infections
Treat persistent diarrhea with blood in the stools with an oral antibiotic effective for Shigella.
Continued breastfeeding
Reduced lactose load by
• Milk-cereal (usually rice-based) diet or
• Replacement of milk with yogurt
Micronutrient supplementation (zinc, vitamin A, folate)
Recovery
Follow-up for growth
Continued or recurrent diarrhea
Poor weight gain
Reinvestigate for infections
Second-line dietary therapy (comminuted chicken or elemental diets)
Continued diarrhea and dehydration
Reinvestigate to exclude intractable diarrhea of infancy
Intravenous hyperalimentation plus
Slow or continuous enteral alimentation

FIG. 366.7 Management of persistent diarrhea. *IV,* intravenous; *NG,* nasogastric tube; *ORS,* oral rehydration solution. *Severely malnourished children require urgent referral for hospitalization and specific treatment.

Among children in low- and middle-income countries, where the dual burden of diarrhea and malnutrition is greatest and where access to proprietary formulas and specialized ingredients is limited, the use of locally available age-appropriate foods should be promoted for the majority of acute diarrhea cases. Even among those children for whom lactose avoidance may be necessary, nutritionally complete diets composed of locally available ingredients can be used at least as effectively as commercial preparations or specialized ingredients. These same conclusions may also apply to the dietary management of children with persistent diarrhea, but the evidence remains limited.

Zinc Supplementation

Zinc supplementation in children with diarrhea in developing countries leads to reduced duration and severity of diarrhea and could potentially prevent a large proportion of cases from recurring. Zinc administration for diarrhea management can significantly reduce all-cause mortality by 46% and hospital admission by 23%. In addition to improving diarrhea recovery rates, administration of zinc in community settings leads to increased use of ORS and reduction in the inappropriate use of antimicrobials. All children older than 6 mo of age with acute diarrhea in at-risk areas should receive oral zinc (20 mg/day) in some form for 10-14 days during and continued after diarrhea. The role of zinc in well nourished, zinc replete populations in developed countries is less certain.

Additional Therapies

The use of probiotic nonpathogenic bacteria for prevention and therapy of diarrhea has been successful in some settings, although the evidence does not support a recommendation for their use in all settings. A variety of organisms *(Lactobacillus, Bifidobacterium)* have a good safety record; therapy has not been standardized and the most effective (and safe) organism has not been identified. *Saccharomyces boulardii* is effective in antibiotic-associated and in *C. difficile* diarrhea, and there is some evidence that it might prevent diarrhea in daycare centers. Two large randomized placebo-controlled trials evaluating the efficacy of two *Lactobacillus* -based probiotic formulations failed to reduce a clinical severity score in Canadian infants and preschool children with acute gastroenteritis. *Lactobacillus rhamnosus GG* or a combination probiotic product containing *L. rhamnosus* R0011 and *L. helveticus* R0052 is has shown variable efficacy; reduction is more evident in cases of childhood rotavirus diarrhea.

Ondansetron (oral mucosal absorption preparation) reduces the incidence of emesis, thus permitting more effective oral rehydration and is well-established in emergency management of AGE in high-resource settings, reducing intravenous fluid requirements and hospitalization. Because persistent vomiting can limit ORS, a single sublingual dose of an oral dissolvable tablet of ondansetron (4 mg for children 4-11 yr old and 8 mg for children older than 11 yr [generally 0.2 mg/kg]) may be given. However, most children do not require specific antiemetic therapy; careful ORS is usually sufficient. Antimotility agents (loperamide) are contraindicated in children with dysentery and probably have no role in the management of acute watery diarrhea in otherwise healthy children. Similarly, antiemetic agents, such as the phenothiazines, are of little value and are associated with potentially serious side effects (lethargy, dystonia, malignant hyperpyrexia).

Antibiotic Therapy

Judicious antibiotic therapy for suspected or proven bacterial infections can reduce the duration and severity of illness and prevent complications (Table 366.14). Several factors justify limited use. First, most episodes of AGE are self-limited among otherwise healthy children. Second, the increasing prevalence of antibiotic resistance has prompted restricted use of these drugs. Third, antibiotics may worsen outcome, because some studies have shown that antibiotic therapy of STEC infection increases the risk of HUS and prolongs excretion of NTS without improving clinical outcome. Therefore antibiotics are used primarily to treat severe infections, prevent complications in high-risk hosts, or to limit the spread of infection. Microbiologic (culture) confirmation of the etiology and susceptibility testing should be sought prior to treatment if possible.

Table 366.14

Antibiotic Therapy for Infectious Diarrhea

ORGANISM	INDICATION FOR THERAPY	DOSAGE AND DURATION OF TREATMENT
Shigella spp.	In high-income countries, judicious treatment is recommended to curtail growing antibiotic resistance because most shigellosis is self-limited. Treatment should be reserved for moderate to severe disease (require hospitalization, have systemic disease or complications), immunocompromised, or to prevent or mitigate outbreaks in certain settings (e.g., childcare or food handling). Also consider treating patients with significant discomfort, intestinal comorbidities, institutional settings, or household exposure to high-risk individuals. WHO recommends empiric antibiotics for all children in developing countries with dysentery assuming that most cases are caused by *Shigella*.	*First line:* • Ciprofloxacin* 15 mg/kg/day PO bid × 3 days; OR • Ceftriaxone 50-100 mg/kg/day IV or IM, qd × 3 days for severe illness requiring parenteral therapy; OR • Azithromycin* 12 mg/kg once on 1st day, then 6 mg/kg once daily on days 2 through 4 (total course: 4 days) *Second line:* • Cefixime 8 mg/kg once daily for 3 days; OR • Trimethoprim-sulfamethoxazole 4 mg/kg/day of TMP and 20 mg/kg/day SMX twice a day for 5 days (if susceptibility known or likely based on local data)
ETEC	Watery diarrhea in a traveler returning from an endemic area that interferes with planned activities or is persistent.	*First line:* • Azithromycin* 12 mg/kg once on first day, then 6 mg/kg once

		daily on days 2 and 3 (total course: 3 days) *Second line:* • Ciprofloxacin* 15 mg/kg/day PO bid × 3 days
STEC	Avoid antimicrobials and anti-motility drugs	
Salmonella , non-typhoidal	Antibiotics for uncomplicated gastroenteritis in normal host are ineffective and may prolong excretion and are not recommended Treatment should be reserved for infection in infants younger than 3 mo, and patients with immunocompromise, malignancy, chronic GI disease, severe colitis hemolytic anemia, or HIV infection. Most strains are resistant to multiple antibiotics	See treatment of *Shigella.* Patients without bacteremia can be treated orally for 5-7 days. Patients with bacteremia (proven or until blood culture results are available in a high-risk host) should be treated parenterally for 10-14 days. Focal or disseminated invasive infections (e.g., osteomyelitis, meningitis) and bacteremic patients with HIV/AIDS should be treated parenterally for 4-6 wk.
Yersinia spp.	Antibiotics are not usually required for diarrhea, which is usually self-limited and clinical benefits of antibiotics are not established. Bacteremia and focal invasive infections should be treated. Deferoxamine therapy should be withheld for severe infections or associated bacteremia	For bacteremia or focal invasive infections, use third generation cephalosporins. Can also consider carbapenem, doxycycline (for children ≥8 yr) plus aminoglycoside, TMP-SMX, or fluoroquinolone at doses recommended for sepsis. Begin IV then switch to oral when clinically stable, for a total course of 2-6 wk.
Campylobacter spp.	Dysentery, moderate and severe gastroenteritis or at risk for severe disease (e.g., elderly, pregnant, or immunocompromised), and bacteremia or focal invasive infection should be treated. Treatment of gastroenteritis appears effective if given within 3 days of onset of illness.	*For gastroenteritis or dysentery:* • Erythromycin PO 40 mg/kg/day divided qid × 5 days; OR • Azithromycin PO 10 mg/kg/day × 3 days *For bacteremia or focal invasive infection:* • Consider parenteral macrolides or carbapenems pending susceptibility results. Fluoroquinolone resistance is >50% in some areas of the world.
Clostridium difficile	Colitis • Discontinue inciting antibiotics if possible; • Infectious disease consult suggested if disease is persistent or recurrent.	*First line (mild-moderate colitis):* • Metronidazole PO 30 mg/kg/day divided tid or qid × 10 days; max 500 mg/dose; OR • Vancomycin PO 40 mg/kg/day divided qid × 10 days, max 125 mg/dose *Second line (severe colitis):* • Vancomycin PO 40 mg/kg/day divided qid × 10 days, max 500

		mg/dose; OR • If ileus, give same dose PR as 500 mg/100 mL normal saline by retention enema with or without plus metronidazole IV 30 mg/kg/day divided tid × 10 days; max 500 mg/dose • Fidaxomicin not yet approved for children; see text
Entamoeba histolytica	Treat the following conditions: • Asymptomatic cyst excretors • Mild to moderate intestinal disease • Severe intestinal or extraintestinal disease (including liver abscess)	*Asymptomatic cyst excretors:* • Iodoquinol PO 30-40 mg/kg/day, max 2 g, divided tid × 20 days; OR • Paromomycin PO 25-35 mg/kg/d divided tid × 7 days; *Mild to moderate intestinal disease and severe intestinal or extra-intestinal disease:* • Metronidazole PO 30-40 mg/kg/day divided tid × 7-10 days; OR • Tinidazole PO 50 mg/kg, single dose, max 2 g (for children ≥ 3 yr old) × 3 days, OR 5 days for severe disease EITHER FOLLOWED BY (to prevent relapse) • Iodoquinol PO 30-40 mg/kg/day tid × 20 days; OR • Paromomycin PO 25-35 mg/kg/day tid × 7 days
Giardia intestinalis	Persistent symptoms	• Tinidazole PO 50 mg/kg, single dose, max 2 g (for children ≥ 3 yr old); OR • Nitazoxanide PO; OR – Age 1-3 yr: 100 mg bid × 3 days – Age 4-11 yr: 200 mg bid × 3 days – Age over 11 yr: 500 mg bid × 3 days • Metronidazole PO 30-40 mg/kg/day divided tid × 7 days (max 250 mg per dose)
Cryptosporidium spp.	Treat immunocompromised and HIV-infected hosts, although efficacy is equivocal Treatment may not be needed in normal hosts	*Immunocompetent children:* • Nitazoxanide, as for *Giardia* *Solid organ transplants:* • Nitazoxanide, as for *Giardia* , × ≥14 days; reduce immunosuppression if possible and consider paromomycin combined with azithromycin for severe symptoms or treatment failure

		HIV-infected children: • Combined antiretroviral therapy is the primary treatment • Nitazoxanide, as for *Giardia* , generally for 3-14 days while awaiting CD4 cell recovery; OR • Consider paromomycin alone or combined with azithromycin in severe disease or treatment failure
Cyclospora spp *Isospora belli* (now designated *Cystoisospora belli*).	All symptomatic children	TMP 5 mg/kg/day and SMX 25 mg/kg/day PO bid × 7-10 days (HIV-infected children may need longer courses)
Blastocystis hominis	The significance of *B. hominis* as a cause of disease is controversial, so treatment should be reserved for those with suggestive symptoms and no other pathogen that could be the cause.	• Metronidazole PO 30-40 mg/kg/day divided tid × 7-10 days; OR • Nitazoxanide, as for *Giardia* ; OR TMP-SMX as for *Cyclospora* ; OR Tinidazole, as for *Giardia*

[*] Azithromycin and fluoroquinolones should be avoided in patients taking the antimalarial artemether. These drugs can prolong the QT interval on the electrocardiogram and trigger arrhythmias.

EIEC, enteroinvasive *Escherichia coli* ; *EPEC,* enteropathogenic *E. coli* ; *ETEC,* enterotoxigenic *E. coli* ; *GI,* gastrointestinal; *IV,* intravenous; *IM* , intramuscular; *max,* maximum; *SMX,* sulfamethoxazole; *TMP,* trimethoprim; *WHO* , World Health Organization.

Treatment of *C. difficile* infection warrants special consideration. Removal of the offending antibiotic, if possible, is the first step. Antibiotic therapy directed against *C. difficile* should be instituted if the symptoms are severe or persistent. Testing for *C. difficile* is discouraged for children with diarrhea who are <2 yr unless there is strong evidence to implicate *C. difficile* as the etiologic agent. This recommendation is based on the high rates of asymptomatic infection with toxigenic and nontoxigenic strains and the rarity of characteristic clinical manifestations not attributed to other pathogens in this age group. Oral vancomycin and metronidazole for 7-14 days (first line agents) displayed equivalent efficacy in a prospective randomized trial; however, metronidazole is preferred because of lower cost and decreased potential for inducing vancomycin-resistant enterococci. Twenty percent of adults treated for *C. difficile* diarrhea have a relapse, but the frequency in children is not known. The first relapse should be treated with another course of antibiotics based on severity of illness. For recurrent disease, tapering and/or pulsed regimen of oral vancomycin over a 4- to 6-wk period has been proposed. In the absence of ongoing symptoms, a test of cure is not necessary. The role of probiotics in the prevention of *C. difficile* -associated diarrhea in children has not been established. Fecal transplant is being explored to treat persistent or recurrent *C. difficile* colitis. *Fidaxomicin* is an alternate agent approved for patients ≥18 yr of age; it is recommended for the initial episode (severe and nonsevere) and recurrences. The adult dose is 200 mg BID for 10 days by mouth. *Bezlotoxumab,* a monoclonal antibody against *C. difficile* toxins A and B, has been shown to reduce the recurrence rate.

Antibiotic therapy for parasitic infections is shown in Table 366.14 .

Prevention

Promotion of Exclusive Breastfeeding and Vitamin A

Exclusive breastfeeding (administration of no other fluids or foods for the first 6 mo of life) protects young infants from diarrheal disease through the promotion of passive immunity and through reduction in the intake of potentially contaminated food and water. In developing countries, exclusive breastfeeding for the first 6 mo of life is widely regarded as one of the most effective interventions to reduce the risk of premature childhood mortality and has the potential to prevent 12% of all deaths of children younger than 5 yr of age. Vitamin A supplementation reduces all-cause childhood mortality by 25% and diarrhea-specific mortality by 30%.

Rotavirus Immunization

Three live oral **rotavirus** vaccines are licensed: the 3-dose pentavalent G1, G2, G3, G4, P[8] human-bovine vaccine (RotaTeq), the 2-dose monovalent human G1P[8] vaccine (ROTARIX), and the 3-dose monovalent human-bovine 116E G6P[11] vaccine (Rotavax). The result has been substantial reductions in rotavirus-associated and all-cause hospitalizations for diarrheal disease in both vaccinated infants (direct protection) and unvaccinated individuals (indirect, or herd protection), as well as reductions in-office visits for less severe rotavirus diarrhea. Reductions in all-cause diarrhea deaths have been demonstrated in some countries.

Programmatic uptake has lagged in low-resource settings where most severe disease and death occurs; however, Gavi, the Vaccine Alliance, has supported introduction of rotavirus vaccine into more than 40 countries to date. Even though vaccine efficacy against severe rotavirus AGE is lower (50–64%) in low- compared with high-resource countries, the number of severe rotavirus AGE prevented per vaccinated child is higher because of the substantially greater baseline rate of severe rotavirus gastroenteritis in developing countries. Vaccine (live virus) associated rotavirus infection has been reported in children with severe combined immunodeficiency disease, but the vaccine has been shown to be safe in HIV-infected populations.

Two licensed, efficacious 2-dose oral inactivated **cholera** vaccines (Dukoral for children 2 yr and older and ShanChol for children 1 yr or older) are available in many countries but currently have no specific indication in endemic and epidemic settings where they could potentially reduce the burden of severe diarrhea and mortality in young children. For travelers, a single-dose live oral cholera vaccine (Vaxchora) was recently licensed for adults in the United States. In addition, 2 forms of typhoid fever vaccine are available: a polysaccharide vaccine delivered intramuscularly that can be administered to children older than 2 yr (Vivotif) and an oral, live attenuated vaccine that can be administered to children over 6 yr of age (Typhim Vi). Conjugate polysaccharide typhoid vaccines that could be used in children younger than 2 yr have recently become available. In 2018, the World Health Organization issued a recommendation for the use of this vaccine in infants and children 6 mo of age or older living in endemic areas, with catch-up vaccination campaigns, if possible, for children up to 15 yr old. The vaccine is not yet available in the United States or Europe.

Improved Water and Sanitary Facilities and Promotion of Personal and Domestic Hygiene

Much of the reduction in diarrhea prevalence in the developed world is the result of improvement in standards of hygiene, sanitation, and water supply. Strikingly, an estimated 88% of all diarrheal deaths worldwide can be attributed to unsafe water, inadequate sanitation, and poor hygiene. Handwashing with soap and safe excreta disposal can reduce the risk of diarrhea by 48% and 36%, respectively, and a 17% reduction is estimated as a result of improvements in water quality.

366.1

Traveler's Diarrhea

Karen L. Kotloff

Keywords

Diarrhea
traveler's diarrhea
gastroenteritis

Traveler's diarrhea is a common complication of visitors to developing countries and is caused by a variety of pathogens, in part depending on the season and the region visited. It is the most common (28%) travel-associated health problem in children. Traveler's diarrhea can manifest with watery diarrhea or as dysentery. Without treatment, 90% will have resolved within a week and 98% within a month of onset. Some individuals develop more severe or persistent diarrhea and become dehydrated or unwell and may experience complications such as bacteremia and intestinal perforation. Children younger than 2 yr are at higher risk for traveler's diarrhea, as well as more severe disease. According to the FoodNet, the pathogens identified most commonly in travelers in the United States were *Campylobacter* (42%), NTS (32%), and *Shigella* (13%). ETEC and intestinal protozoa (*G. intestinalis* and *E. histolytica*) are also important.

Treatment

For infants and children, rehydration, as discussed in Chapter 366, is appropriate, followed by a standard diet. Adolescents and adults should increase their intake of electrolyte-rich fluids. Kaolin-pectin, anticholinergic agents, *Lactobacillus,* and bismuth salicylate are not effective therapies. Loperamide, an antimotility and antisecretory agent, reduces the number of stools in older children with watery diarrhea and improves outcomes when used in combination with antibiotics in traveler's diarrhea. However, loperamide should not be used in febrile or toxic patients with dysentery, in those with bloody diarrhea, and in children younger than 6 yr.

The effectiveness of antibiotics depends on the pathogen and its susceptibility profile. In forming a treatment plan, the potential side effects should be weighed against the treatment need for a short-lasting and self-limiting disease such as traveler's diarrhea. Antibiotics are not recommended for mild diarrhea that is tolerable, is not distressing, and does not interfere with planned activities. When empiric therapy is required abroad, azithromycin is suggested for young children. Fluoroquinolones are recommended for older children and adults and as second line therapy for younger children. Short-duration (3 days) therapy is effective. Travelers should be reminded that diarrhea can be a symptom of other severe diseases, such as malaria. Therefore, if diarrhea persists or additional symptoms such as fever occur, travelers should seek medical advice. For up-to-date information on local pathogens and resistant patterns, see www.cdc.gov/travel .

If the patient has returned home with diarrhea, a microbiologic evaluation can be obtained before initiating antibiotic therapy. Prolonged diarrhea should prompt further investigation into possible parasitic infections or NTS. Prophylactic antibiotics for travelers are not recommended.

Prevention

In the pretravel visit, caregivers should be advised about diarrhea prevention, the signs, symptoms, and management of dehydration, and the use of ORS. ORS and age-appropriate antibiotics should be included in a routine health packet. Travelers should drink bottled or canned beverages or boiled water. They should avoid ice, salads, and fruit they did not peel themselves. Food should be eaten hot, if possible. Raw or poorly cooked seafood is a risk, as is eating in a restaurant rather than a private home. Swimming pools and other recreational water sites can also be contaminated.

Chemoprophylaxis is not routinely recommended for previously healthy children or adults. Nonetheless, travelers should bring azithromycin (younger than 16 yr of age) or ciprofloxacin (older than 16 yr of age) and begin antimicrobial therapy if diarrhea develops.

CHAPTER 367

Chronic Diarrhea

Anat Guz-Mark, Raanan Shamir

Definition of Epidemiology

Chronic diarrhea is defined as stool volume of more than 10 g/kg/day in toddlers/infants and greater than 200 g/day in older children that lasts for 4 wk or more. **Persistent** diarrhea began acutely but lasts longer than 14 days. In practice, this usually means having loose or watery stools more than 3 times a day. *Awakening at night to pass stool is often a sign of an organic cause of diarrhea.* The epidemiology has 2 distinct patterns. In *developing* countries, chronic diarrhea is, in many cases, the result of an intestinal infection that persists longer than expected. This syndrome is often defined as **protracted (persistent) diarrhea** , but there is no clear distinction between protracted (persistent) and chronic diarrhea. In countries with higher socioeconomic conditions, chronic diarrhea is less frequent, and the etiology often varies with age. The outcome of diarrhea depends on the cause and ranges from benign, self-limited conditions, such as toddler's diarrhea, to severe congenital diseases, such as microvillus inclusion disease, that may lead to progressive intestinal failure.

Pathophysiology

The mechanisms of diarrhea are generally divided into **secretory** and **osmotic** , but often diarrhea is a *combination of both mechanisms* . In addition, *inflammation* and *motility disorders* may contribute to diarrhea. Secretory diarrhea is usually associated with large volumes of watery stools and persists when oral feeding is withdrawn. Osmotic diarrhea is dependent on oral feeding, and stool volumes are usually not as massive as in secretory diarrhea (Fig. 367.1).

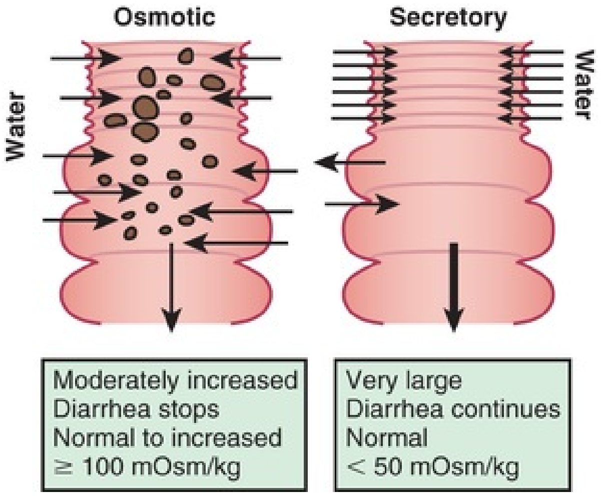

FIG. 367.1 Pathways of osmotic and secretory diarrhea. Osmotic diarrhea is caused by functional or structural damage of intestinal epithelium. Nonabsorbed osmotically active solutes drive water into the lumen. Stool osmolality and ion gap are generally increased. Diarrhea stops in children when not eating. In secretory diarrhea, ions are actively pumped into the intestine by the action of exogenous and endogenous secretagogues. Usually there is no intestinal damage. Osmolality and ion gap are within normal levels. Large volumes of stools are lost independent of food ingestion.

Secretory diarrhea is characterized by active electrolyte and water fluxes toward the intestinal lumen, resulting from either the inhibition of neutral NaCl absorption in villous enterocytes or an increase in electrogenic chloride secretion in secretory crypt cells as a result of the opening of the cystic fibrosis transmembrane regulator (CFTR) chloride channel or both. The result is more secretion from the crypts than absorption in the villous that persists during fasting. The other components of the enterocyte ion secretory machinery are (1) the Na-K 2Cl cotransporter for the electroneutral chloride entrance into the enterocyte; (2) the Na-K pump, which decreases the intracellular Na^+ concentration, determining the driving gradient for further Na^+ influx; and (3) the K^+ selective channel, that enables K^+ , once it has entered the cell together with Na^+ , to return to the extracellular fluid.

Electrogenic secretion is induced by an increase of intracellular concentration of cyclic adenosine monophosphate, cyclic guanosine monophosphate, or calcium in response to microbial enterotoxins, or to endogenous endocrine or nonendocrine molecules, including inflammatory cytokines. Another mechanism of secretory diarrhea is the inhibition of the electroneutral NaCl-coupled pathway that involves the Na^+ /H^+ and the $Cl^- /HCO_3{}^-$ exchangers. Defects in the genes of the Na^+ /H^+ and the $Cl^- /HCO_3{}^-$ exchangers are responsible for congenital Na^+ and Cl^- diarrhea, respectively.

Osmotic diarrhea is caused by nonabsorbed nutrients in the intestinal lumen as a result of one or more of the following mechanisms: (1) intestinal damage (e.g., enteric infection); (2) reduced absorptive surface area (e.g., active celiac disease); (3) defective digestive enzyme or nutrient carrier (e.g., lactase deficiency); (4) decreased intestinal transit time (e.g., functional diarrhea); and (5) nutrient overload, exceeding the digestive capacity (e.g., overfeeding, sorbitol in fruit juice). Whatever the mechanism, the osmotic force generated by nonabsorbed solutes drives water into the intestinal lumen. A very common example of osmotic diarrhea is lactose intolerance. Lactose, if not absorbed in the small intestine, reaches the colon, where it is fermented to short-chain organic acids, releasing hydrogen that is detected in the lactose breath test, and generating an osmotic overload. Another risk for chronic osmotic diarrhea often noted in patients with diarrhea-associated irritable bowel syndrome are foods containing FODMAPs (fermentable oligo-di-monosaccharides and polyols).

In many children chronic diarrhea may be caused by the combination of multiple mechanisms.

Etiology

Table 367.1 summarizes the main etiologies of chronic diarrhea in infants and children.

Table 367.1

Main Etiologies of Chronic Diarrhea in Children Older and Younger Than 2 Yr of Age

ETIOLOGY	YOUNGER THAN 2 YR	OLDER THAN 2 YR
Infections	+++	+++
Postenteritis syndrome	+++	+++
Immune deficiency	++	Rare
Celiac disease	+++ (after gluten introduction)	+++
Food allergy	+++	+
Inflammatory bowel disease	+ (rare)	+++
Pancreatic insufficiency	++	++
Cholestasis and insufficient bile acids	++	++
Cystic fibrosis	++	+
Lactose intolerance	++ (mostly postinfectious)	+++
Intestinal lymphangiectasia	+	+
Motility disorders	++	Rare

Short bowel syndrome	+++	+
Toddler's and functional diarrhea	++	++
Excessive intake of fruit juices and fluids	++	++
Congenital diarrheal disorders, including structural enterocyte defects and enzymatic or transport malabsorption syndromes	++	Unlikely

Infectious

Enteric infections are by far the most frequent cause of persistent or chronic diarrhea, both in developing and industrialized countries, however outcomes are often very different. In the former, comorbid conditions, such as HIV/AIDS, malaria, or tuberculosis, result in malnutrition that impairs the child's immune response, thereby potentiating the likelihood of prolonging diarrhea or acquiring another enteric infection. In children with HIV/AIDS, the viral infection itself impairs immune function and may trigger a vicious circle with malnutrition. Sequential infections with the same or different pathogens may also be responsible for chronic diarrhea. In *developing* countries, enteroadherent *Escherichia coli* and *Giardia lamblia* have been implicated in chronic diarrhea, whereas, in *developed* countries, chronic infectious diarrhea usually runs a more benign course and the etiology is often viral, with a major role of rotavirus and norovirus (Table 367.2).

Table 367.2

A Comparative List of Prevalent Agents and Conditions in Children With Persistent Infectious Diarrhea in Industrialized and Developing Countries

AGENT/DISEASE	
INDUSTRIALIZED COUNTRIES	**DEVELOPING COUNTRIES**
Clostridium difficile Enteroaggregative *Escherichia coli*	Enteroaggregative *E. coli* Atypical *E. coli* Shigella Heat stable/heat labile enterotoxin-producing *E. coli*
Astrovirus Norovirus Rotavirus[*] Small intestinal bacterial overgrowth (SIBO) Postenteritis diarrhea syndrome	Rotavirus[*] Cryptosporidium *Giardia lamblia* Tropical sprue

[*] More frequent in industrialized than in developing countries as agent of chronic diarrhea.

Chronic diarrhea in travelers to or expatriates from developing countries may depend on the country of origin. Nonetheless, common pathogens include giardia, *E. coli* , shigella, campylobacter, salmonella, and enteric viruses. Less common pathogens include amebiasis, strongyloides, and tropical spruce.

Opportunistic microorganisms induce diarrhea exclusively, more severely, or for more prolonged periods, in specific populations, such as immunocompromised children. Specific agents cause chronic diarrhea or exacerbate diarrhea in many chronic diseases. *Clostridium difficile* or cytomegalovirus act as opportunistic agents in oncologic patients as well as in patients with inflammatory bowel diseases. *Cryptosporidium* may induce severe and protracted diarrhea in AIDS patients.

Small intestinal bacterial overgrowth results in chronic diarrhea by either a direct interaction between the microorganism and the enterocyte, or the consequence of deconjugation and dihydroxylation of bile salts and hydroxylation of fatty acids due to an increased proliferation of bacteria in the proximal intestine.

Postenteritis diarrhea syndrome (Chapter 364.4) is a clinicopathologic condition in which small intestinal mucosal damage persists after acute gastroenteritis. Sensitization to food antigens, secondary disaccharidase deficiency, persistent infections, reinfection with an enteric pathogen, or side effects of medication may be responsible for causing postenteritis diarrhea syndrome, thought to be related to dysregulation of the intestinal microbiota. Functional diarrhea which may be related to the pathogenesis of irritable bowel syndrome may be caused by complications of an acute gastroenteritis.

Inflammatory/Immunologic

Celiac disease (Chapter 364.2) is a genetically determined permanent gluten intolerance that affects about 1 in 100 individuals, depending on geographic origin. In the genetically susceptible host, gliadin, the major protein of gluten, reacts with the immune system to cause villous atrophy. A reduction of intestinal absorptive surface is responsible for the diarrhea in celiac disease, which is reversible upon restriction of gluten from the diet.

Food allergy (mainly cow milk protein allergy Chapter 176) may present during infancy with chronic diarrhea. An abnormal immune response to food proteins can cause a proctitis/colitis or an enteropathy. **Eosinophilic gastroenteritis** is characterized by eosinophilic infiltration of the intestinal wall and is strongly associated with atopy. However, whereas diarrhea in food allergy responds to withdrawal of the responsible food, this does not always occur in eosinophilic gastroenteritis, in which immune suppression may be needed.

Inflammatory bowel diseases, including Crohn disease, ulcerative colitis, and inflammatory bowel disease–undetermined, cause chronic diarrhea that is often associated with abdominal pain, elevated inflammatory markers, and increased concentrations of fecal calprotectin or lactoferrin (see Chapter 362). The age of onset of inflammatory bowel disease is broad, with rare cases described in the 1st few mo of life, but the peak incidence in childhood occurs in adolescence. The severity of the symptoms is highly variable with a pattern characterized by long periods of well-being followed by exacerbations.

Autoimmune processes may target the intestinal epithelium, alone or in association with extraintestinal symptoms. **Autoimmune enteropathy** is associated with the production of antienterocyte and antigoblet cell antibodies, primarily immunoglobulin A, but also immunoglobulin G, directed against components of the enterocyte brush-border or cytoplasm and by a cell-mediated autoimmune response with mucosal T-cell activation. An X-linked immune-dysregulation, polyendocrinopathy, and enteropathy (**IPEX syndrome**) is associated with variable gene mutations and phenotypes of chronic diarrhea (more on autoimmune enteropathy and IPEX syndrome is available on Chapter 364.3).

Immune deficiency can present as chronic diarrhea in children. In these cases (for example, severe combined immunodeficiency or AIDS) the child can be infected by an opportunistic pathogen; can exhibit a persistent diarrhea due to a pathogen usually causing an acute gastroenteritis; or be infected by multiple and recurrent different pathogens causing mucosal damage to the intestines. Other immunoregulatory defects, found in patients with agammaglobulinemia, isolated immunoglobulin A deficiency, and common variable immunodeficiency disorder, may result in mild persistent infectious diarrhea.

Pancreatic Deficiency

Chronic diarrhea may be the manifestation of maldigestion caused by exocrine pancreatic disorders (see Chapters 376 and 378.2). In most patients with **cystic fibrosis** , exocrine pancreatic insufficiency results in steatorrhea and protein malabsorption. In **Shwachman-Diamond syndrome** , exocrine pancreatic hypoplasia may be associated with neutropenia, bone changes, and intestinal protein-losing enteropathy. Specific isolated pancreatic enzyme defects, such as lipase deficiency, result in fat and/or protein malabsorption. Familial pancreatitis, associated with a mutation in the trypsinogen gene, may be associated with exocrine pancreatic insufficiency and chronic diarrhea. Mutations in *CFTR* , *CTRC* , *PRSS1* , *PRSS2* , *SPINK 1* , and *SPINK 5* are associated with hereditary pancreatitis.

Liver and Bile Acids Disorders

Liver disorders and **cholestasis** may lead to a reduction in the bile salts pool resulting in fat malabsorption causing chronic diarrhea in the form of steatorrhea. Bile acid loss may be associated with diseases affecting the terminal ileum, such as Crohn disease, or following ileal resection. In **primary bile acid malabsorption** , neonates and young infants present with chronic diarrhea and fat malabsorption caused by mutations of ileal bile transporter. In addition to the fat malabsorption, the bile acid loss from the intestinal lumen is a form of secretory diarrhea by itself (called **cholorrheic diarrhea** , which is usually associated with significant diaper dermatitis).

Carbohydrate Malabsorption

Rare genetic mutations (Chapters 364.9 and 364.11) can cause carbohydrate malabsorption. More commonly, **lactose intolerance** is *secondary* to lactase deficiency caused by intestinal mucosal damage (usually as part of postenteritis syndrome, which is a self-limited process). Depending on ethnicity, a progressive, age-related, loss of lactase activity may begin around 7 yr of age and affects approximately 80% of the non-white population, and acquired hypolactasia may be responsible for chronic diarrhea in older children receiving cow’s milk (adult-type lactase deficiency).

Similarly, **fructose malabsorption** is common in Western countries with estimates as high as 40% of the population. These individuals cannot absorb fructose and often develop bloating, abdominal pain, diarrhea, and flatulence. Typically, they do not have liver disease. This is in contrast to **hereditary fructose intolerance** , a rare genetic disorder with incidence estimated to be 1 in 20,000-30,000. This disease is associated with mutations in the *ASDOB* gene that encodes for the aldolase B enzyme that is found primarily in the liver and is involved in the metabolism of fructose. Individuals with hereditary fructose intolerance may have nausea, abdominal pain/bloating, vomiting, diarrhea, and hypoglycemia. Continued ingestion of fructose results in *hepatomegaly* and eventually cirrhosis.

Protein-Losing Enteropathy

Chronic diarrhea can be the manifestation of obstructed intestinal lymphatic drainage, causing protein-losing enteropathy with steatorrhea, diarrhea, and lymphopenia. Besides **intestinal lymphangiectasia** , many diseases that cause intestinal mucosal injury can also result in protein-losing enteropathy, characterized by low serum protein levels and elevated fecal α_1 -antitrypsin (see Chapter 364.3).

Motility Disorders

Disorders of intestinal motility include abnormal development and function of the enteric nervous system, such as in **Hirschsprung disease** and **chronic intestinal pseudoobstruction** (which encompass both the neurogenic and the myogenic forms). Other motility disorders may be secondary to extraintestinal disorders, such as in *hyperthyroidism* and *scleroderma* . Motility disorders are associated with either constipation or diarrhea or both, with the former usually dominating the clinical picture.

Short Bowel Syndrome

Short bowel syndrome is the single most frequent etiology of intestinal failure in children (Chapter 364.7). Many intestinal abnormalities such as stenosis, segmental atresia, gastroschisis, and malrotation may require surgical resection, but the most frequent primary cause of short bowel is necrotizing enterocolitis. Rarely, a child can be born with congenitally short small bowel. In these conditions, the residual intestine may be insufficient to carry on its digestive–absorptive functions, resulting in severe chronic diarrhea, malnutrition, and failure to thrive, requiring long-term treatment with parenteral nutrition.

Nonspecific Diarrhea, Including Toddler's Diarrhea

The most benign and common etiology of chronic diarrhea is nonspecific diarrhea that encompasses **functional diarrhea** (or **toddler's diarrhea**) in children younger than 4 yr of age and **irritable bowel syndrome** in those 5 yr of age and older. It is the leading cause of chronic diarrhea in an otherwise well child. Toddler's diarrhea is defined by the daily painless recurrent passage of 4 or more large unformed stools, for 4 or more wk, with onset in infancy or preschool years. Nighttime defecation is usually absent. The child appears unperturbed by the diarrhea, there is no evidence of failure to thrive, and the symptoms resolve spontaneously by school age.

Diarrhea may also be the result of an **excessive intake of fluid and nonabsorbable carbohydrate** . If the child's fluid intake were > 150 mL/kg/24 hr, fluid intake should be reduced not to exceed 90 mL/kg/24 hr in order to decrease the stool frequency and volume. If the dietary history suggests that the child is ingesting significant amounts of fruit juice, especially apple juice, then the consumption of juice should be decreased. *Sorbitol, which is a nonabsorbable sugar, is found in apple, pear, and prune juices, and often causes diarrhea in toddlers.* Moreover, apple and pear juices contain higher amounts of fructose than glucose, a feature postulated to cause diarrhea in toddlers. In older children, irritable bowel syndrome is often associated with abdominal pain and may be related to anxiety, depression, and other psychological disturbances (Chapter 368). When the cause of the diarrhea remains undetermined and the clinical course is inconsistent with organic disorders, **factitious** disorder by proxy should be considered.

Congenital Diarrheal Disorders

The most severe etiology of chronic diarrhea includes a number of heterogeneous congenital conditions leading to syndromes often referred to as **intractable or protracted diarrhea** . This is the result of a permanent defect in the structure or function of the enterocyte, leading to progressive, potentially irreversible intestinal failure. The genetic and molecular basis of many causes of protracted diarrhea has been identified recently and a new classification of **congenital diarrheal disorders (CDDs)** has been proposed (Table 367.3). CDDs are a group of rare but severe enteropathies, with a similar clinical presentation despite a different pathogenesis and outcome. The diarrhea can be either secretory or osmotic, depending on the specific defect. Often severe diarrhea presents at birth or shortly thereafter, but in milder forms diarrhea may go unrecognized for years. CDDs can be classified in 4 groups: defects of digestion, absorption and transport of nutrients and electrolytes; defects of enterocyte differentiation and polarization; defects of enteroendocrine cell differentiation; and defects of modulation of intestinal immune response.

Table 367.3

Classification of Congenital Diarrheal Disorders Based on Their Molecular Defect and Their Inheritance

DEFECTS OF DIGESTION, ABSORPTION, AND TRANSPORT OF NUTRIENTS AND ELECTROLYTES				
DISEASE	**GENE NAME**	**GENE LOCATION**	**TRANSMISSION AND INCIDENCE**	**MECHANISM**
GENES ENCODING BRUSH-BORDER ENZYMES				
Congenital lactase deficiency (LD)	*LCT*	2q21.3	AR, 1 in 60,000 in Finland; lower in other ethnic groups	Osmotic
Congenital sucrase-isomaltase deficiency (SID)	*SI*	3q26.1	AR, 1 in 5,000; higher incidence in Greenland, Alaska, and Canada	Osmotic
Congenital maltase-glucoamylase deficiency (MGD)	Not defined	—	Few cases described	Osmotic
GENES ENCODING MEMBRANE CARRIERS				
Glucose-galactose malabsorption (GGM)	*SLC5A1*	22q13.1	AR, few hundred cases described	Osmotic
Fructose malabsorption (FM)	Not defined	—	Up to 40%	Osmotic
Fanconi-Bickel syndrome (FBS)	*SLC2A2*	3q26.2	AR, rare, higher frequency in consanguineous	Osmotic
Acrodermatitis enteropathica (ADE)	*SLC39A4*	8q24.3	AR, 1 in 500,000	Osmotic
Congenital chloride diarrhea (CCD, DIAR 1)	*SLC26A3*	7q31.1	AR, sporadic; frequent in some ethnicities	Osmotic
Lysinuric protein intolerance (LPI)	*SLC7A7*	14q11.2	AR, about 1 in 60,000 in Finland and Japan; rare in other ethnic groups	Osmotic
Primary bile acid malabsorption (PBAM)	*SLC10A2*	13q33.1	AR	Secretory
Cystic fibrosis (CF)	*CFTR*	7q31.2	AR, 1 in 2,500	Osmotic
GENES ENCODING PANCREATIC ENZYMES				
Enterokinase deficiency (EKD)	*PRSS7*	21q21	AR	Osmotic
Hereditary pancreatitis (HP)	*PRSS1* *PRSS2* *SPINK1* *CTRC*	7q34 7q34 5q32 1p36.21	AD, cases with compound mutations in different genes; SPINK1 mutations may also cause tropical pancreatitis	Osmotic
Congenital absence of pancreatic lipase (APL)	*PNLIP*	10q25.3	AR	Osmotic
GENES ENCODING PROTEINS OF LIPOPROTEIN METABOLISM				
Abetalipoproteinemia (ALP)	*MTP*	4q27	AR, about 100 cases described; higher frequency among Ashkenazi	Osmotic

			Jews	
Hypobetalipoproteinemia (HLP)	*APOB*	2p24.1	Autosomal codominant	Osmotic
Chylomicron retention disease (CRD)	*SAR1B*	5q31.1	AR, about 40 cases described	Osmotic
GENES ENCODING OTHER TYPES OF PROTEINS				
Congenital sodium diarrhea (CSD)	*SPINT2* (only syndromic CSD) *SLC9A3*	19q13.2 5p15.33	AR	Osmotic
Shwachman-Diamond syndrome (SDS)	*SBDS*	7q11	AR	Osmotic
Activating guanylate cyclase-C mutation	*GUCY2C*	12p12.3	AD	Secretory
GENES ENCODING FOR OTHER ENZYMES				
Defect in triglyceride synthesis	*DGAT1*	8q24.3	AR	Protein-losing enteropathy
DEFECTS OF ENTEROCYTE DIFFERENTIATION AND POLARIZATION				
Microvillous inclusion disease (MVID, DIAR 2)	*MYO5B*	18q21.1	AR; rare; higher frequency among Navajo	Secretory
Congenital tufting enteropathy (CTE, DIAR 5)	*EPCAM*	2p21	AR; 1 in 50,000-100,000; higher among Arabians	Secretory
Trichohepatoenteric syndrome (THE)	*TTC37* *SKIV2L*	5q15 6p21.33	AR; 1 in 400,000	Secretory
DEFECTS OF ENTEROENDOCRINE CELL DIFFERENTIATION				
Congenital malabsorptive diarrhea (CMD, DIAR 4)	*NEUROG3*	10q22.1	AR; few cases described	Osmotic
Proprotein convertase 1/3 deficiency (PCD)	*PCSK1*	5q15	AR	Osmotic
DEFECTS OF MODULATION OF INTESTINAL IMMUNE RESPONSE				
Autoimmune polyglandular syndrome type 1 (APS1)	*AIRE*	21q22.3	AR; AD (1 family)	Secretory
Immune dysfunction, polyendocrinopathy, X-linked (IPEX)	*FOXP3*	Xp11.23	X-linked (autosomal cases described), very rare	Secretory
IPEX-like syndrome	Not defined	—	Not X-linked	Secretory

AD , autosomal dominant; *AR* , autosomal recessive.

Although CDDs are rare diseases, in most specific disorders the genetic defect and transmission are known. The incidence of genetic disorders associated with CDD can range from 1 in 2,500 for cystic fibrosis, 1 in 5,000 for sucrose-isomaltase deficiency, 1 in 60,000 for congenital lactase deficiency, to 1 in 400,000 for trichohepatoenteric syndrome. For most CDDs, such as IPEX syndrome or autoimmune polyglandular syndrome type 1, the clinical application of exome sequencing is likely to increase identification of more patients with these rare causes of chronic diarrhea. Selected CDDs are more frequent in ethnic groups where consanguineous marriages are common, or in some geographic areas because of founder effects. Congenital lactase deficiency is more common in Finland; lysinuric protein intolerance has a higher incidence either in Finland and in Japan because of founder effect, and a specific mutation is typically found in each of the 2 ethnic groups. A defect in the *DGAT1* gene was identified using whole-exome sequencing in an Ashkenazi Jewish family and associated with the early onset of vomiting and nonbloody diarrhea with protein-losing enteropathy. For specific CDDs see Chapters 364.3 and 364.11 .

Most cases of protracted diarrhea syndrome are not easily treated. The natural history of protracted diarrhea is related to the primary intestinal disease and the specific defect in nutrient absorption. Treatment is more favorable for motility disorders and autoimmune enteropathy than for structural enterocyte defects. Children with motility disorders may have persistent symptoms, but they are rarely fatal, whereas children with structural enterocyte defects have a more severe course, poorer prognosis, and are more likely to be candidates for intestinal transplantation (see Chapter 365). Some late-onset CDDs may be relatively mild and are recognized only later in life.

Evaluation of Patients

Because of the spectrum of etiologies, the medical approach should be based on diagnostic algorithms that begin with assessment for infectious causes, and then consider the age of the child, growth, and clinical and epidemiologic factors. Early onset in the neonatal period is rare and may suggest a congenital or severe condition (see also Table 364.3), however infections and food allergy are more frequent in this age group, and together with gastrointestinal (GI) malformations should be high on the differential diagnosis. In later infancy and up to 2 yr of age, infections and allergies are the most common; inflammatory diseases are more frequent in older children and adolescents. Celiac disease as well as functional nonspecific diarrhea should always be considered independently of age because of their relatively high frequency at all ages.

Specific clues in the family and personal history may provide useful indications, suggesting a congenital, allergic, or inflammatory etiology. A history of *polyhydramnios* is consistent with congenital chloride-sodium diarrhea (where a typical sonographic finding of dilated fetal bowel loops is present), cystic fibrosis, and other CDDs, as well as a family history of a chronic or intractable diarrhea in a relative presenting in the 1st mo of life, as well as *consanguinity* .

An acute onset of diarrhea that runs a protracted course suggests postenteritis diarrhea, secondary lactase deficiency, small intestinal overgrowth, or the onset of chronic nonspecific diarrhea (toddler's diarrhea). The association of diarrhea with specific foods may indicate a nutrient basis, such as intolerance to selected nutrients (fructose). Anthropometric evaluation is essential to understand if diarrhea has affected weight gain and growth, providing estimation of the severity of diarrhea. Normal weight and growth strongly support functional diarrhea that may respond to simple dietary management. It should be noted that a child with functional diarrhea may be inappropriately “treated” with a diluted hypocaloric diet in an effort to reduce the diarrhea, resulting in impaired growth.

Initial clinical examination should include the evaluation of general and nutritional status. Dehydration, marasmus, or kwashiorkor require prompt supportive interventions to stabilize the patient. Nutritional evaluation should start with the evaluation of the weight and height curves, and of the weight-for-height index to determine the impact of diarrhea on growth. Weight is generally impaired before height, but with time, linear growth also becomes affected, and both parameters may be equally abnormal in the long term. Assessment of nutritional status includes a dietary history, physical examination, and biochemical testing including nutritional investigations. Caloric intake should be quantitatively determined, energy requirements determined, and the relationship between weight modifications and energy intake should be carefully considered. Assessment of body composition may be performed by measuring mid-arm circumference and triceps skinfold thickness or by bioelectrical impedance analysis, dual-emission x-ray absorptiometry scans, or air plethysmography. Biochemical markers including albumin, prealbumin, retinol binding protein, serum iron, and transferrin may assist in grading malnutrition, as the half-life of serum proteins may distinguish between short- and long-term malnutrition. Evaluation of micronutrient concentrations should always be considered. Zinc, magnesium, vitamin A, and folate deficiency are associated with chronic diarrhea and should be provided if needed.

In infants with chronic diarrhea, feeding history must be carefully obtained, providing clues for allergy or specific food intolerance, such as cow's-milk protein allergy or sucrose-isomaltase deficiency. Associated symptoms and selected investigations provide important diagnostic clues. Signs of general inflammation such as fever, mucoid or bloody stools, and abdominal pain may suggest inflammatory bowel disease. The presence of eczema or asthma is associated with an allergic disorder, whereas specific extraintestinal manifestations (arthritis, diabetes, thrombocytopenia, etc.) may suggest an autoimmune disease. Specific skin lesions may be suggestive of **acrodermatitis enteropathica** that might respond to zinc supplementation. Typical facial abnormalities and woolly hair are associated with phenotypic diarrhea.

Investigations

Microbiologic investigation should include a thorough list of intestinal bacterial, viral, and protozoan pathogens. Proximal intestinal bacterial overgrowth may be determined using the lactulose hydrogen breath test, but false-positive tests are common (see Chapter 364.4).

Initial investigations of a child with chronic diarrhea should always include an assessment of intestinal inflammation using fecal calprotectin or lactoferrin, and serology for celiac disease (see Chapter 364.2). The role of a mucosal biopsy is determined by the noninvasive diagnostic evaluation in consultation with a pediatric gastroenterologist.

Noninvasive assessment of digestive-absorptive function and of intestinal inflammation plays a key role in the diagnostic workup (Table 367.4). Abnormalities in the digestive-absorptive function tests suggest small bowel involvement, whereas intestinal inflammation, as demonstrated by increased fecal calprotectin or lactoferrin, supports colitis.

Table 367.4

Noninvasive Tests for Intestinal Digestive–Absorptive Function and Inflammation

TEST	NORMAL VALUES	IMPLICATION
α_1 -Antitripsin concentration	<0.9 mg/g	Increased intestinal permeability/protein loss
Steatocrit	<2.5% (older than 2 yr) fold increase over age-related values (younger than 2 yr)	Fat malabsorption
Fecal-reducing substances	Absent	Carbohydrate malabsorption
Elastase concentration	>200 µg/g	Pancreatic function
Chymotrypsin concentration	>7.5 units/g >375 units/24 hr	Pancreatic function
Fecal occult blood	Absent	Blood loss in the stools/inflammation
Fecal calprotectin concentration	<100 µg/g (in children to 4 yr of age) <50 µg/g (older than 4 yr)	Intestinal inflammation
Fecal leukocytes	<5/microscopic field	Colonic inflammation
Fecal lactoferrin	Absent	Inflammation
Nitric oxide in rectal dialysate	<5 µM of NO_2^- /NO_3^-	Rectal inflammation

Dual sugar (cellobiose/mannitol) absorption test	Urine excretion ratio: 0.010 ± 0.018	Increased intestinal permeability
Xylose oral load	25 mg/dL	Reduced intestinal surface

Determining the osmotic versus secretory nature of the diarrhea in neonates and infants with protracted diarrhea is especially important. The **stool osmolar gap** , sometimes called stool ion gap, is calculated as 290 mOsm/kg (or measured stool osmolality) minus [2 × (stool Na + stool K)]. If the osmolar gap is above 100 mOsm/kg, fecal osmolality is derived from ingested or nonabsorbed osmotically active solutes or nonmeasured ions. In contrast, a low gap (<50 mOsm/kg) is typically observed in secretory diarrhea. It is also important to measure Cl^- concentration in the stool to rule out CCD, which is characterized by low osmolar gap due to high Cl^- fecal loss (>90 mmol/L).

Whereas most etiologies of chronic diarrhea can be exaggerated by feeding and have osmotic or mixed nature to the stool, secretory diarrhea necessitates investigation for congenital defects in enterocytes, defects in the intestinal immune response (IPEX and autoimmune enteropathy), and disorders of bile acid malabsorption. Because of the overlap between secretory and osmotic features of the diarrhea in many diseases, a classification based on the response to bowel rest was also introduced. Severe diarrhea that persists at bowel rest is characteristic of **congenital enteropathies** (microvillous inclusion disease, tufting enteropathy, syndromic diarrhea). Diarrhea that disappears at bowel rest can imply carbohydrate or fat malabsorptive syndromes, as well as defects in enteroendocrine cells. In most other etiologies the diarrhea can decrease significantly, but not disappear, in response to bowel rest, including some congenital diseases as well as acquired inflammatory and other enteropathies.

Histology is important in establishing mucosal involvement, noting changes in the epithelial cells, or in identifying specific intracellular inclusion bodies caused by pathogens, such as cytomegalovirus, or the presence of parasites. Electron microscopy is essential to detect subcellular structural abnormalities such as microvillous inclusion disease. Immunohistochemistry allows the study of mucosal immunity as well as of other cell types (smooth muscle cells and enteric neuronal cells).

Imaging has a major role in the diagnostic approach. Abdominal ultrasound may help in detecting liver and pancreatic abnormalities or an increase in distal ileal wall thickness that suggests inflammatory bowel disease. A preliminary plain abdominal x-ray is useful for detection of abdominal distention, suggestive of intestinal obstruction, or increased retention of colonic feces. Intramural or portal gas may be seen in necrotizing enterocolitis or intussusception. Structural abnormalities such as diverticula, malrotation, stenosis, blind loop, and congenital short bowel, as well as motility disorders, may be investigated through a barium meal and a small bowel follow-through. Capsule endoscopy can be done when the patient weighs more than 10 kg and allows the exploration of the entire intestinal tract searching for structural changes, inflammation, or bleeding; the new SmartPill measures pressure, pH, and temperature as it moves through the GI tract, assessing motility.

Specific investigations should be carried out for specific diagnostic indications. Prick and patch test may support a diagnosis of food allergy. However, an elimination diet with withdrawal of the suspected harmful food from the diet and subsequent challenge is the most reliable strategy by which to establish a diagnosis. Bile malabsorption may be explored by the retention of the bile acid analog ^{75}Se-homocholic acid-taurine (^{75}SeHCAT) in the enterohepatic circulation. A scintigraphic examination, with radio-labeled octreotide is indicated in suspected APUD cell neoplastic proliferation. In other diseases, specific imaging techniques such as computed tomography, or nuclear magnetic resonance endoscopic retrograde cholangiopancreatography and magnetic resonance cholangiopancreatography, may have important diagnostic value.

Once infectious agents have been excluded and nutritional assessment performed, a stepwise approach to the child with chronic diarrhea may be applied. The main causes of chronic diarrhea should be investigated, based on the features of the diarrhea and the specific nutrient(s) that is (are) affected. The use of whole-exome sequencing or specific molecular analysis may be especially essential in children suspected of having CDD. A step-by-step diagnostic approach is important to minimize the unnecessary use of invasive procedures as well as the cost, while optimizing the yield of the diagnostic evaluation (Table 367.5).

Table 367.5

Stepwise Diagnostic Approach to Children and Infants With Chronic Diarrhea

INITIAL EVALUATION	
• Personal and family history: Prenatal sonography; feeding history; family history of protracted diarrhea; consanguinity	• Infectious workup: Stool cultures; parasites; viruses • Allergic workup: Elimination diet trial

• Physical examination: Dysmorphism; skeletal abnormalities; organomegaly; dermatitis	
⇩	
LABORATORY TESTS	
• Stool analysis: *Stool volume following fasting; stool electrolytes and ion gap; pH and reducing substances; steatocrit; fecal leukocytes and calprotectin; fecal elastase;* α_1 *-antitrypsin*	• Blood and serum analysis: Serum electrolytes; lipid profile; albumin and pre-albumin; amylase and lipase; inflammatory markers; ammonia; celiac serology
⇩	
IMAGING	
• Abdominal ultrasound: Bowel wall thickening; liver and bile disorders	• X-ray and contrast studies: Congenital malformation; signs of motility disorders
⇩	
ENDOSCOPIES AND INTESTINAL HISTOLOGY	
Endoscopy and standard jejunal/colonic histology* ; morphometry; PAS staining; intestinal immunohistochemistry; electron microscopy	
⇩	
GENETIC INVESTIGATION	
• Specific molecular analysis	• Whole-exome sequencing
⇩	
OTHER SPECIAL INVESTIGATIONS	
Sweat test; specific carbohydrates breath tests; ^{75} SeHCAT measurement; antienterocyte antibodies; metabolic diseases workup; motility studies; neuroendocrine tumor markers	

* The decision to perform an upper or a lower endoscopy may be supported by noninvasive tests.

PAS , Periodic acid–Schiff; ^{75} *SeHCAT* , ^{75} Se-homocholic acid-taurine.

Treatment

Chronic diarrhea associated with impaired nutritional status should always be considered a serious disease, and therapy should be started promptly. Treatment includes general supportive measures, nutritional rehabilitation, elimination diet, and medications. The latter include therapies for specific etiologies as well as interventions aimed at counteracting fluid secretion and/or promoting restoration of disrupted intestinal epithelium. Because death in most instances is caused by dehydration, replacement of fluid and electrolyte losses is the most important early intervention.

Nutritional rehabilitation is often essential and is based on clinical and biochemical assessment. In moderate to severe malnutrition, caloric intake should be carefully advanced to avoid the development of refeeding syndrome and may be progressively increased to 50% or more above the recommended dietary allowances. The intestinal absorptive capacity should be monitored by digestive function tests. In children with steatorrhea, medium-chain triglycerides may be the main source of lipids. A lactose-free diet should be started in all children with chronic diarrhea and is recommended by the World Health Organization. Lactose is generally replaced by maltodextrin or a combination of complex carbohydrates. A sucrose-free formula is indicated in sucrase-isomaltase deficiency. Semi-elemental or elemental diets have the dual purpose of overcoming food intolerance, which may be the primary cause of chronic diarrhea, particularly in infancy and early childhood, and facilitating nutrient absorption. The sequence of elimination should begin from less to more restricted diets, that is, cow's-milk protein hydrolysate to amino-acid–based formulas, depending on the child's situation. In severely compromised infants, it may be prudent to start with amino-acid–based feeding.

When oral nutrition is not feasible or fails, enteral or parenteral nutrition should be considered. Enteral nutrition may be provided via nasogastric or gastrostomy tube and is indicated in a child who is not able to be fed orally, either because of inability to tolerate nutrient requirements or because of extreme weakness. In extreme wasting and in cases of significant intestinal mucosal damage or dysfunction, enteral nutrition may not be tolerated, and **parenteral nutrition** is required.

Micronutrient and vitamin supplementation are part of nutritional rehabilitation, especially in malnourished children in developing countries. Zinc supplementation is important in both prevention and therapy of chronic diarrhea, since it promotes ion absorption, restores epithelial proliferation, and stimulates immune response. Nutritional rehabilitation has a general beneficial effect on the patient's general condition, intestinal function, and immune response.

Functional diarrhea in children may benefit from a diet based on the “4 F” principles (reduce fructose and fluids, increase fat and fiber). The use of probiotics in persistent infectious and postinfectious diarrhea in children appear to hold promise as adjunctive therapy with reduction in symptom duration, but there is still insufficient evidence to recommend their routine use.

Pharmacologic therapy includes, based on the etiology, anti-infectious drugs, immune suppression, and drugs that may inhibit fluid loss and promote cell growth. If a bacterial agent is detected, specific antibiotics should be prescribed. Empiric antibiotic therapy may be used in children with either small bowel bacterial overgrowth or with suspected infectious diarrhea. Table 367.6 summarizes the antimicrobial treatment of infectious persistent diarrhea. Immune suppression should be considered in selected conditions such as autoimmune enteropathy and inflammatory bowel disease.

Table 367.6

Antimicrobial Treatment for Persistent Diarrhea

	DRUG	INDICATIONS	DOSAGE	DURATION
Antibiotics	Trimethoprim-sulfamethoxazole	*Salmonella* spp., *Shigella* spp.	6-12 mg/kg/day (of Trimethoprim) in 2 divided doses–daily os	5-7 days
	Azithromycin	*Shigella* spp., *Campylobacter*	1 day: 12 mg/kg/day once–daily os 2-5 days: 6 mg/kg/day once–daily os *alternative: 10 mg/kg/day once–daily os, for 3 days	5 days
	Ciprofloxacin	*Shigella* spp.	20-30 mg/kg/day in 2 divided doses–os or IV	3 days
	Ceftriaxone	*Shigella* spp.	50-100 mg/kg/day once–IM or IV	2-5 days
	Metronidazole	*Giardia*, *Amebiasis* , *Blastocystis* , *Clostridium difficile*	15-35 mg/kg/day in 2-3 divided doses–os	7-10 days
	Paromomycin	*Amebiasis*	25-35 mg/kg/day in 3 divided doses–os	7 days
	Vancomycin	*Clostridium difficile*	40 mg/kg/day in 4 divided doses–os	10 days
Antiparasitic	Nitazoxanide	*Amebiasis* , *Giardiasis* , *Blastocystis*, *Cryptosporidiosis*	100 mg every 12 hr for children ages 12-47 mo 200 mg every 12 hr for children ages 4-11 yr 500 mg every 12 hr for children older than 11 yr	3 days
	Albendazole	*Ascaris*, *Hookworm*, and *Pinworm* infection	400 mg	Once

Depends on local susceptibility profile. *IM* , intramuscular; *IV* , intravenous; *os* , by mouth.

Treatment may be also directed at modifying specific pathophysiologic processes. Secretion of ions may be reduced by antisecretory agents, such as the enkephalinase inhibitor racecadotril. Some benefit from absorbents, such as diosmectite, has been described, with reduction of diarrhea duration in infectious diarrhea. In diarrhea caused by neuroendocrine tumors (NETs), microvillus inclusion disease and enterotoxin-induced severe diarrhea, a trial of somatostatin analog octreotide may be considered. Zinc promotes both enterocyte growth and ion absorption and may be effective when intestinal atrophy and ion secretion are associated. However, when therapeutic attempts and other nutritional support have failed, the only option to treat children with intestinal failure, while maintaining adequate growth and development, may be long-term parenteral nutrition or eventually intestinal transplantation.

Diarrhea From Neuroendocrine Tumors

Shimon Reif, Raanan Shamir

KeyWords

Neuroendocrine tumor (NET)
multiple endocrine neoplasia (MEN)
carcinoid
carcinoid syndrome
VIP
VIPoma
somatostatin
octreotide

The incidence of neuroendocrine tumors (NET) originating in the gastrointestinal (GI) tract is increasing globally. The commonly perceived notion of NETs is of slow-growing malignancies with a benign course. Indeed, well-differentiated GI-NETs may exhibit indolent clinical behavior, but recent studies indicate that they are frequently already metastatic at diagnosis. The most common tumor in children is **carcinoid** and mostly it is a low-grade tumor especially when it is small, that is <1 cm. It is equally distributed between the small and large intestine and can commonly be found in the appendix. Most carcinoids are found incidentally and are asymptomatic, especially those that are located in the appendix. Some NET patients (around 10%) will develop secretory diarrhea requiring symptom control to optimize quality of life and clinical outcomes. Such patients are defined as having carcinoid syndrome, characterized by excessive production of one or more peptides, which, when released into the circulation, exert their endocrine effects and can be measured by radioimmunologic methods (in the plasma or as their urinary metabolites). These peptides therefore also act as tumor markers. In clinically functioning tumors, the secreted peptides cause a recognizable syndrome that can include watery diarrhea. Compared to carcinoid, vasoactive intestinal polypeptide (VIP)omas are much less frequent. Because it secretes VIP, a more potent vasoactive peptide, it induces more profuse diarrhea, with up to 70% of patients having volumes greater than 3 L/day. Though rare as a cause of watery diarrhea, a NET should be considered in the differential diagnosis when diarrhea is unusually severe or takes a chronic course (resulting in electrolyte and fluid depletion). GI-NETs may be associated with flushing, palpitations, or bronchospasm. Furthermore, patients may have a positive family history of multiple endocrine neoplasia MEN 1 or 2 syndromes. (Table 367.7).

Table 367.7

Diarrhea Caused by Neuroendocrine Tumors

TUMOR AND CELL TYPE	SITE	MARKERS	SIGNS OF HORMONE HYPERSECRETION	THERAPY
Carcinoid	Intestinal argentaffin cells, typically midgut, also foregut and hindgut, ectopic bronchial tree	**Serotonin (5-HT), urine 5-HIAA** * (diagnostic) Also produce substance P, neuropeptide K, somatostatin, VIP Chromogranin A	Secretory diarrhea, crampy abdominal pain, flushing, wheezing (and cardiac valve damage if foregut site)	Resection Somatostatin analog, (palliative) Genetic MEN-1
Gastrinoma, Zollinger-Ellison syndrome	Pancreas, small bowel, liver, and spleen	**Gastrin**	Multiple peptic ulcers, secretory diarrhea	H_2 -blockers, PPI, tumor resection, (gastrectomy) Genetic MEN-1
Mastocytoma	Cutaneous, intestine, liver, spleen	**Histamine** , **VIP**	Pruritus, flushing, apnea If VIP, diarrhea	H_1 - and H_2 -blockers, steroids, resection if solitary
Medullary carcinoma	Thyroid C-cells	**Calcitonin** , **VIP** , **prostaglandins**	Secretory diarrhea	Radical thyroidectomy ± lymphadenectomy (genetic MEN-2A/B, familial MTC)
Ganglioneuroma, pheochromocytoma,	Chromaffin cells; abdominal > other	**Metanephrines** and	Hypertension, tachycardia,	Perioperative α-adrenergic (BP)

ganglioneuroblastoma, neuroblastoma	sites; extraadrenal or adrenal	**catecholamines** , **VIP** VMA, HMA in neuroblastoma	paroxysmal palpitations, sweating, anxiety, watery diarrhea [†]	and β-adrenergic blockade with volume support tumor resection Genetic MEN-2 (*RET* gene), VHL, NF-1, SDH
Somatostatinoma	Pancreas	**Somatostatin**	Secretory diarrhea, steatorrhea, cholelithiasis, diabetes	Resection Genetic MEN-1
VIPoma	Pancreas	**VIP** , **prostaglandins**	Secretory diarrhea, achlorhydria, hypokalemia	Somatostatin analogs, resection Genetic MEN-1

[*] Bold indicates major markers.

[†] Diarrhea has been reported only in adult patients with pheochromocytoma.

BP , blood pressure; H_1 , histamine receptor type 1; H_2 , histamine receptor type 2; *HMA* , homovanillic acid; *MEN-1* , multiple endocrine neoplasia type 1; *MTC* , medullary thyroid carcinoma; *NF-1* , neurofibromatosis type 1; *PPI* , proton pump inhibitor; *SDH* , succinate dehydrogenase; *VHL* , von Hippel-Lindau disease; *VIP* , vasoactive intestinal polypeptide; *VMA* , vanillylmandelic acid.

(Modified from Spoudeas HA, editor: *Paediatric endocrine tumors. A multidisciplinary consensus statement of best practice from a working group convened under the auspices of the British Society of Paediatric Endocrinology and Diabetes (BSPED) and the United Kingdom Children's Cancer Study Group (UKCCSG)* , Crawley, West Sussex, 2005, Novo Nordisk.)

Baseline tests should include plasma chromogranin A and urinary 5-hydroxyindoloacetic acid (metabolite of serotonin) and other specific biochemistry being guided by the suspected syndrome (see Table 367.7). Localization of any NET is best achieved using a multimodality approach. Whole-body CT, MRI, and somatostatin receptor scintigraphy may be required (because nearly all NETs express membrane receptors for small peptides, e.g., somatostatin), with gallium-68 positron emission tomography. Therapeutic interventions to be considered include surgical, pharmacological, and radioisotope therapy. Details to be considered when making therapeutic decisions include disease extent and location, tumor grade, pace of disease progression, symptoms, and co-morbidities.

Tumor resection is the treatment of choice when the tumor is small and localized. However, resection is potentially hazardous as it can precipitate life-threatening adrenergic crises. When arising in the appendix, carcinoid tumors less than 2 cm in size can be managed by simple appendectomy. When greater than 2 cm in size or arising from the base of the appendix, a right hemicolectomy is indicated. Fortunately, in pediatric patients, metastases (most frequently to the liver) are rare. Tumor histochemistry will confirm the NET type and classification. Pharmacologic treatment may include the use of long-acting somatostatin analogues. This usually results in a pronounced improvement of symptoms including diarrhea. However, the improvement is mostly temporary with many patients becoming resistant to somatostatin. An oral medication, Everolimus, a more specific target of Rapamycin (mTOR)-inhibitor, has been reported as add-on treatment to octreotide mainly in adult patients. Data suggest a positive effect of ondansetron, a serotonin-3-receptor antagonist, on diarrhea. Peptide receptor radioisotope therapy also has been reported as a therapeutic modality.

The diagnosis of NET in children should prompt a genetic referral to exclude a familial tumor predisposition syndrome.

CHAPTER 368

Functional Gastrointestinal Disorders

Asim Maqbool, Chris A. Liacouras

Functional gastrointestinal disorders (FGIDs) comprise a group of conditions that relate to the gastrointestinal (GI) tract. These disorders cannot be completely explained by anatomical or biochemical abnormalities (infectious, inflammatory). FGIDs commonly afflict children across a broad range of manifestations and are defined primarily by symptoms. The symptom-based criteria employed to classify FGIDs have been developed by expert consensus and opinion under the auspices of the Rome Foundation, and are referred to as Rome IV Criteria. FGIDs pose diagnostic challenges as there is no anatomical or laboratory-based testing that is used to define them. FGID defining criteria strive not to be entirely based on diagnoses of exclusion, but rather aim to be based on objective, unambiguous, and accurate criteria derived from the presentation as elicited during obtaining the medical history and performing a clinical examination. These criteria strive to be uniform, reliable, reproducible, and to minimize unnecessary evaluations/testing with low diagnostic yield or relevance. FGIDs often coexist across the spectrum of GI disorders, such as inflammatory bowel disease, celiac disease, or irritable bowel syndrome (IBS). FGIDs may be influenced by psychosocial stressors, or a result of an otherwise benign episode of abdominal pain. The brain–gut axis likely plays a prominent role in the pathophysiology of many FGIDs. Some FGID manifestations may relate to dysbiosis and the intestinal microbiota. There may be a genetic basis to some of these disorders as well. Early life physical or psychologic stressors may manifest later as FGID. Maladaptive responses or lack of adequate coping skills may complicate the treatment of FGIDs but may also allow for a valuable approach to management using behavioral therapies.

FGIDs encompass 2 age groups: infants and toddlers or children and adolescents. Aerophagia, functional constipation, and cyclical vomiting span both age groups (Fig. 368.1).

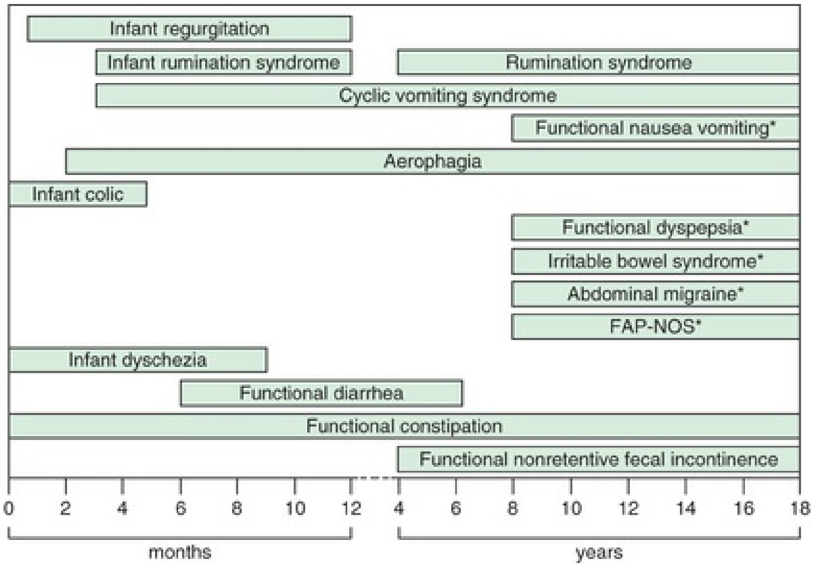

FIG. 368.1 Age distribution of functional gastrointestinal disorders in infants, toddlers, children, and adolescents. *History may not be reliable below this age. *FAP-NOS* , Functional abdominal pain—not otherwise specified. (Modified from Benninga MA, Nurko S, Faure C, et al: Childhood functional gastrointestinal disorders: neonate/toddler, *Gastroenterology* 150[6]:1443–1455.e2, 2016.)

Infant regurgitation implies effortless retrograde and involuntary passage of gastric contents from the stomach cephalad and is more commonly referred to as gastroesophageal reflux (Table 368.1). When refluxate reaches the oropharynx and is visible, it is labelled as regurgitation. This phenomenon is normal for healthy infants, unless there are complications associated with the process, such as esophageal inflammation, dysphagia, feeding difficulties, inadequate oral intake to meet needs leading to failure to thrive, or the inability to protect the airway with risk for aspiration; in this setting gastroesophageal reflux *disease* is the correct designation (Chapter 349). Unlike vomiting, regurgitation does not include the forceful expulsion of gastric contents via the mouth. Rumination is a different phenomenon, in that previously ingested and swallowed food is brought back up to the oral cavity, remasticated and subsequently reswallowed.

Table 368.1

Diagnostic Criteria for Infant Regurgitation

Must include both of the following in otherwise healthy infants 3 wk to 12 mo of age:
1. Regurgitation 2 or more times per day for 3 or more wk
2. No retching, hematemesis, aspiration, apnea, failure to thrive, feeding or swallowing difficulties, or abnormal posturing

From Benninga MA, Nurko S, Faure C, et al: Childhood functional gastrointestinal disorders: neonate/toddler, *Gastroenterology* 150(6):1443–1455.e2, 2016.

Infant rumination is defined as a habitual regurgitation of gastric contents into the oropharynx to allow for remastication and reswallowing (Table 368.2). It is thought to be a form of self-stimulation and may occur in the setting of emotional or sensory deprivation. The regurgitation of gastric contents is effortless and can be remasticated and reswallowed versus expulsion from the oropharynx. Infant rumination occurs between 3 and 8 mo of age and does not respond to measures used to manage regurgitation. This phenomenon does not occur during socialization/interaction with individuals, does not occur during sleep, and is not associated with distress. Empathy and nurturing lay the foundation for management. Behavior management is important to achieve resolution of this phenomenon.

Table 368.2

Diagnostic Criteria for Infant Rumination Syndrome

Must include all of the following for at least 2 mo:

1. Repetitive contractions of the abdominal muscles, diaphragm, and tongue
2. Effortless regurgitation of gastric contents, which are either expelled from the mouth or rechewed and reswallowed
3. Three or more of the following:
    a. Onset between 3 and 8 mo
    b. Does not respond to management for gastroesophageal reflux disease and regurgitation
    c. Unaccompanied by signs of distress
    d. Does not occur during sleep and when the infant is interacting with individuals in the environment

From Benninga MA, Nurko S, Faure C, et al: Childhood functional gastrointestinal disorders: neonate/toddler, *Gastroenterology* 150(6):1443–1455.e2, 2016.

Infant colic (Chapter 22.1) is a normal developmental process associated with fussiness, irritability, and difficultly consoling the infant (Table 368.3). A trigger is not identifiable. This phenomenon usually occurs between 1 and 4 mo of age. The typical behavior usually leads to consultation with a pediatrician or a pediatric gastroenterologist out of suspicion for abdominal pain. Patients are often unnecessarily treated for gastroesophageal reflux, gas, or suspected cow-milk protein or soy allergy leading to dietary changes and the use of medications for the management of acidity or gas. Probiotics have been investigated as a possible treatment. Probiotics may be more beneficial for breast versus cow-milk-fed infants. Soothing in a quiet, tranquil space may also be effective. Providing reassurance, education, support, and ensuring adequate coping skills and support for family members are key. This is a self-limited phenomenon that resolves on its own.

Table 368.3

Diagnostic Criteria for Infant Colic

For clinical purposes, must include all of the following:
1. An infant who is < 5 mo of age when the symptoms start and stop
2. Recurrent and prolonged periods of infant crying, fussing, or irritability reported by caregivers that occur without obvious cause and cannot be prevented or resolved by caregivers
3. No evidence of infant failure to thrive, fever, or illness
“Fussing” refers to intermittent distressed vocalization and has been defined as “[behavior] that is not quite crying but not awake and content either.” Infants often fluctuate between crying and fussing, so that the 2 symptoms are difficult to distinguish in practice.
For clinical research purposes, a diagnosis of infant colic must meet the preceding diagnostic criteria and also include both of the following:
1. Caregiver reports infant has cried or fussed for 3 or more hr per day during 3 or more days in 7 days in a telephone or face-to-face screening interview with a researcher or clinician
2. Total 24-hr crying plus fussing in the selected group of infants is confirmed to be 3 hr or more when measured by at least 1 prospectively kept, 24-hr behavior diary

From Benninga MA, Nurko S, Faure C, et al: Childhood functional gastrointestinal disorders: neonate/toddler, *Gastroenterology* 150(6):1443–1455.e2, 2016.

Functional diarrhea is often also referred to as *toddler's diarrhea* (Table 368.4). This condition excludes steatorrhea. Excessive fruit juice with nonabsorbable carbohydrates (i.e., sorbitol) intake coupled with a low-fat diet drive this osmotic process. An evaluation of the diet for possible other etiologies as well as assessment for infections, inflammation, antibiotic, and laxative use is important. In addition, assessments of growth as well as ruling out fecal impaction and encopresis via digital rectal examination are important. The diarrhea is usually stool colored, painless, liquid-watery, and may contain undigested foods. Growth is usually not affected. Dietary changes such as reducing fruit juice intake as well as fructose are helpful in resolving symptoms.

Table 368.4

Diagnostic Criteria for Functional Diarrhea

Must include all of the following:
1. Daily painless, recurrent passage of 4 or more large, unformed stools

2. Symptoms last more than 4 wk
3. Onset between 6 and 60 mo of age
4. No failure to thrive if caloric intake is adequate

From Benninga MA, Nurko S, Faure C, et al: Childhood functional gastrointestinal disorders: neonate/toddler, *Gastroenterology* 150(6):1443–1455.e2, 2016.

Infant dyschezia is manifested by infants straining prior to defecation associated with visible distress, crying, a red/purple facial discoloration, with symptoms persisting for 10-20 min alleviated by the passage in stools, limited to infants < 9 mo of age. There is no associated obstruction or anal anomaly; stools are passed several times daily and are not associated with other health problems. Dyschezia is thought to represent discoordinated intraabdominal musculature contraction with pelvic floor relaxation. A good medical history and neurological and digital rectal examinations to rule out anatomical or neuromuscular abnormalities are key. Normal growth is to be expected. Reassurance provides the basis of management. Laxative, suppository, or digital manipulation is not required and may be counterproductive.

Functional constipation (Chapter 358.3) is associated with withholding behaviors, which in turn may relate to social stressors or changes in social situations (Table 368.5). These often occur at the time of diet changes in infants and at the initiation of toilet training for toddlers. Painful passage of hard, large caliber stools < 2 times/wk in the setting of withholding behaviors is noted. For those children who have previously been toilet trained, fecal incontinence or encopresis is often observed. Large-caliber stools that obstruct the toilet are also noted frequently. Abdominal examination may reveal a palpable mass, and digital rectal examination may reveal a large rectal stool mass. The differential diagnosis for constipation is extensive, with functional constipation and slow transit constipation common. Dietary factors may play a role. Anorectal malformations, neuromuscular and motility issues may also present as such. Hirschsprung disease is on the differential diagnosis. The evaluation and management are based on a detailed history and thorough physical examination. A defecation history extending to the first 1-2 days of life is particularly important, as almost all children pass their first bowel movement within the first 48 hr of life. Assessment for associated signs and symptoms and growth trends are important. Red flags are noted in Table 368.6 . Imaging plays a role, and rectal suction biopsy or even full thickness rectal biopsy may be required to rule out Hirschsprung disease in cases with high index of suspicion. Management encompasses dietary and lifestyle changes, and medications to soften stool with osmotic laxatives over stimulant laxatives. The goal is to achieve painless defection and resolve fear and withholding revolving around defecation. Behavior modification including reassurance and positive incentive reward systems are useful. Avoidance of toilet training until symptoms resolve and the child shows interest or willingness to proceed are generally advocated.

Table 368.5

Diagnostic Criteria for Functional Constipation

Must include 1 mo of at least 2 of the following in infants up to 4 yr of age:
1. Two or fewer defecations per week
2. History of excessive stool retention
3. History of painful or hard bowel movements
4. History of large-diameter stools
5. Presence of a large fecal mass in the rectum
In toilet-trained children, the following additional criteria may be used:
6. At least 1 episode/wk of incontinence after the acquisition of toileting skills
7. History of large-diameter stools that may obstruct the toilet

From Benninga MA, Nurko S, Faure C, et al: Childhood functional gastrointestinal disorders: neonate/toddler, *Gastroenterology* 150(6):1443–1455.e2, 2016.

Table 368.6

Potential Alarm Features in Constipation

Passage of meconium >48 hr in a term newborn
Constipation starting in the 1st mo of life
Family history of Hirschsprung disease
Ribbon stools
Blood in the stools in the absence of anal fissures
Failure to thrive
Bilious vomiting
Severe abdominal distension
Abnormal thyroid gland
Abnormal position of the anus
Absent anal or cremasteric reflex
Decreased lower extremity strength/tone/reflex
Sacral dimple
Tuft of hair on spine
Gluteal cleft deviation
Anal scars

From Hyams JS, Di Lorenzo C, Saps M, et al: Childhood functional gastrointestinal disorders: child/adolescent, *Gastroenterology* 150(6):1456–1468.e2, 2016 (Table 3, p. 1465).

Functional Gastrointestinal Disorders in Children and Adolescents

Functional nausea and functional vomiting may coexist or may occur independently of one another (Table 368.7). These conditions occur without coincident abdominal pain. The presentation may accompany *autonomic symptoms* such as diaphoresis, pallor, tachycardia, and dizziness. The differential diagnosis includes anatomical, inflammatory, infectious, and motility etiologies. Anxiety and other behavioral conditions can be present with these FGIDs and should be evaluated for and managed accordingly. Cyproheptadine may be effective in the management of nausea.

Table 368.7

Diagnostic Criteria* for Functional Nausea and Functional Vomiting

FUNCTIONAL NAUSEA
Must include all of the following fulfilled for the last 2 mo:
1. Bothersome nausea as the predominant symptom, occurring at least twice per week, and generally not related to meals
2. Not consistently associated with vomiting
3. After appropriate evaluation, the nausea cannot be fully explained by another medical condition
FUNCTIONAL VOMITING
Must include all of the following:
1. On average, 1 or more episodes of vomiting per week
2. Absence of self-induced vomiting or criteria for an eating disorder or rumination
3. After appropriate evaluation, the vomiting cannot be fully explained by another medical condition

[*] Criteria fulfilled for at least 2 mo before diagnosis.

From Hyams JS, Di Lorenzo C, Saps M, et al: Childhood functional gastrointestinal disorders: child/adolescent, *Gastroenterology* 150(6):1456–1468, 2016 (p. 1457).

Rumination in *older* children and adolescents may be associated with an unpleasant sensation or discomfort such as abdominal pressure or burning (Table 368.8). Repeated regurgitation and remastication or oral repulsion of regurgitated gastric contents occurs soon after ingesting foodstuffs and does not occur during sleep. It is not preceded by active expulsion of gastric contents/retching and cannot be explained by any other medical condition. *Eating disorders* may also present and must be considered. There is no expectation that older children and adolescents need to be treated for or fail to respond to treatment for gastroesophageal reflux for this diagnosis to be made. A triggering event can be identified prior to symptoms, which may occur following resolution of an infectious illness or with psychosocial stress. Other GI issues to be considered include anatomical, infectious, inflammatory, and motility disorders. An important distinction between rumination and other GI etiologies of emesis includes effortless versus forceful regurgitation, and the time course, which is usually immediately following ingestion of foodstuffs. Given the significant behavioral component in this behavior, psychologic-behavioral therapy is key in management.

Table 368.8

Diagnostic Criteria* for Rumination Syndrome in Children

Must include all of the following:

1. Repeated regurgitation and rechewing or expulsion of food that:
    a. Begins soon after ingestion of a meal
    b. Does not occur during sleep
2. Not preceded by retching
3. After appropriate evaluation, the symptoms cannot be fully explained by another medical condition. An eating disorder must be ruled out

* Criteria fulfilled for at least 2 mo before diagnosis.

From Hyams JS, Di Lorenzo C, Saps M, et al: Childhood functional gastrointestinal disorders: child/adolescent, *Gastroenterology* 150(6):1456–1468, 2016 (p. 1458).)

Aerophagia is often seen in patients with impairments in neurocognition. Air swallowing is described as excessive, occurring throughout the day with progressive abdominal distention and with repetitive passage of gas via belching and/or flatus. Symptoms may be more severe in those children who cannot belch. Chewing gum and gulping down liquids may be risk factors in cognitively normal children. Symptoms are not attributable to any other causes such as partial obstructions, small bowel bacterial overgrowth, GI dysmotility (pseudoobstruction), or to malabsorptive disorders. Abdominal pain, nausea, and early satiety are reported associated GI symptoms; sleeping difficulty, headaches, and dizziness are also reported. Anxiety is a frequent comorbidity and may contribute to the behavior. Treatment is multidisciplinary and may include behavioral therapy and medications to relieve anxiety.

Functional Abdominal Pain Disorders

Functional Dyspepsia

Functional dyspepsia includes postprandial fullness and early satiety as well as epigastric pain or burning that is exclusive of defecation and not fully explainable by another or an underlying medical condition (Table 368.9). Subtypes may include *postprandial distress syndrome* (symptoms may preclude finishing a meal or be manifest by bloating, nausea, and excessive belching following a meal) as well as *epigastric pain syndrome* (epigastric pain/burning sufficient to preclude or disrupt normal activities, with pain not generalizable or localizable to other abdominal or chest regions, and not relieved by defecation or passage of flatus). An impaired gastric accommodation reflex, food allergy, delayed gastric emptying, or post viral gastroparesis has been implicated. Increased visceral hypersensitivity has also been suspected. The differential diagnosis includes GI etiologies of epigastric pain. Causes for concern can be guided by the family history and by the nature of symptoms including abdominal pain and other alarm features (Tables 368.10 and 368.11). Evaluation is based on symptoms. Initial treatment measures include a trial of diet (avoiding spicy foods, coffee, NSAID) and lifestyle changes if food triggers can be identified, and gastric acid reduction therapy. Assessment by a pediatric gastroenterologist and upper endoscopy/esophagogastroduodenoscopy are often performed. Further treatment with cyproheptadine to improve gastric accommodation or to decrease visceral hypersensitivity can be attempted. Use of amitriptyline or prokinetic medications can be considered. Electrical stimulation of the stomach (or percutaneous) is a potential option for patients refractory to standard therapy.

Table 368.9

Diagnostic Criteria* for Functional Dyspepsia

Must include 1 or more of the following bothersome symptoms at least 4 days/mo:
1. Postprandial fullness
2. Early satiation
3. Epigastric pain or burning not associated with defecation
4. After appropriate evaluation, the symptoms cannot be fully explained by another medical condition.
Within FD, the following subtypes are now adopted:
1. Postprandial distress syndrome includes bothersome postprandial fullness or early satiation that prevents finishing a regular meal. Supportive features include upper abdominal bloating, postprandial nausea, or excessive belching.
2. Epigastric pain syndrome, which includes all of the following: bothersome (severe enough to interfere with normal activities) pain or burning localized to the epigastrium. The pain is not generalized or localized to other abdominal or chest regions and is not relieved by defecation or passage of flatus. Supportive criteria can include (a) burning quality of the pain but without a retrosternal component and (b) the pain commonly induced or relieved by ingestion of a meal but may occur while fasting.

[*] Criteria fulfilled for at least 2 mo before diagnosis.

From Hyams JS, Di Lorenzo C, Saps M, et al: Childhood functional gastrointestinal disorders: child/adolescent, *Gastroenterology* 150(6):1456–1468, 2016 (p. 1460).

Table 368.10

Alarm Symptoms Usually Needing Further Investigations in Children With Chronic Abdominal Pain

- Pain that wakes up the child from sleep
- Persistent right upper or right lower quadrant pain
- Significant vomiting (bilious vomiting, protracted vomiting, cyclical vomiting, or worrisome pattern to the physician)
- Unexplained fever
- Genitourinary tract symptoms
- Dysphagia
- Odynophagia
- Chronic severe diarrhea or nocturnal diarrhea
- Gastrointestinal blood loss
- Involuntary weight loss
- Deceleration of linear growth
- Delayed puberty
- Family history of inflammatory bowel disease, celiac disease, and peptic ulcer disease

Table 368.11

Alarm Signs Usually Needing Further Investigations in Children With Chronic Abdominal Pain

- Localized tenderness in the right *upper* quadrant
- Localized tenderness in the right *lower* quadrant
- Localized fullness or mass
- Hepatomegaly
- Splenomegaly
- Jaundice
- Costovertebral angle tenderness
- Arthritis
- Spinal tenderness
- Perianal disease
- Abnormal or unexplained physical findings
- Hematochezia
- Anemia

Pediatric IBS

Pediatric IBS can be classified into 4 groups: IBS with predominant constipation (IBS-C), IBS with predominant diarrhea (IBS-D), IBS with constipation and diarrhea, and unspecified IBS. IBS includes findings of abdominal pain ≥ 4 days/mo associated with defecation and/or a change in frequency of stool from baseline and/or a change in form/appearance of stool (Table 368.12). It is noteworthy that pain does not resolve following resolution of constipation; if it does, it is then reclassified as functional constipation. In fact, IBS-C is often confused with functional constipation. IBS cannot be explained by another or underlying medical condition. The pathophysiology of IBS is thought to involve the brain-gut axis and includes a psychosocial stressor component. Visceral hypersensitivity may be attenuated or amplified by psychosocial stressors. Abdominal or rectal pain may occur. A *postinfectious* IBS phenomenon is known to occur in children, adolescents, and adults and may be driven by inflammatory cytokines. Perturbations in the intestinal microbiota or by dysbiosis may be coincident, with causality or consequence not yet established. The GI differential diagnosis includes anatomical, infectious, inflammatory, and motility disorders as well as conditions associated with malabsorption. Differentiation between those GI disorders and IBS is guided by the history and physical, and markers of inflammation particularly in the stool such as fecal calprotectin are clinically useful (see Tables 368.10 and 368.11). Management of symptoms can include dietary modification to reduce or restrict foods that may provoke symptoms or cause gas (see fiber section and FODMAPS [fermentable oligo-di-monosaccharides and polyols] discussion Chapter 57). Altering microbiota by use of probiotics has been effective; drug therapy for IBS is noted in Table 368.13 . Peppermint oil has been shown to reduce pain in children with IBS. Cognitive behavioral therapy is important to identify possible psychosocial stressors and to help identify coping mechanisms. Preliminary data suggests that transcutaneous neurostimulation may also be of value.

Table 368.12

Diagnostic Criteria* for Irritable Bowel Syndrome

Must include all of the following:

1. Abdominal pain at least 4 days/mo associated with one or more of the following:
    a. Related to defecation
    b. A change in frequency of stool
    c. A change in form (appearance) of stool
2. In children with constipation, the pain does not resolve with resolution of the constipation (children in whom the pain resolves have functional constipation, not irritable bowel syndrome)
3. After appropriate evaluation, the symptoms cannot be fully explained by another medical condition

* Criteria fulfilled for at least 2 mo before diagnosis.

From Hyams JS, Di Lorenzo C, Saps M, et al: Childhood functional gastrointestinal disorders: child/adolescent, *Gastroenterology* 150(6):1456–1468, 2016 (p. 1461).

Table 368.13

Recommendations for Treatment of Irritable Bowel Syndrome

RECOMMENDATIONS FOR TREATMENT OF IBS
• Mild symptoms often respond to dietary changes. • Antispasmodics can be used as needed for abdominal pain or postprandial symptoms. • Antidepressants can improve abdominal pain and global symptoms. They may be considered for patients with moderate to severe symptoms.
IBS WITH CONSTIPATION (IBS-C)
• Fiber may relieve constipation in patients with mild symptoms. • Polyethylene glycol can increase the frequency of bowel movements, but may not improve overall symptoms or abdominal pain. • Lubiprostone or linaclotide can be tried in patients whose symptoms have not responded to polyethylene glycol.
IBS WITH DIARRHEA (IBS-D)
• Taken as needed, loperamide can reduce postprandial urgency and stool frequency, but it does not improve global symptoms. • Rifaximin and eluxadoline have been modestly more effective than placebo in relieving symptoms. • Alosetron should be reserved for women with severe, chronic IBS-D that is unresponsive to other drugs.

IBS , Irritable bowel syndrome.

From Drugs for irritable bowel syndrome, *The Medical Letter* 58(1504):121–126, 2016 (p. 121).

Abdominal Migraine

Abdominal migraine shares some features with cyclic vomiting syndrome. Stereotypical patterns and symptoms afflict the patient, and are typically of acute onset, intense, lasting for at least an hour, being either periumbilical or generalized, and usually debilitating during a bout (Table 368.14). Episodes can include anorexia, nausea, emesis, headaches, photophobia, and pallor. Episodes are separated by weeks to months, with bouts occurring over at least a 6-mo period. Between bouts, patients return to baseline functioning and are symptom free. *Triggers* include sleep hygiene disruption, fatigue, travel, and are usually alleviated by sleep. The differential diagnosis includes anatomical, infectious, or inflammatory conditions, as well as hepatobiliary and pancreatic disorders, neurological and metabolic conditions, and psychiatric disorders. Anatomical obstruction of the GI or urological tract should be included in the differential diagnosis. Preventing exposure to known triggers once identified is important.

Similar to prophylaxis for cyclic vomiting syndrome, cyproheptadine, propranolol, and amitriptyline may be effective. Oral pizotifen (antiserotonin, antihistamine) is an effective prophylactic agent. Anti-migraine therapies such as triptans may be effective in aborting bouts. This disorder shares many features with both cyclic vomiting syndrome and migraine headaches and may evolve into migraine headaches in adulthood.

Table 368.14

Diagnostic Criteria* for Abdominal Migraine

Must include all of the following occurring at least twice:

1. Paroxysmal episodes of intense, acute periumbilical, midline, or diffuse abdominal pain lasting 1 hr or more (should be the most severe and distressing symptom)
2. Episodes are separated by weeks to months.
3. The pain is incapacitating and interferes with normal activities
4. Stereotypical pattern and symptoms in the individual patient
5. The pain is associated with 2 or more of the following:
    a. Anorexia
    b. Nausea
    c. Vomiting
    d. Headache
    e. Photophobia
    f. Pallor
6. After appropriate evaluation, the symptoms cannot be fully explained by another medical condition.

* Criteria fulfilled for at least 6 mo before diagnosis.

From Hyams JS, Di Lorenzo C, Saps M, et al: Childhood functional gastrointestinal disorders: child/adolescent, *Gastroenterology* 150(6):1456–1468, 2016 (p. 1462).

Functional Abdominal Pain Not Otherwise Specified

Functional abdominal pain not otherwise specified occurs at least 4 times/mo with either intermittent or continuous abdominal pain not associated with a particular activity or coincident to *another physiologic event* such as menses or eating, cannot be explained by any other or underlying medical condition, and is of ≥2 mo duration. In many ways, it is a FGID of exclusion, as it does not meet criteria for IBS, functional dyspepsia, or abdominal migraine. Psychosocial stressors may play a role. There may be increased coincidence with postural orthostatic hypotension. Behavioral approaches may be helpful to identify and manage stressors and exacerbators.

Functional Defecation Disorders

Functional Constipation

Functional constipation in children and adolescents may have onset revolving around a social stressor, change in social situation, and peaks at the time of toilet training, when withholding behaviors emerge (Table 368.15). Encopresis may occur without sensation if the rectum is chronically distended sufficiently. Anorexia, abdominal distention, and pain are often coincident. The diagnosis is based on medical history and physical examination, including digital rectal examination. An abdominal x-ray is not required to make the diagnosis if a digital rectal examination can be performed to appreciate the fecal mass. The differential diagnosis for constipation in children and adolescents is similar to that as for infants and toddlers and is the approach to the evaluation and management of constipation (see Table 368.6). Management includes disimpaction followed by dietary and lifestyle approaches, osmotic laxatives to soften stools, and behavioral approaches similar to those employed for younger children discussed previously (Chapter 358.3).

Table 368.15

Diagnostic Criteria for Functional Constipation in Children With Chronic Abdominal Pain

Must include 2 or more of the following occurring at least once per week for a minimum of 1 mo with insufficient criteria for a diagnosis of irritable bowel syndrome:
1. Two or fewer defecations in the toilet per week in a child of a developmental age of at least 4 yr
2. At least 1 episode of fecal incontinence per week
3. History of retentive posturing or excessive volitional stool retention
4. History of painful or hard bowel movements
5. Presence of a large fecal mass in the rectum
6. History of large diameter stools that can obstruct the toilet
After appropriate evaluation, the symptoms cannot be fully explained by another medical condition.

From Hyams JS, Di Lorenzo C, Saps M, et al: Childhood functional gastrointestinal disorders: child/adolescent, *Gastroenterology* 150(6):1456–1468, 2016 (p. 1464).

Nonretentive Fecal Incontinence

Nonretentive fecal incontinence occurs in the setting of not having fecal retention, occurring in inappropriate settings for a specific society and culture, without evidence of another or underlying medical condition, and occurring for ≥1 mo in a child of ≥4 yr of age. These patients otherwise have normal defecatory patterns and function, differentiating and distinguishing them from functional constipation. An emotional disturbance or disorder should be suspected in these cases. A thorough medical history and physical examination are required to fully appreciate what factors are involved in this condition. A rectal examination is important to differentiate this condition from functional constipation and encopresis. Given the significant comorbidity of behavior and emotional axis issues, involvement of behavioral health professionals is essential to the evaluation and management of this condition.

CHAPTER 369

Cyclic Vomiting Syndrome

Asim Maqbool, B U.K. Li, Chris A. Liacouras

Cyclic vomiting syndrome (CVS) is an idiopathic disorder manifested as episodic vomiting, usually of sudden onset and high intensity/frequency (4/hr:12-15 episodes/day) of vomiting, with eventual resolution and return to a normal baseline between attacks. Typical bouts last for 24-48 hr, and usually respond promptly to hydration. To meet the criteria for CVS, identifiable organic disorders are excluded following an appropriate workup (Table 369.1).

Table 369.1

Consensus Definition for Diagnostic Criteria and Red Flags for Cyclic Vomiting Syndrome

DIAGNOSTIC CRITERIA
• Episodic (≥2 or more) attacks of intense nausea and paroxysmal vomiting lasting hours to days within a 6-mo period
• Stereotypical pattern and symptoms in the individual patient
• Episodes are separated by weeks to months
• Return to baseline between episodes
• Not attributable to another disorder
RED FLAGS
• Bilious emesis, abdominal tenderness, and/or severe abdominal pain
• Attacks precipitated by an intercurrent illness, fasting, and/or a high protein meal
• Neurological abnormalities (mental status changes, ophthalmic abnormalities asymmetry/focal changes, ataxia)
• Atypical pattern or progression/deterioration from a typical presentation for the individual patient to a more continuous or chronic pattern

Modified from the Rome IV Criteria: Li BU, Lefevre F, Chelimsky GG, et al: North American Society for Pediatric Gastroenterology, Hepatology and Nutrition consensus statement on the diagnosis and management of cyclic vomiting syndrome, *J Pediatr Gastroenterol Nutr* 47(3):379–393, 2008.

The prevalence of CVS in children is estimated at ~2% in predominantly Caucasian populations, although it does occur in those of African or Asian descent, and Hispanic ethnicity. There is a slight female predominance. The median age of onset is 5 yr, but it can begin in infancy and adolescence. Typically, there is a delay of 2.5 yr in making the diagnosis despite multiple episodes and emergency room visits. The natural history of CVS is that most children outgrow it during preadolescence or adolescence, and of those, many will develop migraines. There are also later pediatric-onset (mean age 13) and adult-onset (mean age 32) subgroups indicating that in a minority it can begin or persist in adulthood.

One key clinical feature of CVS is its consistent and stereotypical pattern of presentation within individuals. Typically, symptoms start at the same time, often during early morning hours, lasting the same duration and demonstrating identical autonomic symptoms of pallor and listlessness, unrelenting nausea, abdominal pain, and in less than half, headaches and photophobia. CVS bouts occur at a minimum 5 times, or 3 times over a 6-mo period. About half of cases occur on a cycle as often as monthly; some cycle as infrequently as every 3-4 mo. The other patients have unpredictable sporadic bouts that may be associated with a specific trigger. Potential triggers include infectious illnesses, stress and especially excitement (holidays), sleep deprivation (sleepovers), dietary triggers (chocolate, monosodium glutamate), food allergy, onset of menses, and weather changes. Typically, vomiting bouts are particularly intense, with greater than 4 bouts of emesis per hour at the peak, and can include gastric contents or frequent dry heaves. While most attacks last 2 days, an episode can last anywhere from hours and rarely up to 10 days. CVS attacks are debilitating, often necessitating IV rehydration, and resulting in hospitalization. Seasonal variation apparently occurs in approximately a third of patients, with more attacks in winter, fewer during summer. In some adolescent patients, a *coalescent form* develops with daily nausea between episodes of emesis (which becomes less frequent).

Multiple *comorbid* disorders can further comprise quality of life between episodes; these include anxiety, constipation-predominant irritable bowel syndrome, chronic fatigue or limited stamina, sleep disorders, postural orthostatic tachycardia syndrome, daily nausea, and complex regional pain syndrome.

In all cases of CVS, an underlying causative etiology (anatomical, infectious, inflammatory, neoplastic, and metabolic or endocrine) cannot be identified. There is typically a positive family history of migraines in children with CVS; attacks of both conditions share many clinical features. Although the pathophysiology is not fully known, there is suggestive evidence that an overresponsive hypothalamic-pituitary-adrenal axis (including corticotropin-releasing factor), autonomic nervous system dysregulation (sympathetic predominance), mitochondrial dysfunction (16519T and 3010A), and nuclear mutations *(RYR2)* may play contributory roles. Although the role of cannabis is unknown in CVS, *cannabis-induced hyperemesis syndrome* shares many features with CVS, including the relief of symptoms by hot showers (Chapter 140.3).

Patients with chronic vomiting should always be evaluated for potential etiologies other than CVS. The differential diagnosis includes GI anomalies (malrotation, duplication cysts, choledochal cysts, recurrent intussusceptions), CNS disorders (neoplasm, epilepsy, vestibular pathology), nephrolithiasis, cholelithiasis, hydronephrosis, metabolic-endocrine disorders (urea cycle, mitochondrial disorders, fatty acid metabolism, Addison disease, porphyria, hereditary angioedema, familial Mediterranean fever), chronic appendicitis, and inflammatory bowel disease. Laboratory evaluation is based on a careful history and physical examination and may include, if indicated, endoscopy, contrast GI radiography, brain MRI, and metabolic studies (lactate, organic acids, ammonia). Bilious emesis usually suggests a small bowel obstruction and is considered a red flag; however, children with CVS may have bile stained emesis. A tender abdomen is also unusual for CVS and warrants further workup. Acute and chronic appendicitis can mimic CVS. Prior abdominal surgery may increase risk for adhesion-related partial bowel obstructions (see Table 369.1).

Non-gastrointestinal causes of frequent vomiting include renal, metabolic, endocrine, and neurological disorders. Renal abnormalities to consider include acute or chronic ureteropelvic junction (UPJ) obstruction presenting with hydronephrosis (Dietl crisis) and nephrolithiasis. The clinician must also consider metabolic disorders, especially in the infant or toddler less than 2 yr of age. Fasting or high protein meals that provoke emesis raise a red flag for metabolic disorders, such as disorders of fatty acid oxidation, organic acidemias, or partial ornithine transcarbamylase deficiency. Acute intermittent porphyria can present in the adolescent triggered by alcohol or medications. Endocrine disorders, including diabetic ketoacidosis, Addison disease, and pheochromocytoma, can mimic CVS episodes. Although an atypical presentation, CNS tumors can have episodic vomiting and papilledema; altered mental status and focal neurological findings are red flags requiring neuroimaging. Pregnancy can present with CVS-like symptoms.

Children who meet the diagnostic criteria for CVS and have no red flags should have simple screening tests for electrolyte abnormalities, acidosis, hypoglycemia, and renal dysfunction during episodes, and an UGI radiograph to exclude malrotation. Presenting with gastrointestinal (bilious emesis, abdominal tenderness), metabolic (fasting or meal-induced), and neurological (papilledema, altered mental status) red flags warrants further evaluation (see Table 369.1).

In the management of acute episodes, early and aggressive hydration (especially with dextrose) may shorten episodes in addition to correcting fluid losses. Reducing extraneous sensory stimulation, similar to the management approach for migraines, may also be beneficial (Table 369.2). Regardless of intervention, episodes will eventually spontaneously resolve with return to a normal baseline. Triptans can be used as an *abortive medication* in patients with a family history of migraines, at the onset of symptoms. Ondansetron may reduce nausea and emesis. Sedation may reduce severity or stop a CVS episode; drugs include antihistamines such as diphenhydramine and promethazine. Lorazepam or rectal diazepam can be also used. These measures are empiric; a lack of evidence base limits our understanding of efficacy. For rare but severe refractory cases, general anesthetics have been used. A dramatic change in presentation of attacks suggests a red flag such as acute hydronephrosis or small bowel obstruction from volvulus.

Table 369.2

Supportive Care and Abortive Treatment Approaches in Cyclic Vomiting Syndrome

SUPPORTIVE CARE		
Fluid and electrolyte management	Dextrose containing fluid (D10) and normal saline as a single infusion or as a Y infusion	
Nutrition	• Resume enteral nutrition as soon as possible. • If unable to tolerate enteral nutrition and meets criteria, start parenteral nutrition after 3-4 days.	
Medications	Antiemetics	Ondansetron • 0.3-0.4 mg/kg/dose IV every 4-6 hr (maximum 16 mg/dose) • Side effect: constipation, QTc prolongation Alternative: Granisetron
	Sedatives	Diphenhydramine • 1-1.25 mg/kg/dose IV every 6 hr Lorazepam 0.05-0.1 mg/kg/dose IV every 6 hr • Side effects: respiratory depression, hallucinations Chlorpromazine 0.5-1 mg/kg/dose every 6-8 hr + diphenhydramine IV
	Analgesics	Ketorolac 0.5 mg/kg/dose IV every 6 hr (maximum dose 30 mg)
Treatment of specific signs and symptoms	Epigastric pain • Acid reduction therapy with an H_2 RA or a PPI Diarrhea	

	• Antidiarrheals Hypertension • Short-acting ACE inhibitors such as captopril
Treatment of specific complications	• Dehydration and electrolyte deficits: replace calculated deficits • Metabolic acidosis: determine etiology and rectify • SIADH: restrict free water intake • Hyperemesis: IV acid reduction • Weight loss: enteral or parenteral nutrition
ABORTIVE CARE	
Antimigraine (triptans)	Sumatriptan • 20 mg intranasally at episode onset • Side effects: neck pain/burning, coronary vasospasm • Contraindications: basilar artery migraine
RECOVERY AND REFEEDING	
• Feed ad libitum when the child declares that the episode is over	

Medications listed above are for off-label use.

Modified from Li BU, Lefevre F, Chelimsky GG, et al: North American Society for Pediatric Gastroenterology, Hepatology and Nutrition consensus statement on the diagnosis and management of cyclic vomiting syndrome, *J Pediatr Gastroenterol Nutr* 47(3):379–393, 2008.

Prophylactic management begins with lifestyle measures (maintenance fluid intake, adequate calories, sleep hygiene, and exercise), including avoidance of known triggering foods (allergens, chocolate, aged cheese, monosodium glutamate; Table 369.3). Recommendations for prophylactic regimens include cyproheptadine in patients less than 5 yr of age and amitriptyline in patients ≥5 yr; propranolol serves as a secondary agent in both age groups. Supplements such as coenzyme Q10 and L-carnitine have occasionally been reported to be useful adjuncts. When standard care fails, the addition of anticonvulsants such as topiramate has been implemented. For those with catamenial CVS, low-dose estrogen oral contraceptives or Depo-Provera may prevent episodes. Treatment of *comorbid disorders* , especially anxiety (cognitive behavioral therapy, antianxiety agents) and postural orthostatic tachycardia syndrome (fluids, salt, fludrocortisone), may be needed for effective management of CVS.

Table 369.3

Prophylactic Lifestyle Changes and Pharmacological Options for Cyclic Vomiting Syndrome

LIFESTYLE MEASURES	
Reassurance and anticipatory Guidance	• Episodes are not intentional. • The natural history of CVS is that it will resolve with time.
Avoidance of triggers	• Identify dietary triggers (“vomit diary”) and avoid precipitating factors. • Triggering foods may include chocolate, cheese, monosodium glutamate. • Fasting a common trigger

	• Excitement a potential trigger • Excessive activity/exhaustion • Avoid sleep deprivation and practice good sleep hygiene	
Managing triggers	• Provide supplemental energy as carbohydrates for fasting induced episodes. • Provision of snacks between meals, before sleep and before exertion	
Migraine headache type lifestyle interventions	• Aerobic exercise and avoidance of overexertion • Regular mealtime schedule—avoid skipping meals • Avoid/moderate caffeine intake	
PROPHYLACTIC PHARMACOLOGICAL APPROACHES		
	Age <5 yr	Age ≥5 yr
	Antihistamines: • Cyproheptadine • 0.25-0.5 mg/kg/day in 2 daily divided doses or as a single dose qhs • Side effects of increased appetite, weight gain, and sedation • Pizotifen β-blockers: (2nd choice) • Propranolol • 0.25-1 mg/kg/day, most often 10 mg 2-3×/day. • Side effects include lethargy and reduced exercise tolerance. • Contraindicated in asthma, diabetes, heart disease, depression • Taper over 1-2 wk to discontinue	Tricyclic antidepressants: • Amitriptyline • Begin at 0.25-0.5 mg/kg qhs and increase weekly by 5-10 mg until achieve 1-1.5 mg/kg • Monitor EKG for prolonged QTc interval at baseline before initiation and 10 days after peak dose achieved • Side effects: constipation, sedation, arrhythmias, behavioral changes Alternatives: nortriptyline β-blockers: (2nd choice): • Propranolol Other agents: Anticonvulsants: • Phenobarbital 2 mg/kg qhs • Side effects: sedation, cognitive impairment Alternatives: • Topiramate, valproic acid, gabapentin, levetiracetam
DIETARY SUPPLEMENTS		
	• L-Carnitine 50-100 mg/kg/day divided 2-3×/day, maximum dose of 2 g 2×/day • Coenzyme Q10 200 mg 2×/day divided 2-3×/day, maximum dose 100 mg 3×/day	

Medications listed above are for off-label use. *CVS* , cyclic vomiting syndrome.

CHAPTER 370

Acute Appendicitis

John J. Aiken

Acute appendicitis remains the most common acute surgical condition in children and a major cause of childhood morbidity and health care costs, mostly associated with complicated/perforated appendicitis (PA). The peak incidence of acute appendicitis occurs in children in the second decade, and approximately 100,000 children are treated in children's hospitals for appendicitis each year. The broad spectrum of clinical presentation in acute appendicitis has been associated with significant practice variation in evaluation, diagnostic measures, and treatment of abdominal pain and suspected appendicitis. The traditional strategy of the liberal use of computed tomography (CT) to avoid misdiagnosis and early surgery to avoid progression to perforation has lacked validation in large reviews and resulted in high negative appendectomy rates and excessive radiation exposure. Perforation rates have remained around 40% and negative appendectomy rates as high as 10–20% in the past several decades. In current practice, most centers have adopted clinical practice guidelines (CPGs) combining history, physical examination findings, laboratory data, and appendicitis risk scoring systems to standardize care, improve diagnostic accuracy and outcomes, and direct cost-conscious resource utilization. Appendiceal ultrasound has emerged as a highly sensitive and specific imaging modality for diagnosis and led to a significant decrease in the use of CT and radiation exposure in the initial evaluation of children presenting with abdominal pain and possible suspected appendicitis. While prompt appendectomy remains the standard treatment in acute appendicitis, advances in imaging techniques, improved antibiotic regimens, increased use of percutaneous drainage procedures by interventional radiologists, and emerging data on high success rates with initial antibiotic treatment alone have led to an increase in the initial nonoperative management of both simple and complicated (abscess, phlegmon) appendicitis. Laparoscopic appendectomy (LA, minimally invasive technique) has emerged as the preferred surgical approach for both simple and PA, with an open surgical approach reserved as an alternative for selected cases or when attempted LA is technically difficult and/or deemed unsafe.

Epidemiology

The incidence of acute appendicitis increases with age, from a rate of 1-2 per 10,000 children from birth to 4 yr of age, to a rate of 19-28 per 10,000 children younger than age 14 yr annually. Children have a lifetime risk of 7–9% and appendicitis is diagnosed in 1–8% of children presenting to the emergency department (ED) for evaluation of abdominal pain. Appendicitis is most common in older children, with peak incidence between the ages of 10 and 18 yr; it is rare in children younger than 5 yr of age (<5% of cases) and extremely rare (<1% of cases) in children younger than 3 yr of age.

Infants with appendicitis are often misdiagnosed with sepsis and because of the diagnostic delay, they present in advanced stages of the disease. Most infant cases are primary, but some may be associated with Hirschsprung disease, cystic fibrosis, inguinal hernia, prematurity, meconium plug syndrome, or complex multiorgan syndromes.

Incidence rates for acute appendicitis are higher in males, whites, and Hispanics compared to African Americans and Asians; Hispanics, Asians, and patients with nonprivate insurance have higher odds of perforation. There is a peak incidence of appendicitis in the third quarter between July and September and the incidence is higher in the West and North Central regions compared with the Mid-Atlantic States. The reasons for these ethnic, geographic, and socioeconomic disparities remain unclear with possibilities including cultural differences in interaction with the medical system, limitations in access to care, or differences in disease progression by race.

Mortality is low (<1%), but morbidity remains high, mostly in association with PA. Up to 40% of children have PA at presentation, and perforation rates approach 90% in young children (<3 yr). Children with simple (nonperforated) appendicitis typically recover easily, with a low complication rate and rapid return to premorbid state and full activities. In contrast, PA is associated with substantial postoperative morbidity including readmission rates estimated at 12.8%, postoperative intraabdominal abscess rate ∼20%, surgical site infection (SSI) rate ∼20%, prolonged length of stay (LOS), need for prolonged antibiotic exposure, increased postoperative use of CT, and significant delay in return to wellness and normal activities. The Healthcare Cost and Utilization Project estimated that appendicitis with peritonitis accounted for 25,410 pediatric hospital admissions in 2012, with a mean LOS of 5.2 days and mean costs of $13,076.

Pathophysiology

The clinical entity of acute appendiceal inflammation followed by perforation, abscess formation, and peritonitis is most likely a disease of multiple etiologies, the final common pathway of which involves invasion of the appendiceal wall by bacteria. Genetic, environmental, and infectious etiologies (bacterial, viral, fungal, and parasitic) have all been implicated in acute appendicitis. Family history confers a nearly threefold increased risk for appendicitis. One pathway to acute appendicitis begins with luminal obstruction; inspissated fecal material, lymphoid hyperplasia, ingested foreign body, parasites, and tumors have been described. Obstruction of the appendiceal lumen initiates a progressive cascade involving increasing intraluminal pressure, lymphatic and venous congestion and edema, impaired arterial perfusion, ischemia of the appendiceal wall, bacterial proliferation and invasion of the wall, and necrosis. This sequence correlates with the clinical disease progression from simple appendicitis to gangrenous appendicitis and, thereafter, appendiceal perforation.

Because the appendix has the highest concentration of gut-associated lymphoid tissue (GALT) in the intestine, some have hypothesized that the appendix may have an immune function similar to that of the thymus or bursa of Fabricius. Submucosal lymphoid follicles, which can obstruct the appendiceal lumen, are few at birth but multiply steadily during childhood, reaching a peak in number during the teen years, when acute appendicitis is most common.

Enteric infection likely plays a role in many cases of acute appendicitis in association with mucosal ulceration and invasion of the appendiceal wall by bacteria. Bacteria such as *Yersinia* , *Salmonella*, and *Shigella* spp., and viruses such as infectious mononucleosis, mumps, coxsackievirus B, and adenovirus, are implicated. In addition, case reports demonstrate the occurrence of appendicitis from ingested foreign bodies, in association with carcinoid tumors of the appendix, *Ascaris* infestation and rarely, following blunt abdominal trauma. Children with cystic fibrosis have an increased incidence of appendicitis; the cause is believed to be the abnormal thickened mucus. Appendicitis in neonates is rare and warrants diagnostic evaluation for cystic fibrosis and Hirschsprung disease.

Appendectomy decreases the risk of ulcerative colitis and increases the risk of recurrent *Clostridium difficile-associated colitis.* Appendicoliths and appendicitis are more common in developed countries with refined, low-fiber diets than in developing countries with a high-fiber diet; no causal relationship has been established between lack of dietary fiber and appendicitis. In a large database analysis for genetic inheritability of appendicitis one locus had genome-wide significance, and a candidate gene *(PITX2)* was identified which was associated with a protective risk of appendicitis. A family history is associated with a nearly threefold increased appendicitis risk and genetic factors may account for 30% of appendicitis risk.

Clinical Features

Appendicitis in children has an immensely broad spectrum of clinical presentation; <50% of cases have the classic presentation. The signs and symptoms in acute appendicitis can vary depending on the timing of presentation, patient age, the abdominal/pelvic location of the appendix, and most importantly, individual variability in the evolution of the disease process. Children early in the disease process can appear well and demonstrate mild symptoms, minimal findings on physical examination, and normal laboratory studies, while those with perforation and advanced peritonitis can demonstrate severe illness with bowel obstruction, renal failure, and septic shock. Most patients with appendicitis demonstrate an insidious onset of illness characterized by generalized nonspecific malaise or anorexia in the first 12 hr, and a steady, escalating progression in severity of signs and symptoms over 2-3 days with increasing abdominal pain, vomiting, fever, and tachycardia; perforation is common beyond 48 hr of illness. Thus, the opportunity for diagnosis before perforation in acute appendicitis in children is most often brief (48-72 hr) and a high percentage of patients are perforated at presentation.

Abdominal pain is consistently the *primary* symptom in acute appendicitis; beginning shortly (hours) after the onset of illness. As with other visceral organs, there are no somatic pain fibers within the appendix; therefore, early appendiceal inflammation results in pain which is vague, poorly localized, unrelated to activity or position, often colicky, and periumbilical in location as a result of visceral inflammation from a distended appendix. Progression of the inflammatory process in the next 24 hr leads to involvement of the adjacent parietal peritoneal surfaces, resulting in somatic pain localized to the right lower quadrant (RLQ); *thus, the classic description of periumbilical mid-abdominal pain migrating to the RLQ. The position of the appendix is a critical factor affecting interpretation of presenting signs and symptoms and accurate diagnosis.* When the appendix is in a retrocecal or pelvic position, a slower progression of illness is typical and clinical presentation is likely to be delayed. Localized pain in the RLQ leads to spasm in the overlying abdominal wall muscles and now the pain is predictably exacerbated by movement. The child often describes marked discomfort with the bumpy car ride to the hospital, moves cautiously, and has difficulty getting onto the examining room stretcher. Nausea and vomiting occur in more than half the patients, and typically *follow* the onset of abdominal pain by several hours. Anorexia is a classic and consistent finding in acute appendicitis, but occasionally affected patients are hungry. Diarrhea and urinary symptoms are also common, particularly in cases of PA when there is likely inflammation near the rectum and possible abscess in the pelvis. Painful voiding may not be from dysuria, but pressure transmitted to an inflamed peritoneum. As it progresses, appendicitis is often associated with adynamic ileus, leading to the complaint of constipation and possible misdiagnosis.

Because enteric infections can cause appendicitis, diarrhea may be a manifestation and gastroenteritis may be the assumed diagnosis. In contrast to gastroenteritis, the abdominal pain in early appendicitis is *constant* (not cramping or relieved by defecation), the emesis may become bile stained and persistent, and the clinical course worsens steadily rather than demonstrating a waxing and waning pattern often seen in viral gastroenteritis. Fever is common in appendicitis and typically low-grade unless perforation has occurred. Most patients demonstrate at least mild tachycardia, likely secondary to pain and dehydration. The temporal progression of symptoms from vague, mild pain, malaise, and anorexia to severe localized pain, fever, and vomiting typically occurs rapidly (24-48 hr) in the majority of cases. If the diagnosis is delayed beyond 48 hr, perforation is likely (>65%). When several days have elapsed in the progression of appendicitis, patients typically develop signs and symptoms evidencing advanced disease, including worsening and diffuse pain, abdominal distension, and bilious emesis suggestive of developing small bowel obstruction. The retrocecal appendix can demonstrate symptoms suggestive of septic arthritis of the hip or a psoas muscle abscess.

A primary focus in the management of appendicitis is the avoidance of sepsis and the infectious complications leading to increased morbidity, mostly seen with PA.

Bacteria can be cultured from the serosal surface of the appendix before microscopic or gross perforation and bacterial invasion of the mesenteric veins (pylephlebitis) can result (rarely) in thrombosis and possible liver abscess or portal hypertension. A period after perforation of lessened abdominal pain and acute symptoms has been described, presumably with the elimination of pressure within the appendix. If, following perforation, the omentum or adjacent intestine is able to wall off the fecal contamination, the evolution of illness is less predictable and delay in presentation is likely. If perforation leads to diffuse peritonitis, the child generally has escalating diffuse abdominal pain and rapid development of toxicity evidenced by dehydration and signs of sepsis including hypotension, oliguria, acidosis, and high-grade fever. Young children have a poorly developed omentum and are often unable to control the spread of infection. Perforation and abscess formation with appendicitis can lead to intestinal fistula formation, scrotal cellulitis and abscess through a patent processus vaginalis (indirect inguinal hernia), or small bowel obstruction. The most likely diagnosis in children who present with signs and symptoms of mechanical small bowel obstruction who have not had prior abdominal surgery is complicated appendicitis.

Physical Examination

Although the hallmark of diagnosing acute appendicitis remains a careful and thorough history and physical examination, all clinicians know the arcane nature of acute appendicitis, the consistent or typical clinical features are not present in all patients, and the diagnosis can be a humbling experience even for the most experienced clinicians. A primary focus of the initial assessment is attention to the *temporal evolution* of the illness in relation to specific presenting signs and symptoms. In some patients, the diagnosis can be made on history and physical examination alone; in current practice the selective use of advanced imaging has improved diagnostic accuracy and resulted in significant progress in lowering of negative appendectomy rates.

Physical examination begins with inspection of the child's demeanor as well as the appearance of the abdomen. Because appendicitis most often has an insidious onset, children rarely present <12 hr from the onset of illness. Children with early appendicitis (18-36 hr) typically appear mildly ill and move tentatively, hunched forward and, often, with a slight limp favoring the right side. Supine, they often lie quietly on their right side with their knees pulled up to relax the abdominal muscles, and when asked to lie flat or sit up, they move cautiously and might use a hand to protect the RLQ. Early in appendicitis, the abdomen is typically flat; abdominal distention suggests more advanced disease characteristic of perforation or developing small bowel obstruction. Auscultation can reveal normal or hyperactive bowel sounds in early appendicitis, which are replaced by hypoactive bowel sounds as the disease progresses to perforation. *The judicious use of morphine analgesia to relieve abdominal pain does not change diagnostic accuracy or interfere with surgical decision making, and patients should receive adequate pain control.* Localized abdominal tenderness is the single most reliable finding in the diagnosis of acute appendicitis. McBurney described the classic point of localized tenderness in acute appendicitis, which is the junction of the lateral and middle thirds of the line joining the right anterior–superior iliac spine and the umbilicus, but the tenderness can also localize to any of the aberrant locations of the appendix. Localized tenderness is a later and less-consistent finding when the appendix is retrocecal in position (>50% of cases). In cases of an appendix localized entirely in the pelvis, tenderness on abdominal examination may be minimal. A gentle touch on the child's arm at the beginning of the examination with the reassurance that the abdominal examination will be similarly gentle can help to establish trust and increase the chance for a reliable and reproducible examination. The examination is best initiated in the left lower abdomen, so that the immediate part of the exam is not uncomfortable and conducted in a counterclockwise direction moving gently to the left upper abdomen, right upper abdomen, and, lastly, the right lower abdomen. This should alleviate anxiety, allow relaxation of the abdominal musculature, and enhance trust. The examiner makes several circles of the abdomen with sequentially more pressure. A soft, compressible, nontender abdominal wall is reassuring. In appendicitis, any abdominal wall movement, including coughing (Dunphy sign), may elicit pain. A consistent finding in acute appendicitis is guarding—rigidity of the overlying abdominal wall muscles in the RLQ. This rigidity may be voluntary, to protect the area of tenderness from the examiner's hand, or involuntary, if the inflammation has progressed to peritonitis causing spasm of the overlying muscle.

Abdominal tenderness may be vague or even absent early in the course of appendicitis and is often diffuse after rupture. Rebound tenderness and referred tenderness (Rovsing sign) are also consistent findings in acute appendicitis, but not always present. Rebound tenderness is elicited by deep palpation of the abdomen followed by the sudden release of the examining hand. This is often very painful to the child and has demonstrated poor correlation with peritonitis, so it should be avoided. Gentle finger percussion is a better test for peritoneal irritation. Similarly, digital rectal examination is uncomfortable and unlikely to contribute to the evaluation of appendicitis in most cases of appendicitis in children. Psoas and obturator internus signs are pain with passive stretch of these muscles. The psoas sign is elicited with active right thigh flexion or passive extension of the hip and typically positive in cases of a retrocecal appendix. The obturator sign is demonstrated by adductor pain after internal rotation of the flexed thigh and typically positive in cases of a pelvic appendix. Physical examination may demonstrate a mass in the RLQ representing an inflammatory mass (phlegmon) around the appendix or a localized intraabdominal abscess (fluid collection).

Appendicitis Risk Scoring Systems

Several risk scoring systems have become commonly used tools to promote standardization of the approach to the child with abdominal pain and suspected appendicitis. The clear aim is to maximize diagnostic accuracy in acute appendicitis, and guide imaging evaluation and resource utilization. They all combine the predictive value of consistent symptoms, physical examination findings, and laboratory data yielding a numerical score. The systems most widely utilized are the Alvarado score and the Pediatric Appendicitis Score (PAS). The PAS combines elements of history (migration of pain, anorexia, nausea, vomiting) with physical examination findings (RLQ tenderness, rebound tenderness, fever) and laboratory data (white blood cell [WBC] >10,000, polymorphonuclear neutrophils >75%) to assign a risk score in the low, intermediate, or high-risk range for acute appendicitis (Table 370.1). Scores of ≤4 suggest a very low likelihood of appendicitis, whereas scores ≥8 are highly sensitive and specific for appendicitis. Intermediate scores, between 4 and 7 on the PAS, are considered inconclusive and typically trigger advanced imaging studies. Targeted (appendiceal) ultrasound has demonstrated high sensitivity and specificity (∼90%) in the diagnosis of acute appendicitis in centers experienced with the technique and has become the initial imaging study of choice for suspected appendicitis. The notable benefits of ultrasound compared to CT scan include that it is well-tolerated, non-invasive, and lacks ionizing radiation exposure. CT is reserved for cases of nonvisualization of the appendix on ultrasound, or when the ultrasound findings are inconclusive.

Table 370.1

Pediatric Appendicitis Scores

FEATURE	SCORE
Fever > 38°C (100.4°F)	1
Anorexia	1
Nausea/vomiting	1
Cough/percussion/hopping tenderness	2
Right lower quadrant tenderness	2
Migration of pain	1
Leukocytosis > 10,000 (10^9 /L)	1
Polymorphonuclear-neutrophilia > 7,500 (10^9 /L)	1
Total	10

From Acheson J, Banerjee J: Management of suspected appendicitis in children, *Arch Dis Child Educ Pract Ed.* 95:9–13, 2010.

The use of appendicitis risk scoring systems, in conjunction with clinical judgment, have demonstrated high sensitivity and specificity for acute appendicitis (80–90%) and their application has reduced practice variability, improved diagnostic accuracy, decreased preoperative radiation exposure, and enabled efficient resource utilization—all important elements of current quality improvement and safety initiatives. Their greatest value to date appears to be in predicting patients that have a low likelihood of the diagnosis of appendicitis (negative predictive value) and can avoid imaging studies, and particularly ionizing radiation exposure.

Laboratory Findings

A variety of laboratory tests have been used in the evaluation of children with suspected appendicitis. Individually, none are very sensitive or specific for appendicitis, but collectively they can affect the clinician's level of suspicion and decision-making to proceed with pediatric surgery consultation, discharge, or imaging studies.

A complete blood count with differential and urinalysis are obtained. The leukocyte count in early appendicitis may be normal, and typically is only mildly elevated (11,000-16,000/mm^3) with a left shift as the illness progresses in the initial 24-48 hr. Whereas a normal WBC count never completely eliminates appendicitis, a count <8,000/mm^3 in a patient with a history of illness longer than 48 hr should be viewed as highly suspicious for an alternative diagnosis. The leukocyte count may be markedly elevated (>20,000/mm^3) in PA and rarely in nonperforated cases; a markedly elevated WBC count, other than in cases of advanced PA, should raise suspicion of an alternative diagnosis. Urinalysis often demonstrates a few white or red blood cells as a result of the proximity of the inflamed appendix to the ureter or bladder, but it should be free of bacteria. The urine is often concentrated and contains ketones from diminished oral intake and vomiting. Gross hematuria is uncommon, and in association with purpuric skin lesions and arthritis may indicate Henoch-Schönlein purpura.

Electrolytes and liver chemistries are generally normal unless there has been a delay in diagnosis, leading to severe dehydration and/or sepsis. Amylase and liver enzymes are only helpful to exclude alternative diagnoses such as pancreatitis and cholecystitis and are not commonly obtained if appendicitis is the strongly suspected diagnosis. C-reactive protein (CRP) increases in proportion to the degree of appendiceal inflammation. It has not demonstrated high sensitivity or specificity in the diagnosis of appendicitis; some studies have demonstrated an association between disease severity (PA and abscess formation) and elevated CRP levels. In this context, CRP may have a role in identifying patients with complicated appendicitis, which may be managed initially nonoperatively with antibiotics and drainage of fluid collections.

Imaging Studies

Following a thorough initial evaluation including history, physical examination, review of vital signs, and laboratory studies, if the diagnosis is uncertain, radiographic studies can substantially improve diagnostic accuracy.

Plain Radiographs

In the majority of cases, appendiceal ultrasound and CT scan have become the predominant studies in inconclusive cases of acute appendicitis. Plain abdominal radiographs may be helpful in rare select cases of abdominal pain/suspected appendicitis. Plain abdominal x-rays may demonstrate several findings suggestive of acute appendicitis, including sentinel loops of bowel and localized ileus, scoliosis from psoas muscle spasm, a colonic air–fluid level above the right iliac fossa (colon cutoff sign), an RLQ soft tissue mass, or a calcified appendicolith (5–10% of cases); they are normal in 50% of patients, have a low sensitivity, and are not generally recommended (Fig. 370.1). Plain films are most helpful in evaluating complicated cases in which small bowel obstruction or free air is suspected.

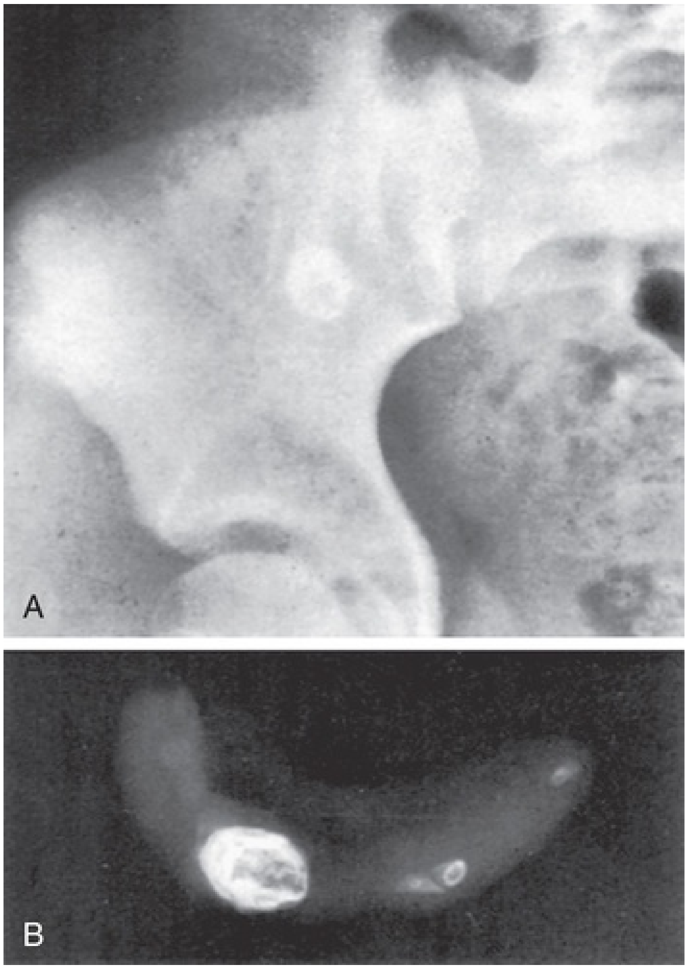

FIG. 370.1 Calcified appendicoliths are seen in a coned-down anteroposterior view of the right lower quadrant **(A)** and in the resected appendix of a 10 yr old girl with acute appendicitis **(B)** . (From Kuhn JP, Slovis TL, Haller JO: *Caffrey's pediatric diagnostic imaging,* vol 2, ed 10, Philadelphia, 2004, Mosby, p. 1682.)

Ultrasound

Ultrasound has emerged as the first-choice tool for children requiring an imaging study in the evaluation of suspected acute appendicitis. Ultrasound has demonstrated sensitivity and specificity approaching 90% in pediatric centers experienced with the technique, and has substantial advantages including low cost, ready availability, rapidity, and avoidance of sedation, contrast agents, and radiation exposure. Ultrasound can be particularly helpful in adolescent females, a group with a high negative appendectomy rate (normal appendix found at surgery), because of its ability to evaluate for ovarian pathology without ionizing radiation. Graded abdominal compression is used to displace the cecum and ascending colon and identify the appendix, which has a typical target appearance (Fig. 370.2). The ultrasound criteria for appendicitis include wall thickness ≥6 mm, luminal distention, lack of compressibility, a complex mass in the RLQ, or an appendicolith. The visualized appendix usually coincides with the site of localized pain and tenderness. In addition, ultrasound may identify PA on *initial evaluation* ; initial management of PA has increasingly moved toward percutaneous drainage procedures, broad spectrum antibiotics, and nonoperative treatment. An enlarged appendix (>6 mm), hyperemia, noncompressibility of the appendiceal wall, localized tenderness, and associated mesenteric fat stranding or fluid are all consistent with acute appendicitis. Findings that suggest advanced appendicitis on ultrasound include asymmetric wall thickening, abscess formation, associated free intraabdominal/pelvic fluid, surrounding tissue edema, and decreased local tenderness to compression. *The main limitation of ultrasound is an inability to visualize the appendix, which is reported in 25–60% of cases*. It has been postulated that a normal appendix must be visualized to exclude the diagnosis of appendicitis by ultrasound; however, one report concluded that in patients with a nonvisualized appendix on ultrasound imaging and no evidence of secondary inflammatory changes, the likelihood of appendicitis was <2%. Certain conditions predictably decrease the sensitivity and reliability of ultrasound for appendicitis, including obesity, bowel distention, and uncontrolled pain.

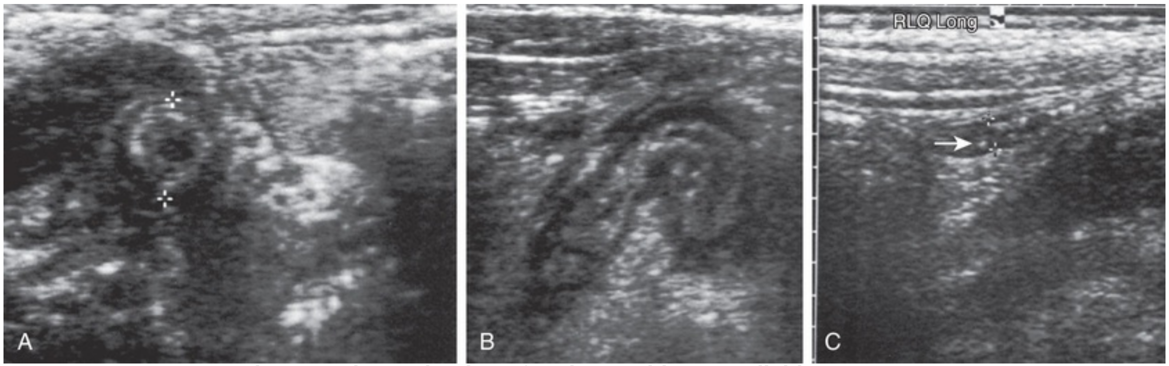

FIG. 370.2 Ultrasound examination of patients with appendicitis. A, Transverse ultrasound scan of the appendix demonstrates the characteristic “target sign.” In this case, the innermost portion is sonolucent, compatible with fluid or pus. B, Longitudinal view of another patient demonstrates the alternating hyperechoic and hypoechoic layers with an outermost hypoechoic layer, suggesting periappendiceal fluid. C, Longitudinal ultrasound scan of the right lower quadrant demonstrates a dilated, non-compressible appendix. The bright echo within the appendix represents an appendicolith with acoustic shadowing *(arrow).* (From Kuhn JP, Slovis TL, Haller JO: *Caffrey's pediatric diagnostic imaging,* vol 2, ed 10, Philadelphia, 2004, Mosby, p. 1684.)

Computed Tomography

CT scan has been the gold standard imaging study for evaluating children with suspected appendicitis, and has sensitivity of 97%, specificity 99%, positive predictive value 98%, and negative predictive value 98% (Figs. 370.3 and 370.4). The advantages of CT imaging include ready availability, rapid acquisition time, and lack of operator dependency. CT carries the significant negative effects of exposure of children to ionizing radiation and increased costs. The exam can be performed using intravenous and enteral (oral or rectal) contrast; however, the administration of enteral contrast has several drawbacks including increasing abdominal distension, risk of emesis and aspiration, and increasing radiation exposure without demonstrable improvement in accuracy of diagnosis. The use of oral contrast should be reserved for patients in whom alternative diagnoses are suspected, particularly Crohn disease. Because the finding of fat stranding in surrounding tissues is a key component of CT evaluation for appendicitis, CT is less reliable in thin children with minimal body fat.

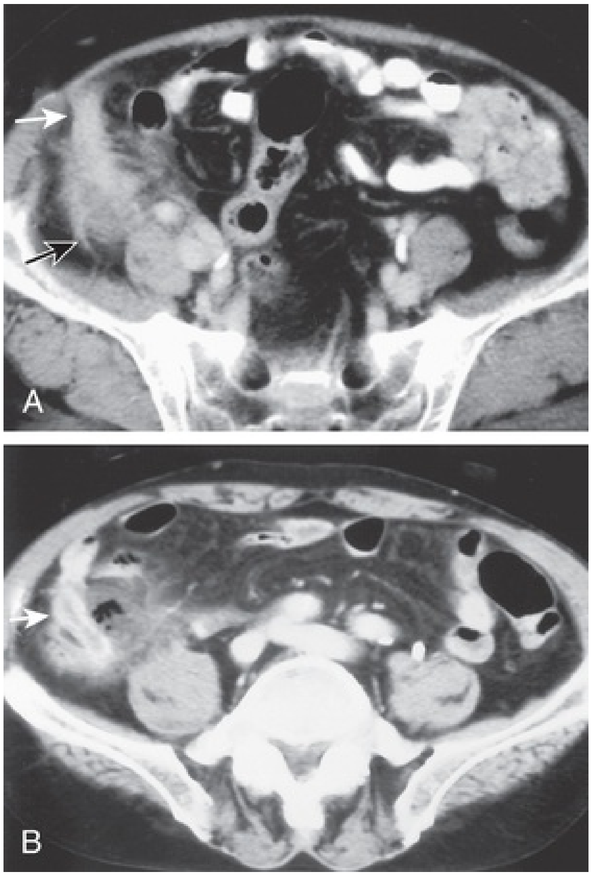

FIG. 370.3 **A,** Phlegmon *(open arrow)* is noted around the enlarged appendix *(solid arrow)* in perforated appendicitis. **B,** Extraluminal air is shown adjacent to the wall-enhanced appendix *(arrow)* in perforated appendicitis. (From Yeung KW, Chang MS, Hsiao CP: Evaluation of perforated and non-perforated appendicitis with CT, *Clin Imaging* 28(6):422–427, 2004.)

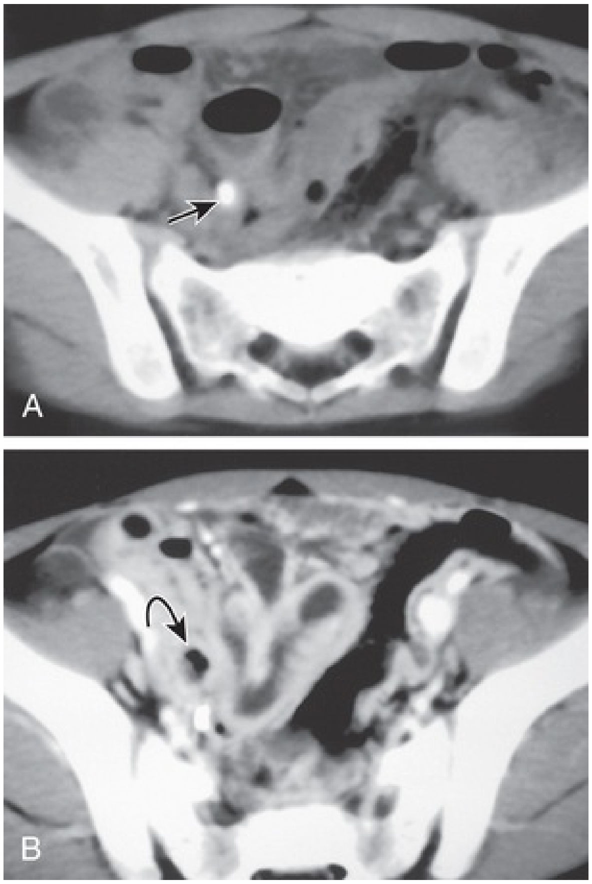

FIG. 370.4 **A,** Precontrast-enhanced CT reveals an appendicolith *(arrow)* in perforated appendicitis. **B,** Postcontrast-enhanced CT (1 cm below the level in **A**) reveals intraluminal air in the appendix *(curved arrow)* associated with ileal wall enhancement in perforated appendicitis. (From Yeung KW, Chang MS, Hsiao CP: Evaluation of perforated and non-perforated appendicitis with CT, *Clin Imaging* 28(6):422–427, 2004.)

The avoidance of enteral contrast, targeted CT imaging, and the use of pediatric specific protocols can significantly lower radiation dosages without sacrificing diagnostic accuracy. The use of appendicitis risk scoring systems, in conjunction with CPGs, and increasing experience with appendiceal ultrasound have led to a decreased use of CT scans (<6.6% in most reports), without negatively affecting time to appendectomy or negative appendectomy rates.

Magnetic Resonance Imaging and White Blood Cell Scans

MRI is at least equivalent to CT in diagnostic accuracy for appendicitis and does not involve ionizing radiation; however, its use in the evaluation of appendicitis is limited because it is less available, associated with higher costs, often requires sedation, and does not offer equivalent access for drainage of fluid collections. MRI may prove most useful in adolescent females when ultrasound imaging is equivocal. Radionuclide-labeled WBC scans have also been used in some centers in evaluating atypical cases of possible appendicitis in children and demonstrated a high sensitivity (97%) but only modest specificity (80%).

Diagnosis and Treatment

Acute appendicitis is believed to be a time-sensitive condition, thus, any delay in diagnosis or treatment may lead to an increased risk of perforation and its attendant morbidity. The misdiagnosis of appendicitis is second only to meningitis as a cause of medical malpractice suits in pediatric emergency care. A careful history and physical examination remains primary in the initial assessment of a child presenting with abdominal symptoms. The classic history in acute appendicitis, although possibly not most common, is a 24-hr history of diffuse mid-abdominal pain which migrates and becomes localized to the RLQ. Patients should have a WBC count with differential analysis, as this is a component of most appendicitis risk scoring systems. A urinalysis is also typically obtained and a pregnancy test in appropriately selected patients. CPGs have become common practice in many centers for evaluation of patients with abdominal pain and suspected appendicitis to reduce practice variability and improve diagnostic accuracy and resource utilization. CPGs have been shown to have a high positive and negative predictive value (∼95%), and to decrease both LOS and costs without increasing morbidity or complications. These guidelines combine initial history, physical examination, and laboratory data with predictive risk scoring systems to cohort patients into low, intermediate, and high risk for the diagnosis of acute appendicitis. In general, low-risk patients can be discharged without imaging studies, high-risk patients would have pediatric surgical consultation, and the inconclusive or intermediate risk group would most predictably benefit from a period of observation or proceeding with advanced imaging studies. If the initial assessment leads to a high level of suspicion for appendicitis, pediatric surgical consultation should be the next step, with the likelihood of an appendectomy without further studies. In patients with a low concern for appendicitis, the child may be discharged with family education regarding the natural history and progression of acute appendicitis and advice to return for repeat evaluation if the child is not improving on liquids and a bland diet in the next 24 hr. The group of patients with an intermediate risk score would proceed with targeted ultrasound of the appendix if the center has experience with the technique. If the ultrasound study is unable to visualize the appendix, or the appendix is visualized but the findings inconclusive, the next options would include admission for a period of observation and planned reassessment, CT imaging, or diagnostic laparoscopy.

The use of observation units, where the child may be observed with intravenous fluids, serial vital signs, and planned re-examinations is another strategy. At the end of a period of observation, typically 12-24 hr, the clinician decides on discharge based on reassuring clinical status, proceeds to diagnostic laparoscopy and appendectomy, or proceeds with advanced imaging evaluation. The period of observation can occur at home provided the patient is physiologically well; a hospital-based observational unit has the advantage of being able to provide intravenous fluids. An observation strategy seems most useful in patients who present with a brief history of illness (<12 hr) when advanced imaging studies predictably have lower sensitivity and specificity. If observed patients remain equivocal, advanced imaging should be more reliable further into the disease process.

Differential Diagnosis

The list of illnesses that can mimic acute appendicitis is extensive because many gastrointestinal, gynecologic, and inflammatory disorders can manifest with similar illness history, signs, and symptoms. Differential diagnosis, even limited to common conditions, includes gastroenteritis, mesenteric adenitis, Meckel diverticulitis, intussusception, inflammatory bowel disease, diabetes mellitus, sickle cell disease, streptococcal pharyngitis, lower lobe pneumonia, cholecystitis, pancreatitis, urinary tract infection (UTI), infectious enteritis, and, in females, ovarian torsion, ectopic pregnancy, ruptured/hemorrhagic ovarian cysts, and pelvic inflammatory disease (including tuboovarian abscess). *Epiploic appendagitis* , an inflammation of the fat-filled structures on the antimesenteric surface of the colon, may present with acute lower quadrant abdominal pain after torsion, thrombosis, and ischemic injury to the structure. Viral infections, bacterial infections, and parasitic infections can all closely mimic acute appendicitis. Intestinal tract lymphoma, tumors of the appendix (carcinoid in children), and ovarian tumors are rare but can also masquerade as acute appendicitis. Henoch-Schönlein purpura can initially present as severe abdominal pain. Urinary tract causes of abdominal pain include UTI, nephrolithiasis, and pyelonephritis. In patients with pyelonephritis, the fever and WBC count are likely much higher, symptoms of dysuria will be present, and the tenderness is located more in the flank or costovertebral angle. Rarely, appendicitis may recur in the stump of a previous appendectomy. *Children younger than 3 yr of age and adolescent girls have historically proven to be at particularly high risk for an incorrect diagnosis* .

Viral illnesses are common in children, often are associated with abdominal pain and vomiting, and thus mimic acute appendicitis. The classic patient with acute appendicitis describes abdominal pain as the preeminent symptom, and in general, symptoms of systemic illness such as headache, chills, and myalgias are infrequent in appendicitis and common when viral illness is the correct diagnosis.

The diagnosis of appendicitis in adolescent females is especially challenging, and some series report negative appendectomy rates as high as 30–40%. Ovarian cysts are often acutely painful as a result of rupture, rapid enlargement, or hemorrhage. Rupture of an ovarian follicle associated with ovulation often causes mid-cycle lateralizing pain (mittelschmerz), but there is no progression of symptoms and systemic illness is absent. Ovarian tumors and torsion can also mimic acute appendicitis, although ovarian torsion is typically characterized by the acute onset of severe pain and is associated with more frequent and forceful nausea and vomiting than is typically seen in early appendicitis. In pelvic inflammatory disease, the pain is typically suprapubic, bilateral, and of longer duration. The need for accurate urgent diagnosis in females is influenced by concern that PA can predispose the patient to future ectopic pregnancy or tubal infertility, although data have not consistently demonstrated increased incidence of infertility after PA. For these reasons, adjunct diagnostic studies (ultrasound, CT, MRI, or diagnostic laparoscopy) should be used more liberally in females to keep negative appendectomy rates low.

Torsion of an undescended testis and epididymitis are common but should be discovered on physical exam. Meckel's diverticulitis is an infrequent condition, but the clinical presentation closely mimics appendicitis. The diagnosis is rarely made before surgery. Primary spontaneous peritonitis (PSP) is classically seen in prepubertal females or patients with either nephrotic syndrome or cirrhosis and is frequently mistaken for appendicitis.

Atypical presentations of appendicitis are expected in association with other conditions such as pregnancy, Crohn disease, steroid treatment, and immunosuppressive therapy. Appendicitis in association with Crohn disease often has a protracted presentation with an atypical pattern of recurring but localized abdominal pain. It should be recognized that *missed* appendicitis is the most common cause of small bowel obstruction in children without history of prior abdominal surgery.

Antibiotics

Antibiotics should be initiated promptly once the diagnosis of appendicitis is made or highly suspected. Antibiotics substantially lower the incidence of postoperative wound infections, SSIs and intraabdominal abscesses—the source of the majority of the substantial morbidity and costs in PA. Many believe the time from onset of illness to the initiation of antibiotics has more impact on postoperative complication rates, LOS, and overall costs than time from diagnosis to surgery.

The antibiotic regimen should be directed against the typical bacterial flora found in the appendix, including anaerobic organisms (*Bacteroides, Clostridia,* and *Peptostreptococcus* spp.) and Gram-negative aerobic bacteria (*Escherichia coli, Pseudomonas aeruginosa, Enterobacter,* and *Klebsiella* spp.). Many antibiotic combinations have demonstrated equivalent efficacy in controlled trials in terms of wound infection rate, resolution of fever, LOS, and incidence of complications. Historically, a triple-antibiotic regimen consisting of ampicillin, gentamicin, and clindamycin was standard. Exhaustive studies of different antibiotic regimens have been performed, mostly aimed at lowering costs and frequency of dosing while maintaining efficacy. Both piperacillin/tazobactam and cefoxitin have demonstrated equivalent effectiveness and may decrease LOS and pharmaceutical costs compared to the triple-antibiotic regimen.

For simple (nonperforated) appendicitis, one preoperative dose of a single broad-spectrum agent (Zosyn) or equivalent is sufficient. In PA, the antibiotic is continued intravenously for 2-3 days postoperatively until the child is afebrile (≥24 hr), tolerating a general diet, and ready for discharge. Some centers prefer to add metronidazole in PA to augment coverage of anaerobes. The decision to discharge patients with PA managed with upfront appendectomy on a course of oral antibiotics (typically 3-5 days) remains controversial. The literature does not support improved outcomes with PA if antibiotics are extended beyond a 4- to 5-day course.

Surgical Intervention

Once the diagnosis of appendicitis is confirmed or highly suspected, the standard treatment for acute appendicitis, both simple and complicated, in current practice is most often prompt appendectomy. LA (minimally invasive technique) is the preferred surgical approach (65–70%) in both simple and PA, with open appendectomy markedly declining in the past decade. The laparoscopic approach has demonstrated slight improvement in clinical outcome measures (wound infection rate, intraabdominal abscess, analgesic requirements, wound cosmesis, and return to full activity), however, costs can be higher. The laparoscopic approach (diagnostic laparoscopy/LA) has particular advantages for obese patients, when alternative diagnoses are suspected, and in adolescent females to evaluate for ovarian pathology and alternative diagnoses while avoiding the ionizing radiation associated with CT imaging. The operation should proceed semi-electively within 12-24 hr of diagnosis. Children with appendicitis are typically at least mildly dehydrated and should receive supportive care prior to surgery, including fluid resuscitation to correct hypovolemia and electrolyte abnormalities, antipyretics to lower fever, and broad-spectrum antibiotics. These important fundamentals of care ensure safe anesthesia and optimize outcomes. In most cases, preoperative management can be accomplished during the period of diagnostic evaluation and prompt appendectomy can be performed. Pain management begins even before a definitive diagnosis is made, and consultation of a pain service, if available, is appropriate. Emergency surgery (middle of the night) *is rarely* indicated in acute appendicitis and should only be performed in the rare circumstance when physiologic resuscitation requires urgent control of advanced intraabdominal sepsis not amenable to percutaneous drainage by IR, or when this is not available. No correlation has been demonstrated between timing of surgery and perforation rates or postoperative morbidity when the operation proceeds within 24 hr of diagnosis. When comparing emergent appendectomy (within 5 hr of admission) with urgent appendectomy (within 17 hr of admission), no difference in PA, operative time, readmission rate, postoperative complications, LOS, or hospital charges have been noted. In addition, occasionally unexpected pathology (appendiceal tumors, intestinal lymphoma, congenital renal anomalies, Crohn disease) is discovered at operation, and intraoperative consultation with other specialists and/or frozen section evaluation may be required. The laparoscopic approach, in conjunction with standardized, expedited postoperative recovery protocols, and improved (single drug) and shorter duration antibiotic regimens have led to decreased LOS in both simple and complicated (perforated) appendicitis. The average LOS in most centers is approximately 24 hr for simple appendicitis and 4-5 days for perforated cases that recover without postoperative complications. In simple appendicitis, some centers have initiated same-day discharge.

Perforated Appendicitis

A major area of focus and challenge in the management of acute appendicitis is the group of patients with delayed presentation (>48 hr of symptoms). In most busy centers, because acute appendicitis often has an insidious onset of generalized malaise, as many as 40–50% of patients have delayed presentation. This cohort of patients has a high incidence of PA at presentation (40–59%) and a 56% greater LOS stay than those presenting within ≤24 hr of the onset of symptoms. The risk for development of postoperative complications (SSI, intraabdominal abscess, small bowel obstruction) approaches 20–30% for children with PA versus an approximately 3% risk of complications in patients with simple appendicitis.

Management options for children presenting with PA include upfront appendectomy following a brief period of stabilization with intravenous fluids and antibiotics, antibiotics alone, and antibiotics in conjunction with percutaneous drainage of intraabdominal fluid collections/abscesses. The past decade has witnessed a substantial trend toward nonoperative management in children with delayed presentation and suspected PA to avoid the high complication rate in these patients and the potential technical challenges of operative treatment in the setting of marked intraabdominal inflammation/peritonitis. Based on patient status, findings on imaging studies, and availability of experienced interventional radiologists, initial nonoperative management of PA with percutaneous drainage of fluid collections, intravenous fluids and broad-spectrum antibiotics has demonstrated success in >80% of patients. Antibiotics are initiated and typically continued intravenously for 1-2 days along with pain control. If the child demonstrates clinical recovery by resolution of fever and pain, and the patient can tolerate a general diet, the child is converted to oral antibiotics and discharged to complete an outpatient antibiotic course (typically 7-10 days of ciprofloxacin/Flagyl). A patient who fails to demonstrate clinical recovery proceeds to prompt appendectomy. This nonoperative management, and particularly the transition to oral antibiotics, has contributed to a decreased LOS and costs in the management of PA. Patients who do not have upfront appendectomy will require a decision regarding interval appendectomy (IA) in 4-6 wk, provided she/he does not fail nonoperative management after discharge by recurrence of pain, fever, or vomiting.

Nonoperative Management of Uncomplicated Appendicitis

Multiple studies in adults have demonstrated highly effective treatment of appendicitis with antibiotics alone. In addition, other conditions similar to appendicitis, such as diverticulitis, intraabdominal abscess in Crohn disease, and tubo-ovarian abscess, are primarily treated with antibiotics alone, with surgery reserved for failures of medical management. These outcomes have led many centers to evaluate initial nonoperative management of acute (simple) appendicitis in children and currently several randomized controlled studies are ongoing. Previous studies demonstrated a success rate for nonoperative management of simple appendicitis in children of 75–80%, with no increased rates of PA in patients who fail initial nonoperative management. Advantages of the antibiotic alone/nonoperative approach in acute appendicitis include avoidance of surgical complications and the risk of general anesthesia, and an operative procedure that may not be necessary. In some children's centers, the nonoperative approach is being offered on experimental protocol. Selection criteria for nonoperative management typically include <48-hr duration of symptoms, age >7 yr, imaging confirmation of acute non-PA, appendiceal diameter <1.2 cm, *absence* of appendicolith, abscess, or phlegmon, WBC >5,000, and <18,000 cells/µL. The clinical pathway for children enrolled consists of an initial 1-2 days of intravenous broad-spectrum antibiotics and pain control. If the child demonstrates clinical recovery by resolution of pain and fever and is tolerating a general diet, he/she is discharged to complete 7-10 days of oral antibiotics. If the child does not demonstrate clinical recovery, prompt appendectomy is performed. Early nonoperative trials found that predictors of failure of nonoperative management included pain >48 hr duration, presence of an appendicolith, inflammatory mass or abscess on imaging, and elevated laboratory values (WBC > 18,000, CRP > 4 mg/dL). Reports of this approach suggest a more rapid return to full activities and lower costs associated with the hospitalization for nonoperative management; however, others have reported that patients with nonoperative management had more subsequent ED visits, advanced imaging studies, and hospitalizations compared with those managed operatively at the first visit.

Recurrent Appendicitis

Prospective studies of the incidence of early recurrent appendicitis (within 1 yr) describe a range between 10 to 20% in patients initially managed nonoperatively. The lifetime risk of recurrent appendicitis in children treated nonoperatively is unknown. Controversies remain in the initial nonoperative management of PA. Most studies have reported significantly fewer overall complications (wound infections, intraabdominal abscesses, bowel obstruction, re-operations) in patients with initial nonoperative management of PA compared to patients with PA managed with upfront appendectomy; other reviews have supported early appendectomy in PA because initial nonoperative management and delayed appendectomy was associated with a significantly longer time to return to normal activities and an adverse event rate of 30% versus 55% in the initial nonoperative cohort. The initial nonoperative management and delayed appendectomy patients also incurred higher costs. Currently under review is the need for delayed appendectomy IA in patients with complicated appendicitis initially managed nonoperatively. While the trend in cases of PA at presentation is toward initial nonoperative management, the data remains uncertain, and there is no convincing data to recommend one approach in all patients.

Interval Appendectomy

In patients with PA initially treated nonoperatively, the decision to proceed with IA, typically in 4-6 wk, is another area of management lacking consensus. Traditionally, most surgeons recommended IA to avoid recurrent appendicitis and to confirm the original diagnosis, citing reports which demonstrated an incidence of unexpected pathology in 30% of IA specimens. This has been questioned with nonoperative management of simple appendicitis gaining acceptance and many debating the risk of recurrent appendicitis (5–20%), believing it to be lower. The lifetime risk of recurrent appendicitis is unknown. Decision-making for IA must be individualized to balance the risks of recurrent appendicitis with the risks of anesthesia and comorbid conditions such as obesity, congenital heart disease, chronic respiratory conditions, and others.

Incidental Appendicoliths

The question of the incidental appendicolith is an intriguing one for pediatric practitioners. These are patients who do not have appendicitis but are found to have an appendicolith on imaging studies. An appendicolith is defined as a calcification within the appendiceal lumen. In adults, incidental appendicoliths identified by CT scans vary in incidence from <1% to as high as 10%. They have a characteristic dense and laminated appearance when compared to other lower abdominal calcifications, including phleboliths (venous calcifications) and, in females, ovarian calcifications, most commonly seen in ovarian tumors. They can be appreciated on plain film, ultrasound, and CT scan. When an appendicolith is noted in the evaluation of a child with abdominal pain and suspected appendicitis, the finding of the appendicolith confirms the diagnosis; surgical consultation and prompt appendectomy is indicated. Appendicoliths may be noted in the evaluation of patients who have no signs of appendicitis, such as imaging obtained after trauma or for nonspecific abdominal complaints in patients with low likelihood of appendicitis. The concern in this setting is that the appendicolith may increase the eventual development of acute appendicitis. In addition, there is the concern that should appendicitis develop in association with an appendicolith, there may be a rapidly escalating course and early perforation. Some physicians believe that a persistent appendicolith may be associated with recurrent RLQ/iliac fossa pain.

Incidental appendicoliths may be transient and in most short-term follow-up studies have a low risk of subsequent acute appendicitis. In addition, the lifetime risk for the development of appendicitis in patients with an incidental appendicolith is approximately 5%, which is not different from the normal population. The risk of subsequent appendicitis may be higher in those presenting with abdominal pain or those younger than 19 yr of age. Radiographically detected incidental appendicoliths are usually managed with observation, planned follow-up, and patient education for signs of acute appendicitis. After discussing the risks and benefits with the family, and persistence of the appendicolith, an individualized approach is best between the physician and family relative to elective appendectomy.

ACE Antegrade continence enema

MACE Malone antegrade continence enema

To fully understand the spectrum of anorectal anomalies, it is necessary to consider the importance of the sphincter complex, a mass of muscle fibers surrounding the anorectum (Fig. 371.1). This complex is the combination of the puborectalis, levator ani, external and internal sphincters, and the superficial external sphincter muscles, all meeting at the rectum. Anorectal malformations are defined by the relationship of the rectum to this complex and include varying degrees of stenosis to complete atresia. The incidence is 1/3,000 live births. Significant long-term concerns focus on bowel control and urinary and sexual functions.

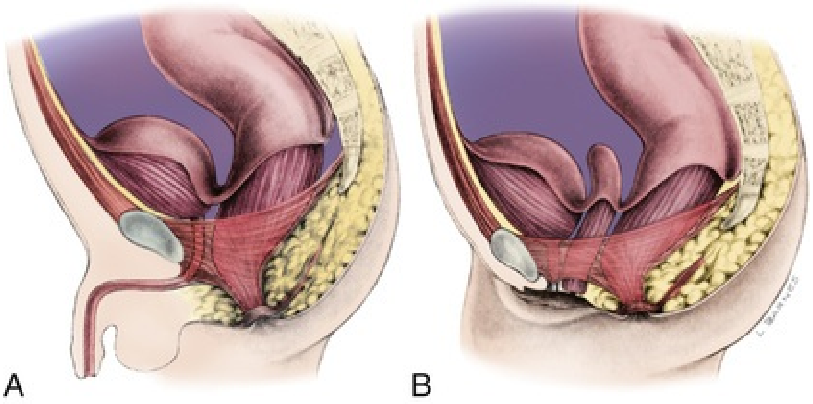

FIG. 371.1 **Normal anorectal anatomy in relation to pelvic structures. A, Male. B, Female. (From Peña A: *Atlas of surgical management of anorectal malformations* , New York, 1989, Springer-Verlag, p 3.)**

Embryology

The hindgut forms early as the part of the primitive gut tube that extends into the tail fold in the 2nd wk of gestation. At about day 13, it develops a ventral diverticulum, the allantois, or primitive bladder. The junction of allantois and hindgut becomes the cloaca, into which the genital, urinary, and intestinal tubes empty. This is covered by a cloacal membrane. The urorectal septum descends to divide this common channel by forming lateral ridges, which grow in and fuse by the middle of the 7th wk. Opening of the posterior portion of the membrane (the anal membrane) occurs in the 8th wk. Failures in any part of these processes can lead to the clinical spectrum of anogenital anomalies.

Imperforate anus can be divided into low lesions, where the rectum has descended through the sphincter complex, and high lesions, where it has not. Most patients with imperforate anus have a fistula. There is a spectrum of malformation in males and females. In males, low lesions usually manifest with meconium staining somewhere on the perineum along the median raphe (Fig. 371.2*A*). Low lesions in females also manifest as a spectrum from an anus that is only slightly anterior on the perineal body to a fourchette fistula that opens on the moist mucosa of the introitus distal to the hymen (Fig. 371.3*A*). A high imperforate anus in a male has no apparent cutaneous opening or fistula, but it usually has a fistula to the urinary tract, either the urethra or the bladder (see Fig. 371.2*B*). Although there is occasionally a rectovaginal fistula, in females, high lesions are usually cloacal anomalies in which the rectum, vagina, and urethra all empty into a common channel or cloacal stem of varying length (see Fig. 371.3*B*). The interesting category of males with imperforate anus and no fistula occurs mainly in children with trisomy 21. The most common lesions are the rectourethral bulbar fistula in males and the rectovestibular fistula in females; the 2nd most common lesion in both sexes is the perianal fistula (Fig. 371.4).

Associated Anomalies

There are many anomalies associated with anorectal malformations (Table 371.1). The most common are anomalies of the kidneys and urinary tract in conjunction with abnormalities of the sacrum. This complex is often referred to as *caudal regression syndrome* . Males with a rectovesical fistula and patients with a persistent cloaca have a 90% risk of urologic defects. Other common associated anomalies are cardiac anomalies and esophageal atresia with or without tracheoesophageal fistula. These can cluster in any combination in a patient. When combined, they are often accompanied by abnormalities of the radial aspect of the upper extremity and are termed the VACTERL (*v* ertebral, *a* nal, *c* ardiac, *t* racheal, *e* sophageal, *r* enal, *l* imb) anomalad.

Table 371.1

Associated Malformations

GENITOURINARY
• Vesicoureteric reflux • Renal agenesis • Renal dysplasia • Ureteral duplication • Cryptorchidism • Hypospadias • Bicornuate uterus • Vaginal septa
VERTEBRAL
• Spinal dysraphism • Tethered chord • Presacral masses • Meningocele • Lipoma • Dermoid • Teratoma
CARDIOVASCULAR
• Tetralogy of Fallot • Ventricular septal defect • Transposition of the great vessels • Hypoplastic left-heart syndrome
GASTROINTESTINAL
• Tracheoesophageal fistula • Duodenal atresia • Malrotation • Hirschsprung disease
CENTRAL NERVOUS SYSTEM
• Spina bifida • Tethered cord

Anorectal malformations, particularly anal stenosis and rectal atresia, can also present as Currarino triad, which includes sacral agenesis, presacral mass, and anorectal stenosis. These patients present with a funnel appearing anus, have sacral bony defects on plain x-ray, and have a presacral mass (teratoma, meningocele, dermoid cyst, enteric cyst) on exam or imaging. It is an autosomal dominant disorder due in most patients to a mutation in the *MNX1* gene.

A good correlation exists between the degree of sacral development and future function. Patients with an absent sacrum usually have permanent fecal and urinary incontinence. Spinal abnormalities and different degrees of dysraphism are often associated with these defects. Tethered cord occurs in approximately

25% of patients with anorectal malformations. Untethering of the cord can lead to improved urinary and rectal continence in some patients, although it seldom reverses established neurologic defects. The diagnosis of spinal defects can be screened for in the first 3 mo of life by spinal ultrasound, although MRI is the imaging method of choice if a lesion is suspected. In older patients, MRI is needed.

Manifestations and Diagnosis

Low Lesions

Examination of a newborn includes the inspection of the perineum. The absence of an anal orifice in the correct position leads to further evaluation. Mild forms of imperforate anus are often called *anal stenosis* or *anterior ectopic anus* . These are typically cases of an imperforate anus with a perineal fistula. The normal position of the anus on the perineum is approximately halfway (0.5 ratio) between the coccyx and the scrotum or introitus. Although symptoms, primarily constipation, have been attributed to anterior ectopic anus (ratio: <0.34 in females, <0.46 in males), many patients have no symptoms.

If no anus or fistula is visible, there may be a low lesion or *covered anus* . In these cases, there are well-formed buttocks and often a thickened raphe or *bucket handle* . After 24 hr, meconium bulging may be seen, creating a blue or black appearance. In these cases, an immediate perineal procedure can often be performed, followed by a dilation program.

In a male, the perineal (cutaneous) fistula can track anteriorly along the median raphe across the scrotum and even down the penile shaft. This is usually a thin track, with a normal rectum often just a few millimeters from the skin. Extraintestinal anomalies are seen in <10% of these patients.

In a female, a low lesion enters the vestibule or fourchette (the moist mucosa outside the hymen but within the introitus). In this case, the rectum has descended through the sphincter complex. Children with a low lesion can usually be treated initially with perineal manipulation and dilation. Visualizing these low fistulas is so important in the evaluation and treatment that one should avoid passing a nasogastric tube for the first 24 hr to allow the abdomen and bowel to distend, pushing meconium down into the distal rectum.

High Lesions

In a male with a high imperforate anus, the perineum appears flat. There may be air or meconium passed via the urethra when the fistula is high, entering the bulbar or prostatic urethra, or even the bladder. In *rectobulbar urethral fistulas* (the most common in males), the sphincter mechanism is satisfactory, the sacrum may be underdeveloped, and an anal dimple is present. In *rectoprostatic urethral fistulas* , the sacrum is poorly developed, the scrotum may be bifid, and the anal dimple is near the scrotum. In *rectovesicular fistulas* , the sphincter mechanism is poorly developed, and the sacrum is hypoplastic or absent. In males with trisomy 21, all the features of a high lesion may be present, but there is no fistula, the sacrum and sphincter mechanisms are usually well developed, and the prognosis is good.

In females with high imperforate anus, there may be the appearance of a rectovaginal fistula. A true rectovaginal fistula is rare. Most are either the fourchette fistulas described earlier or are forms of a cloacal anomaly.

Persistent Cloaca

In persistent cloaca, the embryologic stage persists in which the rectum, urethra, and vagina communicate in a common orifice, the cloaca. It is important to realize this, because the repair often requires repositioning the urethra and vagina as well as the rectum. Children of both sexes with a high lesion require a colostomy before repair.

Rectal Atresia

Rectal atresia is a rare defect occurring in only 1% of anorectal anomalies. It has the same characteristics in both sexes. The unique feature of this defect is that affected patients have a normal anal canal and a normal anus. The defect is often discovered while rectal temperature is being taken. An obstruction is present approximately 2 cm above the skin level. These patients need a protective colostomy. The functional prognosis is excellent because they have a normal sphincteric mechanism (and normal sensation), which resides in the anal canal.

Approach to the Patient

Evaluation includes identifying associated anomalies (see Table 371.1). Careful inspection of the perineum is important to determine the presence or absence of a fistula. If the fistula can be seen there, it is a low lesion. The invertogram or upside-down x-ray is of little value, but a prone crosstable lateral plain x-ray at 24 hr of life (to allow time for bowel distention from swallowed air) with a radiopaque marker on the perineum can demonstrate a low lesion by showing the rectal gas bubble <1 cm from the perineal skin (see Fig. 371.4). A plain x-ray of the entire sacrum, including both iliac wings, is important to identify sacral anomalies and the adequacy of the sacrum. An abdominal-pelvic ultrasound and voiding cystourethrogram must be performed. The clinician should also pass a nasogastric tube to identify esophageal atresia and should obtain an echocardiogram. In males with a high lesion, the voiding cystourethrogram often identifies the rectourinary fistula. In females with a high lesion, more invasive evaluation, including vaginogram and endoscopy, is often necessary for careful detailing of the cloacal anomaly.

Good clinical evaluation and a urinalysis provide enough data in 80–90% of male patients to determine the need for a colostomy. Voluntary sphincteric muscles surround the most distal part of the bowel in cases of perineal and rectourethral fistulas, and the intraluminal bowel pressure must be sufficiently high to overcome the tone of those muscles before meconium can be seen in the urine or on the perineum. The presence of meconium in the urine and a flat bottom are considered indications for the creation of a colostomy. Clinical findings consistent with the diagnosis of a perineal fistula represent an indication for an anoplasty without a protective colostomy. Ultrasound is valuable not only for the evaluation of the urinary tract, but it can also be used to investigate spinal anomalies in the newborn and to determine how close to the perineum the rectum has descended.

More than 90% of the time, the diagnosis in females can be established on perineal inspection. The presence of a single perineal orifice is a cloaca. A palpable pelvic mass (hydrocolpos) reinforces this diagnosis. A vestibular fistula is diagnosed by careful separation of the labia, exposing the vestibule. The rectal orifice is located immediately in front of the hymen within the female genitalia and in the vestibule. A perineal fistula is easy to diagnose. The rectal orifice is located somewhere between the female genitalia and the center of the sphincter and is surrounded by skin. Less than 10% of these patients fail to pass meconium through the genitalia or perineum after 24 hr of observation. Those patients can require a prone crosstable lateral film.

Operative Repair

Sometimes a perineal fistula, if it opens in good position, can be treated by simple dilation. Hegar dilators are employed, starting with a No. 5 or 6 and letting the baby go home when the mother can use a No. 8. Twice-daily dilatations are done at home, increasing the size every few weeks until a No. 14 is achieved. By 1 yr of age, the stool is usually well formed and further dilation is not necessary. By the time No. 14 is reached, the examiner can usually insert a little finger. If the anal ring is soft and pliable, dilation can be reduced in frequency or discontinued.

Occasionally, there is no visible fistula, but the rectum can be seen to be filled with meconium bulging on the perineum, or a covered anus is otherwise suspected. If confirmed by plain x-ray or ultrasound of the perineum that the rectum is <1 cm from the skin, the clinician can do a minor perineal procedure to perforate the skin and then proceed with dilation or do a simple perineal anoplasty.

When the fistula orifice is very close to the introitus or scrotum, it is often appropriate to move it back surgically. This also requires postoperative dilation to prevent stricture formation. This procedure can be done any time from the newborn period to 1 yr. It is preferable to wait until dilatations have been done for several weeks and the child is bigger. The anorectum is a little easier to dissect at this time. The posterior sagittal approach of Peña is used, making an incision around the fistula and then in the midline to the site of the posterior wall of the new location. The dissection is continued in the midline, using a muscle stimulator to be sure there is adequate muscle on both sides. The fistula must be dissected cephalad for several centimeters to allow posterior positioning without tension. If appropriate, some of the distal fistula is resected before the anastomosis to the perineal skin.

In children with a high lesion, a double-barrel colostomy is performed. This effectively separates the fecal stream from the urinary tract. It also allows the performance of an augmented pressure colostogram before repair to identify the exact position of the distal rectum and the fistula. The definitive repair or posterior sagittal anorectoplasty (PSARP) is performed at about 1 yr of age. A midline incision is made, often splitting the coccyx and even the sacrum. Using a muscle stimulator, the surgeon stays strictly in the midline and divides the sphincter complex and identifies the rectum. The rectum is then opened in the midline and the fistula is identified from within the rectum. This allows a division of the fistula without injury to the urinary tract. The rectum is then dissected proximally until enough length is gained to suture it to an appropriate perineal position. The muscles of the sphincter complex are then sutured around (and especially behind) the rectum.

Other operative approaches (such as an anterior approach) are used, but the most popular procedure is by laparoscopy. This operation allows division of the fistula under direct visualization and identification of the sphincter complex by transillumination of perineum. Other imaging techniques in the management of anorectal malformations include 3D endorectal ultrasound, intraoperative MRI, and colonoscopy-assisted PSARPs, which may help perform a technically better operation. None of these other procedures or innovations has demonstrated improved outcomes.

A similar procedure can be done for female high anomalies with variations to deal with separating the vagina and rectum from within the cloacal stem. When the stem is longer than 3 cm, this is an especially difficult and complex procedure.

Usually the colostomy can be closed 6 wk or more after the PSARP. Two weeks after any anal procedure, twice-daily dilatations are performed by the family. By doing frequent dilatations, each one is not so painful and there is less tissue trauma, inflammation, and scarring.

Outcome

The ability to achieve rectal continence depends on both motor and sensory elements. There must be adequate muscle in the sphincter complex and proper positioning of the rectum within the complex. There must also be intact innervation of the complex and of sensory elements, as well as the presence of these sensory elements in the anorectum. Patients with low lesions are more likely to achieve true continence. They are also, however, more prone to constipation, which leads to overflow incontinence. It is very important that all these patients are followed closely, and that the constipation and anal dilation are well managed until toilet training is successful. Tables 371.2 and 371.3 outline the results of continence and constipation in relation to the malformation encountered.

Table 371.2

Types of Anorectal Malformation by Sex

MALE (PERCENTAGE CHANCE OF BOWEL CONTROL [*])
• Rectoperineal fistula (100%)
• Rectourethral bulbar fistula (85%)
• Imperforate anus without fistula (90%)
• Rectourethral prostatic fistula (65%)
• Rectobladder neck fistula (15%)
FEMALE (PERCENTAGE CHANCE OF BOWEL CONTROL [*])
• Rectoperineal fistula (100%)
• Rectovestibular fistula (95%)
• Imperforate anus without fistula (90%)
• Rectovaginal fistula (rare anomaly) [†]
• Cloaca (70%) [‡]

[*] Provided patients have a normal sacrum, no tethered cord, and they receive a technically correct operation without complications.

[†] Rectovaginal anomalies are extremely unusual; usually their prognosis is like rectovestibular fistula.

[‡] Cloaca represents a spectrum; those with a common channel length <3 cm have the best functional prognosis.

Table 371.3

Constipation and Type of Anogenital Malformation

TYPE	PERCENTAGE
Vestibular fistula	61
Bulbar urethral fistula	64
Rectal atresia/stenosis	50
Imperforate with no fistula	55
Perineal fistula	57
Long cloaca	35
Prostatic fistula	45
Short cloaca	40
Bladder neck fistula	16

Modified from Levitt MA, Peña A: Outcomes from the correction of anorectal malformations, *Curr Opin Pediatr* 17:394–401, 2005.

Children with high lesions, especially males with rectoprostatic urethral fistulas and females with cloacal anomalies, have a poorer chance of being continent, but they can usually achieve a socially acceptable defecation (without a colostomy) pattern with a bowel management program. Often, the bowel management program consists of a daily enema to keep the colon empty and the patient clean until the next enema. If this is successful, an *antegrade continence enema* (ACE) procedure, sometimes called the Malone or Malone antegrade continence enema (MACE) procedure, can improve the patient's quality of life. These procedures provide access to the right colon either by bringing the appendix out the umbilicus in a nonrefluxing fashion or by putting a plastic button in the right lower quadrant to access the cecum. The patient can then sit on the toilet and administer the enema through the ACE, thus flushing out the entire colon. Antegrade regimens can produce successful 24 hr cleanliness rates of up to 95%. Of special interest is the clinical finding that most patients improve their control with growth. Patients who wore diapers or pull-ups to primary school are often in regular underwear by high school. Some groups have taken advantage of this evidence of psychologic influences to initiate behavior modification early with good results.

Anal Fissure

Christina M. Shanti

Keywords

Anal fissure
Skin tag
Sphincterotomy
Botulinum toxin
Calcium channel blockers

Anal fissure is a laceration of the anal mucocutaneous junction. It is an acquired lesion of unknown etiology. While likely secondary to the forceful passage of a hard stool, it is mainly seen in infants younger than 1 yr of age when the stool is frequently quite soft. Fissures may be the consequence and not the cause of constipation.

Clinical Manifestations

A history of constipation is often described, with a recent painful bowel movement corresponding to the fissure formation after passing of hard stool. The patient then voluntarily retains stool to avoid another painful bowel movement, exacerbating the constipation, resulting in harder stools. Complaints of pain on defecation and bright red blood on the surface of the stool are often elicited.

The diagnosis is established by inspection of the perineal area. The infant's hips are held in acute flexion, the buttocks are separated to expand the folds of the perianal skin, and the fissure becomes evident as a minor laceration. Often a small skin appendage is noted peripheral to the lesion. This *skin tag* represents epithelialized granulomatous tissue formed in response to chronic inflammation. Findings on rectal examination can include hard stool in the ampulla and rectal spasm.

Treatment

The parents must be counseled as to the origin of the laceration and the mechanism of the cycle of constipation. The goal is to ensure that the patient has soft stools to avoid overstretching the anus. The healing process can take several weeks or even several months. A single episode of impaction with passing of hard stool can exacerbate the problem. Treatment requires that the primary cause of the constipation be identified. The use of dietary and behavioral modification and a stool softener is indicated. Parents should titrate the dose of the stool softener based on the patient's response to treatment. Stool softening is best done by increasing water intake or using an oral polyethylene glycolate such as MiraLAX or GlycoLax. Surgical intervention, including stretching of the anus, “internal” anal sphincterotomy, or excision of the fissure, is not indicated or supported by scientific evidence.

Chronic anal fissures in older patients are associated with constipation, prior rectal surgery, Crohn disease, and chronic diarrhea. They are managed initially like fissures in infants, with stool softeners with the addition of sitz baths. Topical 0.2% glyceryl trinitrate reduces anal spasm and heals fissures, but it is often associated with headaches. Calcium channel blockers, such as 2% diltiazem ointment and 0.5% nifedipine cream, are more effective and cause fewer headaches than glyceryl trinitrate. Injection of botulinum toxin from 1.25 to 25 units is also effective and probably chemically replicates the action of internal sphincterotomy, which is the most effective treatment in adults, although seldom used in children.

Perianal Abscess and Fistula

Christina M. Shanti

Keywords

Cryptitis
Anal fistula
Seton
Fistulotomy
Fistulectomy
Crohn's disease

Perianal abscesses usually manifest in infancy and are of unknown etiology. Fistula appears to be secondary to the abscess rather than a cause. Links to congenitally abnormal crypts of Morgagni have been proposed, suggesting that deeper crypts (3-10 mm rather than the normal 1-2 mm) lead to trapped debris and cryptitis (Fig. 371.5).

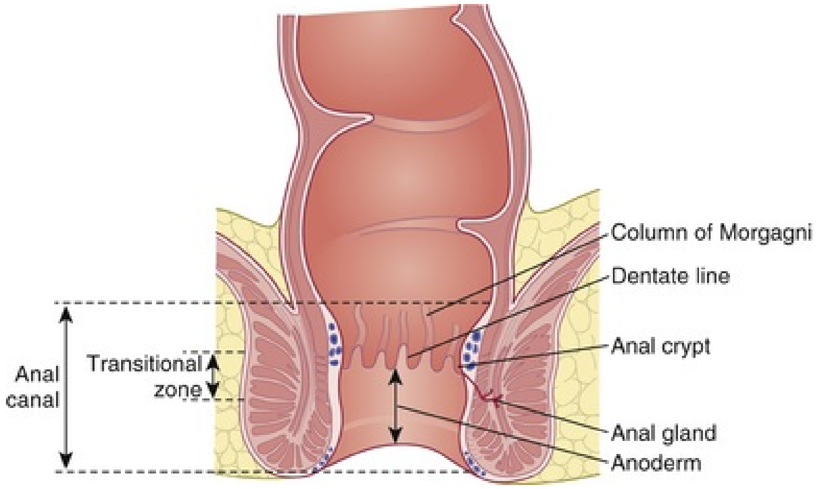

FIG. 371.5 **Anatomy of the anal canal. (Adapted from Brunicardi FC, Anderson DK, Billar TR, et al: *Schwartz's principles of surgery* , ed 8, New York, 2004, McGraw-Hill.)**

Conditions associated with the risk of an anal fistula include Crohn disease, tuberculosis, pilonidal disease, hidradenitis, HIV, trauma, foreign bodies, dermal cysts, sacrococcygeal teratoma, actinomycosis, lymphogranuloma venereum, and radiotherapy.

The most common organisms isolated from perianal abscesses are mixed aerobic *(Escherichia coli, Klebsiella pneumoniae, Staphylococcus aureus)* and anaerobic (*Bacteroides* spp., *Clostridium*, *Veillonella*) flora. A total of 10–15% yield pure growth of *E. coli, S. aureus,* or *Bacteroides fragilis.* There is a strong male predominance in those affected who are younger than 2 yr of age. This imbalance corrects in older patients, where the etiology shifts to associated conditions such as inflammatory bowel disease, leukemia, or immunocompromised states.

Clinical Manifestations

In younger patients, symptoms are usually mild and can consist of low-grade fever, mild rectal pain, and an area of perianal cellulitis. Often these spontaneously drain and resolve without treatment. In older patients with underlying predisposing conditions, the clinical course may be more serious. A compromised immune system can mask fever and allow rapid progression to toxicity and sepsis. Abscesses in these patients may be deeper in the ischiorectal fossa or even supralevator in contrast to those in younger patients, which are usually adjacent to the involved crypt.

Progression to fistula in patients with perianal abscesses occurs in up to 85%

of cases and usually manifests with drainage from the perineal skin or multiple recurrences. Similar to abscess formation, fistulas have a strong male predominance. Histologic evaluation of fistula tracts typically reveals an epithelial lining of stratified squamous cells associated with chronic inflammation. It might also reveal an alternative etiology such as the granulomas of Crohn disease or even evidence of tuberculosis.

Treatment

Treatment is rarely indicated in infants with no predisposing disease because the condition is often self-limited. Even in cases of fistulization, conservative management (observation) is advocated because the fistula often disappears spontaneously. In one study, 87% of fistulas (in 97/112 infants) closed after a mean of 5 mo of observation and conservative management. Antibiotics are not useful in these patients. When dictated by patient discomfort, abscesses may be drained under local anesthesia. Fistulas requiring surgical intervention may be treated by fistulotomy (unroofing or opening), fistulectomy (excision of the tract leaving it open to heal secondarily), or placement of a seton (heavy suture threaded through the fistula, brought out the anus and tied tightly to itself). In patients with inflammatory bowel disease, topical tacrolimus has been effective.

Older children with predisposing diseases might also do well with minimal intervention. If there is little discomfort and no fever or other sign of systemic illness, local hygiene and antibiotics may be best. The danger of surgical intervention in an immunocompromised patient is the creation of an even larger, nonhealing wound. There certainly are such patients with serious systemic symptoms who require more aggressive intervention along with treatment of the predisposing condition. Broad-spectrum antibiotic coverage must be administered, and wide excision and drainage are mandatory in cases involving sepsis and expanding cellulitis.

Fistulas in older patients are mainly associated with Crohn disease, a history of pull-through surgery for the treatment of Hirschsprung disease, or, in rare cases, tuberculosis. Those fistulas are often resistant to therapy and require treatment of the predisposing condition.

Complications of treatment include recurrence and, rarely, incontinence.

Hemorrhoids

Christina M. Shanti

Keywords

Hemorrhoids
Portal hypertension
Thrombosed hemorrhoid
Internal hemorrhoid

External hemorrhoid

Hemorrhoidal disease occurs in both children and adolescents, often related to a diet deficient in fiber and poor hydration. In younger children, the presence of hemorrhoids should also raise the suspicion of portal hypertension. A third of patients with hemorrhoids require treatment.

Clinical Manifestations

Presentation depends on the location of the hemorrhoids. External hemorrhoids occur below the dentate line (see Figs. 371.5 and 371.6) and are associated with extreme pain and itching, often due to acute thrombosis. Internal hemorrhoids are located above the dentate line and manifest primarily with bleeding, prolapse, and occasional incarceration.

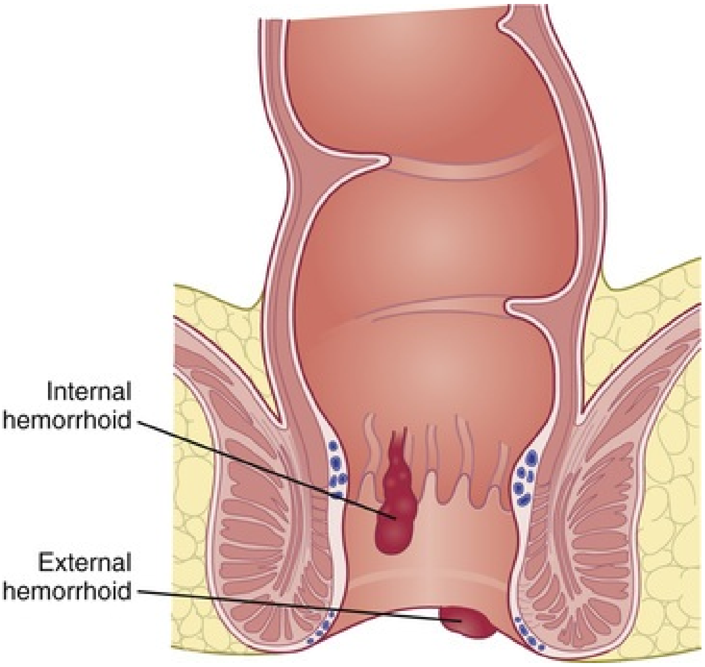

FIG. 371.6 **Formation of hemorrhoids.**

Treatment

In most cases, conservative management with dietary modification, decreased straining, and avoidance of prolonged time spent sitting on the toilet results in resolution of the condition. Discomfort may be treated with topical analgesics or anti-inflammatories such as Anusol (pramoxine) and Anusol-HC (hydrocortisone) and sitz baths. The natural course of thrombosed hemorrhoid involves increasing pain, which peaks at 48-72 hr, with gradual remission as the thrombus organizes and involutes over the next 1-2 wk. In cases where the patient with external hemorrhoids presents with excruciating pain soon after the onset of symptoms, thrombectomy may be indicated. This is best accomplished with local infiltration of bupivacaine 0.25% with epinephrine 1:200,000, followed by incision of the vein or skin tag and extraction of the clot. This provides immediate relief; recurrence is rare and further follow-up is unnecessary.

Internal hemorrhoids can become painful when prolapse leads to incarceration and necrosis. Pain usually resolves with reduction of hemorrhoidal tissue. Surgical treatment is reserved for patients failing conservative management. Techniques described in adults include excision, rubber banding, stapling, and excision using the LigaSure device. Complications are rare (<5%) and include recurrence, bleeding, infection, nonhealing wounds, and fistula formation.

Rectal Mucosal Prolapse

Christina M. Shanti

Keywords

Rectal prolapse
Procidentia
Rectocele
Ehler-Danlos Syndrome
Cystic fibrosis
Imperforate anus
Delorme resection
Thiersch procedure
Rectopexy
Altemeier resection

Rectal mucosal prolapse is the exteriorization of the rectal mucosa through the anus. In the unusual occurrence when all the layers of the rectal wall are included, it is called *procidentia* or *rectocele* . Most cases of rectal tissue protruding through the anus are prolapse and not polyps, hemorrhoids, intussusception, or other tissue.

Most cases of prolapse are idiopathic. The onset is often between 1 and 5 yr of age. It usually occurs when the child begins standing and then resolves by approximately 3-5 yr of age when the sacrum has taken its more adult shape and the anal lumen is oriented posteriorly. Thus the entire weight of the abdominal viscera is not pushing down on the rectum, as it is earlier in development.

Other predisposing factors include intestinal parasites (particularly in endemic areas), malnutrition, diarrhea, ulcerative colitis, pertussis, Ehlers-Danlos syndrome, meningocele (more often associated with procidentia owing to the lack of perineal muscle support), cystic fibrosis, and chronic constipation. Patients treated surgically for imperforate anus can also have varying degrees of rectal mucosal prolapse. This is particularly common in patients with poor sphincteric development. Rectal prolapse is also seen with higher incidence in patients with mental issues and behavior problems. These patients are particularly difficult to manage and are more likely to fail medical treatment.

Clinical Manifestations

Rectal mucosal prolapse usually occurs during defecation, especially during toilet training. Reduction of the prolapse may be spontaneous or accomplished manually by the patient or parent. In severe cases, the prolapsed mucosa becomes congested and edematous, making it more difficult to reduce. Rectal prolapse is usually painless or produces mild discomfort. If the rectum remains prolapsed after defecation, it can be traumatized by friction with undergarments, with resultant bleeding, wetness, and potentially ulceration. The appearance of the prolapse varies from bright red to dark red and resembles a beehive. It can be as long as 10-12 cm. See Chapter 372 for a distinction from a prolapsed polyp.

Treatment

Initial evaluation should include tests to rule out any predisposing conditions, especially cystic fibrosis and sacral root lesions. Reduction of protrusion is aided by pressure with warm compresses. An easy method of reduction is to cover the finger with a piece of toilet paper, introduce it into the lumen of the mass, and gently push it into the patient's rectum. The finger is then immediately withdrawn. The toilet paper adheres to the mucous membrane, permitting release of the finger. The paper, when softened, is later expelled.

Conservative treatment consists of careful manual reduction of the prolapse after defecation, attempts to avoid excessive pushing during bowel movements (with patient's feet off the floor), use of laxatives and stool softeners to prevent constipation, avoidance of inflammatory conditions of the rectum, and treatment of intestinal parasitosis when present. If all this fails, surgical treatment may be indicated. Existing surgical options are associated with some morbidity, and therefore medical treatment should always be attempted first.

Sclerosing injections have been associated with complications such as neurogenic bladder. We have found linear cauterization effective and with few complications other than recurrence. In the operating room, the prolapse is recreated by traction on the mucosa. Linear burns are made through nearly the full thickness of the mucosa using electrocautery. One can usually make 8 linear burns on the outside and 4 on the inside of the prolapsed mucosa. In the immediate postoperative period, prolapse can still occur, but in the next several weeks, the burned areas contract and keep the mucosa within the anal canal. The Delorme mucosal sleeve resection addresses mucosal prolapse via a transanal approach by incising, prolapsing, and amputating the redundant mucosa. The resulting mucosal defect is then approximated with absorbable suture.

For patients with procidentia or full-thickness prolapse or intussusception of the rectosigmoid (usually from myelodysplasia or other sacral root lesions), other, more invasive options exist. Those most commonly in use by pediatric surgeons today include the following: A modification of the Thiersch procedure involves placing a subcutaneous suture to narrow the anal opening. Complications include obstruction, fecal impaction, and fistula formation. Laparoscopic rectopexy is effective and can be performed as an outpatient. The Altemeier perineal rectosigmoidectomy is a transanal, full-thickness resection of redundant bowel with a primary anastomosis to the anus.

371.6

Pilonidal Sinus and Abscess

Christina M. Shanti

Keywords

Pilonidal sinus
Pilonidal abscess
Sacral dimple

The etiology of pilonidal disease remains unknown; 3 hypotheses explaining its origin have been proposed. The first states that trauma, such as can occur with prolonged sitting, impacts hair into the subcutaneous tissue, which serves as a nidus for infection. The second suggests that in some patients, hair follicles exist in the subcutaneous tissues, perhaps the result of some embryologic abnormality, and that they serve as a focal point for infection, especially with secretion of hair oils. The third speculates that motion of the buttocks disturbs a particularly deep midline crease and works bacteria and hair beneath the skin. This theory arises from the apparent improved short-term and long-term results of operations that close the wound off the midline, obliterating the deep natal cleft.

Pilonidal disease usually manifests in adolescents or young adults with significant hair over the midline sacral and coccygeal areas. It can occur as an acute abscess with a tender, warm, flocculent, erythematous swelling or as draining sinus tracts. This disease does not resolve with nonoperative treatment. An acute abscess should be drained and packed open with appropriate anesthesia. Oral broad-spectrum antibiotics covering the usual isolates (*S. aureus* and *Bacteroides* species) are prescribed, and the patient's family withdraws the packing over the course of a week. When the packing has been totally removed, the area can be kept clean by a bath or shower. The wound usually heals completely in 6 wk. Once the wound is healed, most pediatric surgeons feel that elective excision should be scheduled to avoid recurrence. There are some reports, however, this is only necessary if the disease recurs. Usually, patients who present with sinus tracts are managed with a single elective excision.

Most surgeons carefully identify the extent of each sinus tract and excise all skin and subcutaneous tissue involved to the fascia covering the sacrum and coccyx. Some close the wound in the midline; others leave it open and packed for healing by secondary intention. This method has been modified by the application of a vacuum-assisted (VAC sponge) dressing. This is a system that applies continuous suction to a porous dressing. It is usually changed every 3 days and can be done at home with the assistance of a nurse. Some marsupialize the wound by suturing the skin edges down to the exposed fascia covering the sacrum and coccyx. There appears to be improved success with excision and closure in such a way that the suture line is not in the midline. Currently there appears to be enthusiasm for the less radical methods that Bascom has introduced, treating simple sinus tracts with small local procedures and limiting excision to only diseased tissues, while still keeping the incision off the midline. Recurrence or wound-healing problems are relatively common, occurring in 9–27% of cases. The variety of treatments and procedures currently being described indicates that all are associated with significant complications and delays in return to normal activity. Still, it is rare for problems to persist beyond 1-2 yr. Recalcitrant cases are treated by a large, full-thickness gluteal flap or skin grafting.

A simple dimple located in the midline intergluteal cleft, at the level of the coccyx, is seen relatively commonly in normal infants. No evidence indicates that this little sinus provokes any problems for the patient. An open dermal sinus is an asymptomatic, benign condition that does not require operative intervention.

CHAPTER 372

Tumors of the Digestive Tract

Danielle Wendel, Karen F. Murray

Tumors of the digestive tract in children are mostly polypoid. They are also commonly syndromic tumors and tumors with known genetic identification (Table 372.1). They usually manifest as painless rectal bleeding, but when large they can cause obstruction or serve as lead points for intussusception. Most intestinal tumors can be generally classified into 2 groups: hamartomatous or adenomatous.

Table 372.1

General Features of the Inherited Colorectal Cancer Syndromes

SYNDROME	POLYP DISTRIBUTION	AGE OF ONSET	RISK OF COLON CANCER	GENETIC LESION	CLINICAL MANIFESTATIONS	ASSOCI LESION
HAMARTOMATOUS POLYPS						
Juvenile polyposis	Large and small intestine, gastric polyps	1st decade	~10–50%	*PTEN, SMAD4, BMPR1A* Autosomal dominant	Possible rectal bleeding, abdominal pain, intussusception	Congenit abnormal 20% of t nonfamil type, clu AV malforma
Peutz-Jeghers syndrome	Small and large intestine	1st decade	Increased	*LKB1/STK11* Autosomal dominant	Possible rectal bleeding, abdominal pain, intussusception	Orocutan melanin pigment
Cowden syndrome	Colon	2nd decade	Not increased	*PTEN* gene	Macrocephaly, breast/thyroid/endometrial cancers, developmental delay	
Bannayan-Riley-Ruvalcaba syndrome	Colon	2nd decade	Not increased	*PTEN* gene	Macrocephaly, speckled penis, thyroid/breast cancers, hemangiomas, lipomas	

ADENOMATOUS POLYPS						
Familial adenomatous polyposis (FAP)	Large intestine, often >100	16 yr (range: 8-34 yr)	100%	5q (*APC* gene), autosomal dominant	Rectal bleeding, abdominal pain, bowel obstruction	Desmoid CHRPE, GI polyp osteoma, hepatobla thyroid c
Attenuated familial adenomatous polyposis (AFAP)	Colon (fewer in number)	>18 yr	Increased	*APC* gene	Same as FAP	Fewer associate lesions
MYH-associated polyposis	Colon	>20 yr	High risk	*MYH* autosomal recessive	Same as FAP	May be confused sporadic AFAP; fe extrainte findings
Gardner syndrome	Large and small intestine	16 yr (range: 8-34 yr)	100%	5q (*APC* gene)	Rectal bleeding, abdominal pain, bowel obstruction	Desmoid tumors, multiple osteomas fibromas epidermo cysts
Hereditary nonpolyposis colon cancer, (Lynch syndrome)	Large intestine	40 yr	30%	DNA mismatch repair genes *(MMR)* Autosomal dominant	Rectal bleeding, abdominal pain, bowel obstruction	Other tur (e.g., ova ureter, pa stomach)

APC, adenomatous polyposis coli; *AV* , arteriovenous; *CHRPE* , congenital hypertrophy of the retinal pigment epithelium; *GI,* gastrointestinal; *PTEN* , phosphatase and tensin homolog.

Hamartomatous Tumors

Hamartomas are benign tumors composed of tissues that are normally found in an organ but that are not organized normally. Juvenile, retention, or inflammatory polyps are hamartomatous polyps, which represent the most common intestinal tumors of childhood, occurring in 1–2% of children. Patients generally present in the 1st decade, most often at ages 2-5 yr, and rarely at younger than 1 yr. Polyps may be found anywhere in the gastrointestinal (GI) tract, most commonly in the rectosigmoid colon; they are often solitary but may be multiple.

Histologically, juvenile polyps are composed of hamartomatous collections of mucus-filled glandular and stromal elements with inflammatory infiltrate, covered with a thin layer of epithelium. These polyps are often bulky, vascular, and prone to bleed as their growth exceeds their blood supply with resultant mucosal ulceration, or autoamputation with bleeding from a residual central artery.

Patients often present with painless rectal bleeding after defecation. Bleeding is generally scant and intermittent; rarely presenting findings can include iron deficiency anemia and/or hypoalbuminemia. Extensive bleeding can occur but is generally self-limited, requiring supportive care until the bleeding stops spontaneously after autoamputation. Occasionally endoscopic polypectomy is required for control of bleeding. Abdominal pain or cramps are uncommon unless associated with intussusception. Patients can present with prolapse, with a dark, edematous, pedunculated mass protruding from the rectum. Mucus discharge and pruritus are associated with prolapse.

Patients presenting with rectal bleeding require a thorough workup; differential diagnosis includes anal fissure, other intestinal polyposis syndromes, Meckel diverticulum, inflammatory bowel disease, intestinal infections, Henoch-Schönlein purpura, or coagulopathy.

Diagnosis and therapy are best accomplished via endoscopy. Polyps may be visualized via ultrasound or cross-sectional imaging, but this provides no therapeutic advantage. Colonoscopy affords opportunity for biopsy, polypectomy by snare cautery, and visualization of synchronous lesions; up to 50% of children have one or more additional polyps, and approximately 20% may have more than 5 polyps. Retrieved polyps should be sent for histologic evaluation for definitive diagnosis.

Juvenile Polyposis Syndrome

Patients with juvenile polyposis syndrome (JPS) present with multiple juvenile polyps, ≥5 but typically 50-200. Polyps may be isolated to the colon or distributed throughout the GI tract. There is often a family history (20–50%) with an autosomal dominant pattern of variable penetrance. Alterations in transforming growth factor-β pathways have been identified in some JPS patients and families; mutations in *SMAD4* or *BMPR1A* are found in 50–60% of patients with JPS. Genetic testing is available for both of these mutations. Clinical diagnosis of JPS is established by presence of one of the following: a lifetime total of 5 or more juvenile polyps in the colon, juvenile polyps outside the colon, or any number of juvenile polyps in a patient with a family history of

JPS.

Histologically, these polyps are identical to solitary juvenile polyps; however, the GI malignancy risk is greatly increased (10–50%). Most malignancy is colorectal, although gastric, upper GI, and pancreatic tumors have been described. The risk of malignancy is greater in patients with increased polyp burden and a positive family history. These patients should therefore undergo routine esophagogastroduodenoscopy, colonoscopy, and upper GI contrast studies. Serial polypectomy or polyp biopsy should be undertaken if possible. If dysplasia or malignant degeneration is found, a total colectomy is indicated.

Juvenile polyposis of infancy is characterized by early polyp formation (younger than 2 yr of age) and may be associated with protein-losing enteropathy, hypoproteinemia, anemia, failure to thrive, and intussusception. Early endoscopic or surgical intervention may be needed.

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome (PJS) is a rare autosomal dominant disorder (incidence: ~1 : 120,000 total population) characterized by mucocutaneous pigmentation and extensive GI hamartomatous polyposis. Macular pigmented lesions may be dark brown to dark blue and are found primarily around the lips and oral mucosa, although these lesions may also be found on the hands, feet, or perineum. Lesions can fade by puberty or adulthood.

Polyps are primarily found in the small intestine (in order of prevalence: jejunum, ileum, duodenum) but may also be colonic or gastric. Histologically, polyps are defined by normal epithelium surrounding bundles of smooth muscle arranged in a branching or frond-like pattern. Symptoms arising from GI polyps in PJS are similar to those of other polyposis syndromes—namely bleeding and abdominal cramping from obstruction or recurrent intussusception. Patients can require repeated laparotomies and intestinal resections.

The diagnosis of PJS is made clinically in patients with histologically proven hamartomatous polyps if 2 of 3 conditions are met: positive family history with an autosomal dominant inheritance pattern, mucocutaneous hyperpigmentation, and small bowel polyposis. Genetic testing can reveal mutations in *LKB1/STK11* (19p13.3), a serine-threonine kinase that acts as a tumor-suppressor gene. Up to 94% of patients with clinical characteristics of PJS have a mutation at this locus. Only 50% of patients with PJS have an affected family member, suggesting a high rate of spontaneous mutations.

Patients with PJS have increased risk of GI and extraintestinal malignancies. Lifetime cancer risk has been reported to be in the range of 47–93%. Colorectal, breast, and reproductive tumors are most common. GI surveillance should begin in childhood (by age 8 yr or when symptoms occur) with upper and lower endoscopy. The small bowel may be evaluated radiographically, with magnetic resonance enterography, endoscopically with balloon or push enteroscopy, or with video capsule endoscopy. Polyps larger than 1.5 cm should be removed, although resection does not lower the cancer risk and is mainly to avoid complications. Screening for breast, gynecologic, and testicular cancers should be routine after age 18 yr.

Phosphatase and Tensin Homolog Hamartoma Tumor Syndromes

Mutations in the tumor-suppressor gene protein tyrosine phosphatase and tensin homolog *(PTEN)* are associated with several rare autosomal dominant syndromes, including Cowden syndrome and Bannayan-Riley-Ruvalcaba syndrome. These patients present with multiple hamartomas in skin (99%), brain, breast, thyroid, endometrium, and GI tract (60%). Other extraintestinal manifestations include macrocephaly, developmental delay, lipomas, and genital pigmentation. Patients are at increased risk for breast and thyroid malignancies; the risk of GI cancer does not appear to be elevated.

Adenomatous Tumors

Adenomatous Polyposis Coli-Associated Polyposis Syndromes

Familial adenomatous polyposis (FAP) is the most common genetic polyposis syndrome (incidence 1 : 5,000 to 1 : 17,000 persons) and is characterized by numerous adenomatous polyps throughout the colon, as well as extraintestinal manifestations. FAP and related syndromes (attenuated FAP; Gardner and Turcot syndromes) are linked to mutations in the adenomatous polyposis coli *(APC)* gene, a tumor suppressor mapped to 5q21. *APC* regulates degradation of β-catenin, a protein with roles in regulation of the cytoskeleton, tissue architecture organization, cell migration and adherence, and numerous other functions.

Intracellular accumulation of β-catenin may be responsible for colonic epithelial cell proliferation and adenoma formation. More than 400 APC mutations have been described, and up to 30% of patients present with no family history (spontaneous mutations).

Polyps generally develop late in the 1st decade of life or in adolescence (mean age of presentation is 16 yr). At the time of diagnosis, 5 or more adenomatous polyps are present in the colon and rectum. By young adulthood, the number typically increases to hundreds or even thousands. Adenomatous polyps (or adenomas) are precancerous lesions within the surface epithelium of the intestine, displaying various degrees of dysplasia. Without intervention, the risk of developing colon cancer is 100% by the 5th decade of life (average age of cancer diagnosis is 40 yr). Other GI adenomas can develop, particularly in the stomach and duodenum (50–90%). The risk of periampullary or duodenal carcinoma is significantly elevated (4–12% lifetime risk). Extraintestinal malignancies occur at an increased rate in FAP, including hepatoblastoma in young patients (1.6% before age 5 yr) and follicular or papillary thyroid cancer in teens.

Extraintestinal manifestations of FAP may be present from birth or develop in early childhood. Lesions include congenital hypertrophy of retinal pigment epithelium, desmoid tumors, epidermoid cysts, osteomas, fibromas, and lipomas. Many of these benign soft-tissue tumors appear before intestinal polyps develop. Expression of extraintestinal findings can depend on location of mutation on the *APC* gene.

Other syndromes associated with *APC* mutations include *Gardner syndrome* , classically characterized by multiple colorectal polyps, desmoid tumors, and soft-tissue tumors, including fibromas, osteomas (typically mandibular), epidermoid cysts, and lipomas. Once thought to be a distinct clinical entity, Gardner syndrome shares many characteristics with FAP. Up to 20% of FAP patients present with the classic extraintestinal manifestations once associated with Gardner syndrome. Some (but not all) cases of *Turcot syndrome* are also related to *APC.* These patients present with colorectal polyposis and primary brain tumors (medulloblastoma). Attenuated FAP is characterized by a significantly increased risk of colorectal cancer but fewer polyps than classic FAP (average: 30 polyps). The average age of cancer diagnosis in this form of FAP is 50-55 yr. Upper GI tumors and extraintestinal manifestations may be present but are less common.

The clinical presentation of FAP is variable. Polyps are generally sessile, of variable size, and initially asymptomatic. If symptoms develop, they can include rectal bleeding (possibly with secondary anemia), cramping, and diarrhea. The presence of symptoms at presentation does not correlate with malignant changes. Diagnosis should be suspected from family history, and ensuing colonoscopy is confirmatory. Histologic examination of biopsied polyps reveals adenomatous architecture (as opposed to inflammatory or hamartomatous polyps found in other polyposis syndromes) with varying degrees of dysplasia. Genetic testing for *APC* mutations is clinically available, and index patients should be tested. If a mutation is identified, affected family members should be screened and appropriate genetic counseling should be provided. If the index patient does not demonstrate a defined mutation, family members may undergo genetic testing, which might identify novel *APC* mutations. Children with identified *APC* mutations must undergo careful surveillance, with colonoscopy every 1-2 yr. Once polyps are identified, colonoscopy should be performed annually. Patients should also have upper endoscopy after development of colonic polyps to monitor for gastric and especially duodenal lesions.

Treatment of FAP requires prophylactic proctocolectomy to prevent cancer. Ileoanal pull-through procedures restore bowel continuity, with acceptable functional outcomes. Resection should be done once polyposis has become extensive (>20-30) or by the midteens. Nonsteroidal anti-inflammatory agents, such as sulindac, and cyclooxygenase-2 inhibitors, such as celecoxib, might inhibit polyp progression. No guidelines have been established, however, and their efficacy in preventing malignant transformation of existing polyps is unknown.

Carcinoma

Primary carcinomas of the small bowel or colon are extremely rare in children. Development of adenocarcinoma in adolescence or early adulthood may be associated with a genetic predisposition or syndrome such as FAP, hereditary nonpolyposis colon carcinoma, PJS, radiation exposure, or inflammatory bowel disorders such as Crohn disease or ulcerative colitis.

Colorectal carcinoma, though rare (reported incidence of 1 case per 1,000,000 persons younger than 19 yr of age), is the most common primary GI carcinoma in children. Many cases are spontaneous (i.e., not associated with a genetic predisposition or syndrome). Histologically, tumors tend to be poorly differentiated and pathologically aggressive. Patients may be asymptomatic, or they present with nonspecific signs and symptoms such as abdominal pain, constipation, and vomiting. Delay in diagnosis is common. Many patients present with advanced-stage disease, with microscopic or gross metastases at the time of diagnosis. Surgical resection is the primary treatment modality, although with delayed presentation and advanced-stage disease, complete resection may not be possible. Chemotherapy and radiation have a limited role in patients with metastatic disease.

Other Gastrointestinal Tumors

Lymphoma

Lymphoma is the most common GI malignancy in the pediatric population. Approximately 30% of children with non-Hodgkin lymphoma present with abdominal tumors. Immunocompromised patients have an increased incidence of lymphoma. Predisposing conditions include HIV/AIDS, agammaglobulinemia, long-standing celiac disease, and bone marrow or solid-organ transplantation. Lymphoma can occur anywhere in the GI tract, but it most commonly occurs in distal small bowel and ileocecal region. Presenting symptoms include crampy abdominal pain, vomiting, obstruction, bleeding, or palpable mass. Lymphoma should be considered in patients older than 3 yr of age who present with intussusception. Treatment consists of a combination of surgical resection and chemotherapy, depending on the extent of the tumor burden.

Nodular Lymphoid Hyperplasia

Lymphoid follicles in the lamina propria and submucosa of the gut normally aggregate in Peyer patches, most prominently in the distal ileum. These follicles can become hyperplastic, forming nodules that protrude into the lumen of the bowel during times of developmental lymphoid proliferation such as early childhood and adolescence. Some suggested etiologies are infectious (classically *Giardia*), allergic, or immunologic. Nodular lymphoid hyperplasia has been described in infants with enterocolitis secondary to dietary protein sensitivity. This phenomenon has also been described in patients with inflammatory bowel disease and Castleman disease. Patients may be asymptomatic or, especially in cases of immunodeficiency, may present with abdominal pain, rectal bleeding, diarrhea, or intussusception. Nodular lymphoid hyperplasia usually resolves spontaneously. The use of anti-inflammatory medications or elimination diets is unlikely to change the clinical course, although in cases with severe pain or bleeding, corticosteroids may be effective.

Carcinoid Tumor

Carcinoids are neuroendocrine tumors of enterochromaffin cells, which can occur throughout the GI tract, but in children they are typically found in the appendix. This is often an incidental diagnosis at the time of appendectomy. Complete resection of small tumors (<1 cm) with clear surgical margins is curative. Appendiceal tumors >2 cm mandate further bowel resection, typically a right hemicolectomy. Carcinoid tumors outside the appendix (small intestine, rectum, stomach) are more likely to metastasize. Metastatic carcinoid tumor within the liver can give rise to the carcinoid syndrome. Serotonin, 5-hydroxytryptophan, or histamine is elaborated by the tumor, and elevated serum levels cause cramps, diarrhea, vasomotor disturbances (flushing), bronchoconstriction, and right-heart failure. The diagnosis is confirmed by elevated urinary 5-hydroxyindoleacetic acid. Symptomatic relief of carcinoid symptoms may be achieved with administration of somatostatin analogs (octreotide).

Leiomyoma

Leiomyomas are rare benign tumors that can arise anywhere in the GI tract, although most often in the stomach, jejunum, or distal ileum. Age of presentation is variable, from the newborn period through adolescence. Patients may be asymptomatic or can present with an abdominal mass, obstruction, intussusception, volvulus, or pain and bleeding from central necrosis of the tumor. Surgical resection is the treatment of choice. Pathologically, these tumors may be difficult to distinguish from malignant leiomyosarcomas. Smooth muscle tumors occur with increased incidence in children with HIV or those requiring immunosuppression after transplantation.

Gastrointestinal Stromal Cell Tumors

Gastrointestinal stromal cell tumors (GISTs) are intestinal mesenchymal tumors that probably arise from interstitial cells of Cajal or their precursors. Historically, these may have been diagnosed as tumors of smooth muscle or neural cell origin. The World Health Organization recognized GIST in 1990 as a distinct neoplasm. Typically GISTs arise in adults, after the 3rd decade of life. Cases have also been reported in the pediatric population, generally in adolescents with a female predominance. In the pediatric population, tumors are most commonly found in the stomach, though they can occur anywhere in the GI tract or even the mesentery or omentum. Many patients (~45%) present with metastatic disease primarily to the lymph nodes, although metastases to the peritoneum or liver occur as well. Patients may be asymptomatic for years to decades or can present with an abdominal mass, lower GI bleeding, or obstruction. Treatment consists of surgical resection of local disease. Recurrence rates are high, and early postoperative surveillance is recommended. GISTs occurring in adults are typically associated with mutation in the *KIT* oncogene. This mutation is less commonly found in pediatric GISTs (~15%). Adjuvant therapy for *KIT* $^+$ lesions is imatinib or sunitinib, tyrosine kinase inhibitors that are available as oral therapy. Patients with persistent disease or metastases might benefit from treatment.

Vascular Tumors

Vascular malformations and hemangiomas are rare in children. The usual presentation is painless rectal bleeding, which may be chronic or acute, with massive or even fatal hemorrhage. There are usually no associated symptoms, although intussusception has been described. Half of patients have associated cutaneous hemangiomas or telangiectasia. These lesions may be associated with blue rubber bleb nevus syndrome, hereditary hemorrhagic telangiectasia, as well as other syndromes. About half of these lesions are in the colon and can be identified on colonoscopy. During acute bleeding episodes, bleeding can be localized via nuclear medicine bleeding scans, mesenteric angiography, or endoscopy. Colonic bleeding may be controlled by endoscopic means. Surgical intervention is required occasionally for isolated lesions.

CHAPTER 373

Inguinal Hernias

John J. Aiken

Inguinal hernias are one of the most common conditions seen in pediatric practice, with an overall incidence of 0.8–4.5% in term infants and children and increasing to nearly 30% in premature and low birthweight (<1 kg) infants. The repair of congenital inguinal hernia is the most common surgical procedure performed in pediatric surgical practice. The frequency of this condition, along with its potential morbidity of ischemic injury to the intestine, testis, or ovary, makes proper diagnosis and management an important aspect of daily practice for pediatric practitioners and pediatric surgeons. Most inguinal hernias in infants and children are **congenital indirect** hernias (99%) because of a patent processus vaginalis (PV), an evagination of peritoneum in the inguinal area important in testicular descent. There is rarely any defect/deficiency in the abdominal wall musculature in congenital indirect inguinal hernia. Inguinal hernias are more common in males compared with females (8 : 1 ratio), but females have a higher incidence of bilateral inguinal hernias (~25%) compared with males (~12%). Two other types of inguinal hernia are seen rarely in children: **direct** (acquired) hernia (0.5–1.0%) and **femoral** hernia (<0.5%). Femoral hernias are substantially more common in females (2 : 1 ratio). Approximately 50% of inguinal hernias manifest clinically in the 1st yr of life, most in the first 6 mo. The incidence of incarceration in untreated hernias varies between 6% and 18% across ages. The risk of incarceration is greatest in infancy, with some reports of incarceration rates of 30–40% in the 1st yr of life, mandating prompt identification and operative repair to minimize morbidity and complications related to incarceration and strangulation. Laparoscopic hernia (LH) repair has increasingly emerged in many pediatric centers as an effective alternative to traditional open hernia (OH) repair.

Embryology and Pathogenesis

Indirect inguinal hernias in infants and children are congenital and result from an arrest of embryologic development—failure of obliteration of the PV rather than a weakness in the abdominal wall musculature. The pertinent developmental anatomy of indirect inguinal hernia relates to development of the gonads and descent of the testis through the inguinal canal and into the scrotum late in gestation. The testes descend from the urogenital ridge in the retroperitoneum to the area of the internal ring by about 28 wk of gestation. The final descent of the testes into the scrotum occurs late in gestation, between weeks 28 and 36, guided by the PV and the gubernaculum. The PV, an outpouching of peritoneum in the inguinal region, is present in the developing fetus at 12 wk gestation. The PV develops lateral to the deep inferior epigastric vessels and descends anteriorly along the spermatic cord within the cremasteric fascia through the internal inguinal ring. The testis accompanies the PV as it exits the abdomen and descends into the scrotum. The gubernaculum testis forms from the mesonephros (developing kidney), attaches to the lower pole of the testis, and directs the testis through the internal ring, inguinal canal and into the scrotum. The testis passes through the inguinal canal in a few days but takes about 4 wk to migrate from the external ring to its final position in the scrotum. The cordlike structures of the gubernaculum occasionally pass to ectopic locations (perineum or femoral region), resulting in ectopic testes.

In the last few weeks of gestation or shortly after birth, the layers of the PV normally fuse together and obliterate the patency from the peritoneal cavity through the inguinal canal to the testis. The PV also obliterates distally just above the testes, and the portion of the PV that envelops the testis becomes the tunica vaginalis. In females, the PV obliterates earlier, at approximately 7 mo of gestation, and may explain why females demonstrate a much lower incidence of inguinal hernia. Proper closure of the PV effectively *seals off* the opening from the abdominal cavity into the inguinal region, containing the abdominal viscera within the abdominal cavity. Failure of the PV to close permits fluid or abdominal viscera to escape the abdominal cavity into the extra-abdominal inguinal canal and accounts for a variety of inguinal–scrotal abnormalities commonly seen in infancy and childhood. Involution of the left-sided PV precedes that of the right, which is consistent with the increased incidence of indirect inguinal hernias on the right side (60%).

The ovaries descend into the pelvis from the urogenital ridge but do not exit from the abdominal cavity. The cranial portion of the gubernaculum in females differentiates into the ovarian ligament, and the inferior aspect of the gubernaculum becomes the round ligament, which passes through the internal ring and terminates in the labia majora. The PV in females is also known as the canal of Nuck.

Androgenic hormones produced by the fetal testis, adequate end-organ receptors, and mechanical factors such as increased intraabdominal pressure combine to regulate complete descent of the testis. The testes and spermatic cord structures (spermatic vessels and vas deferens) are located in the retroperitoneum but are affected by increases in intraabdominal pressure as a consequence of their intimate attachment to the descending PV. The genitofemoral nerve also has an important role: it innervates the cremaster muscle, which develops within the gubernaculum, and experimental division or injury to both nerves in the fetus prevents testicular descent. Failure of regression of smooth muscle (present to provide the force for testicular descent) has also been postulated to play a role in the development of indirect inguinal hernias. Several studies have investigated genes involved in the control of testicular descent for their role in closure of the patent PV—for example, hepatocyte growth factor and calcitonin gene-related peptide. Unlike in adult hernias, there does not appear to be any deficiency in collagen synthesis associated with inguinal hernia in children (Fig. 373.1).

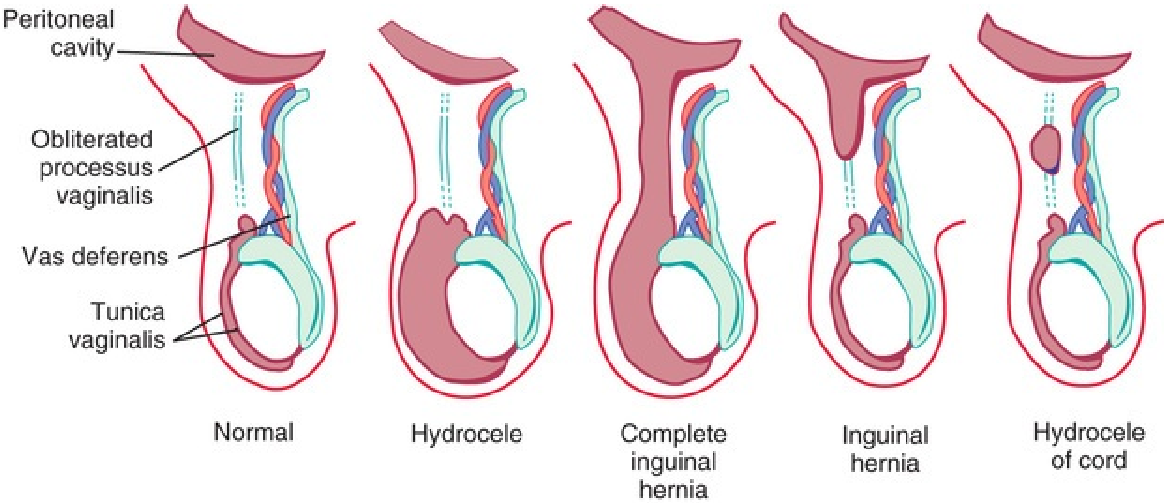

FIG. 373.1 **Hernia and hydroceles. (Modified from Scherer LR III, Grosfeld JL: Inguinal and umbilical anomalies, *Pediatr Clin North Am* 40:1121–1131, 1993.)**

A **direct inguinal hernia** results from a weakness in the abdominal wall musculature in the inguinal region, specifically the transverses abdominis muscle, which forms the floor of the inguinal canal. A direct inguinal hernia originates **medial** to the deep inferior epigastric vessels and is external to the cremasteric fascia; the hernia sac protrudes directly through the posterior wall of the inguinal canal and does not protrude through the external ring. A **femoral hernia** originates medial to the femoral vein and descends inferior to the inguinal ligament along the femoral canal.

Incidence

The incidence of congenital indirect inguinal hernia in full-term newborn infants is estimated at 3.5–5.0%. The incidence of hernia in preterm and low birthweight infants is considerably higher, ranging from 9% to 11%, and approaches 30% in very-low birthweight infants (<1,000 g) and preterm infants (<28 wk of gestation). Inguinal hernia is much more common in males than females, with a male-to-female ratio of approximately 8 : 1. Approximately 60% of inguinal hernias occur on the right side, 30% are on the left side, and 10% are bilateral. The incidence of bilateral hernias is higher in females (20–40%) and young children (<2 yr). An increased incidence of congenital inguinal hernia has been documented in twins and in family members of patients with inguinal hernia. There is a history of another inguinal hernia in the family in 11.5% of patients. The sisters of affected females are at the highest risk, with a relative risk of 17.8. In general, the risk of brothers of a sibling is approximately 4-5, as is the risk of a sister of an affected brother. Both a multifactorial threshold model and autosomal dominance with incomplete penetrance and sex influence have been suggested as an explanation for this pattern of inheritance.

Inguinal hernia, scrotal hydrocele (communicating and noncommunicating), and hydrocele of the spermatic cord are conditions resulting from varying degrees of failure of closure of the PV. Closure of the PV is often incomplete at birth and continues postnatally; the rate of patency is inversely proportional to the age of the child. It has been estimated that the patency rate of the PV is as high as 80% at birth and decreases to ≈40% during the 1st yr of life, and that ≈20% of males have a persistent patency of the PV at 2 yr of age. Patency of the PV after birth is an opening from the abdominal cavity into the inguinal region and therefore a potential hernia, but not all patients will develop a clinical hernia. An inguinal hernia occurs clinically when intraabdominal contents escape the abdominal cavity and enter the inguinal region through the PV patency. Depending on the extent of patency of the PV, the hernia may be confined to the inguinal region or pass down into the scrotum. Complete failure of obliteration of the PV, mostly seen in infants, predisposes to a complete inguinal hernia characterized by a protrusion of abdominal contents into the inguinal canal and extending into the scrotum. Obliteration of the PV distally (around the testis) with patency proximally results in the classic indirect inguinal hernia with a bulge in the inguinal canal.

A **hydrocele** occurs when only fluid enters the patent PV; the swelling may exist only in the scrotum (scrotal hydrocele), only along the spermatic cord in the inguinal region (hydrocele of the spermatic cord), or extend from the scrotum through the inguinal canal and even into the abdomen (abdominal–scrotal hydrocele). A hydrocele is termed a **communicating hydrocele** if it demonstrates fluctuation in size, often increasing in size after activity and, at other times, being smaller when the fluid decompresses into the peritoneal cavity often after laying recumbent. Occasionally, hydroceles develop in older children following trauma, inflammation, torsion of the appendix testes, or in association with tumors affecting the testis.

Although reasons for failure of closure of the PV are unknown, it is more common in cases of testicular nondescent (cryptorchidism) and prematurity. In addition, persistent patency of the PV is twice as common on the right side, presumably related to later descent of the right testis and interference with obliteration of the PV from the developing inferior vena cava and external iliac vein. Table 373.1 lists the risk factors identified as contributing to failure of closure of the PV and to the development of clinical inguinal hernia. The incidence of inguinal hernia in patients with cystic fibrosis is approximately 15%, believed to be related to an altered embryogenesis of the wolffian duct structures, which leads to an absent vas deferens and infertility in males with this condition. There is also an increased incidence of inguinal hernia in patients with **testicular feminization syndrome** and other disorders of sexual development. The rate of recurrence after repair of an inguinal hernia in patients with a connective tissue disorder approaches 50%, and often the diagnosis of connective tissue disorders in children results from investigation following development of a recurrent inguinal hernia.

Table 373.1

Predisposing Factors for Hernias

- Prematurity

- Urogenital
  - Cryptorchidism
  - Exstrophy of the bladder or cloaca
  - Ambiguous genitalia
  - Hypospadias/epispadias
- Increased peritoneal fluid
  - Ascites
  - Ventriculoperitoneal shunt
  - Peritoneal dialysis catheter
- Increased intraabdominal pressure
  - Repair of abdominal wall defects
  - Severe ascites (chylous)
  - Meconium peritonitis
- Chronic respiratory disease
  - Cystic fibrosis
- Connective tissue disorders
  - Ehlers-Danlos syndrome
  - Hunter-Hurler syndrome
  - Marfan syndrome
  - Mucopolysaccharidosis

Clinical Presentation and Diagnosis

An inguinal hernia typically appears as an intermittent, asymptomatic bulge or mass in the inguinal region or scrotum, most often noted on routine physical examination or by a parent; after bathing or urination are classic presentations. In females, the mass typically occurs in the upper portion of the labia majora. The bulge or mass is most visible at times of irritability or increased intraabdominal pressure (crying, straining, coughing). Most inguinal hernias present clinically in young children, approximately 50% in the 1st yr, and most are asymptomatic or minimally symptomatic. The classic history from the parents is of intermittent groin, labial, or scrotal swelling that spontaneously reduces but that is gradually enlarging or is more persistent and is becoming more difficult to reduce. The **hallmark signs** of an inguinal hernia on physical examination are a smooth, firm mass that emerges through the external inguinal ring lateral to the pubic tubercle and enlarges with increased intraabdominal pressure. When the child relaxes, the hernia typically reduces spontaneously or can be reduced by gentle pressure, 1st posteriorly to free it from the external ring and then upward toward the peritoneal cavity. In males, the hernia sac contains intestines; female infants often have an ovary and fallopian tube in the hernia sac.

The diagnosis of inguinal hernia is clinical and generally is made by history and physical examination. Methods used to demonstrate the hernia on examination vary depending on the age of the child. A quiet infant can be made to strain the abdominal muscles by stretching the infant out supine on the bed with legs extended and arms held straight above the head. Most infants struggle to get free, thus increasing the intraabdominal pressure and pushing out the hernia. Older children can be asked to perform the Valsalva maneuver by blowing up a balloon or coughing. The older child should be examined while standing, and examination after voiding also can be helpful. With increased intraabdominal pressure, the protruding mass is obvious on inspection of the inguinal region or can be palpated by an examining finger invaginating the scrotum to palpate at the external ring. Another subtle and less definitive test is the *silk glove sign,* which describes the feeling of the layers of the hernia sac as they slide over the spermatic cord structures with rolling of the spermatic cord beneath the index finger at the pubic tubercle. In the absence of a bulge, the finding of increased thickness of the inguinal canal structures on palpation also suggests the diagnosis of an inguinal hernia. It is important on examination to note the position of the testes because retractile testes are common in infants and young males and can mimic an inguinal hernia with a bulge in the region of the external ring. Because in the female patient approximately 20–25% of inguinal hernias are **sliding** hernias (the contents of the hernia sac are adherent within the sac and therefore not reducible), a fallopian tube or ovary can be palpated in the inguinal canal as a firm, slightly mobile, nontender mass in the labia or inguinal canal. A **femoral** hernia appears as a protrusion on the medial aspect of the thigh, below the inguinal region, and does not enter the scrotum or labia.

Because most young child hernias reduce spontaneously, the physical examination in the office can be equivocal. Infants and children with a strong history suggestive of inguinal hernia and an equivocal clinical examination may be offered ultrasound or referral to a pediatric surgeon. Diagnostic laparoscopy has been increasingly used to evaluate for suspected inguinal hernia; particularly in infants where the risk of incarceration and potential injury to the intestines or testis is high. In an older child with low risk of incarceration, the parents can be reassured and educated relative to the low risk of incarceration and morbidity. If an inguinal hernia is present, it will predictably become increasingly observed. A plan for a period of observation is thoughtful and safe, and the parents can be asked to take a digital image at home if the bulge is noted.

Evaluation of Acute Inguinal–Scrotal

Swelling

Commonly in pediatric practice, an inguinal–scrotal mass appears suddenly in an infant or child and is associated with pain/discomfort. The differential diagnosis includes incarcerated inguinal hernia, acute hydrocele, torsion of an undescended testis, infection (epididymitis/orchitis), and suppurative inguinal lymphadenitis. Differentiating between the incarcerated inguinal hernia and the acute hydrocele is probably the most difficult. The infant or child with an incarcerated inguinal hernia is likely to have associated findings suggesting intestinal obstruction, such as colicky abdominal pain, abdominal distention, vomiting, and cessation of stool, and may appear ill. Plain radiographs, if obtained, typically demonstrate distended intestines with multiple air–fluid levels. The infant with an acute hydrocele may have discomfort but is consolable and tolerates feedings without signs or symptoms suggesting intestinal obstruction.

On examination of the child with the acute scrotal hydrocele, the clinician may note that the mass is somewhat mobile. In addition, the inguinal region is flat and the mass confined to the scrotum. With the incarcerated hernia, there is a lack of mobility of the groin mass and marked swelling or mass extending from the scrotal mass through the inguinal area and up to and including the internal ring. An experienced clinician can selectively use a bimanual examination to help differentiate groin abnormalities. The examiner palpates the internal ring per rectum, with the other hand placing gentle pressure on the inguinal region over the internal ring. In cases of an indirect inguinal hernia, intraabdominal viscera can be palpated extending through the internal ring.

Another method used in diagnostic evaluation is **transillumination** to ascertain if the mass contains only fluid (hydrocele) versus intestine (hernia); however, it must be noted that transillumination can be misleading because the thin wall of the infant's intestine can approximate that of the hydrocele wall and both may transilluminate. This is also the reason aspiration to assess the contents of a groin mass is discouraged. **Ultrasonography** can help distinguish between a hernia, a hydrocele, and lymphadenopathy, and is a simple and well-tolerated test. An expeditious diagnosis is important to avoid the potential complications of an incarcerated hernia, which can develop rapidly. Diagnostic laparoscopy is an effective and reliable tool in this setting by pediatric surgeons but requires general anesthesia.

The occurrence of suppurative adenopathy in the inguinal region can be confused with an incarcerated inguinal hernia. Examination of the watershed area of the inguinal lymph nodes might reveal a superficial infected or crusted skin lesion. In addition, the swelling associated with inguinal lymphadenopathy is typically located more inferior and lateral than the mass of an inguinal hernia, and there may be other associated enlarged nodes in the area. Torsion of an undescended testis can manifest as a painful erythematous mass in the groin. The absence of a gonad in the scrotum in the ipsilateral side should clinch this diagnosis. Infectious etiologies typically demonstrate swelling and tenderness of the testis, but often there is associated urinary symptoms and the swelling is confined to the scrotum and does not extend into the inguinal canal.

Incarcerated Hernia

Incarceration is a common consequence of untreated inguinal hernia in infants and presents as a *nonreducible* mass in the inguinal canal, scrotum, or labia. Contained structures can include small bowel, appendix, omentum, colon, bladder, or, rarely, Meckel diverticulum. In females, the ovary, fallopian tube, or both are commonly incarcerated. Rarely, the uterus in infants can also be pulled into the hernia sac. A **strangulated hernia** is one that is tightly constricted in its passage through the inguinal canal, and as a result, the hernia contents have become ischemic or gangrenous. The incidence of incarceration of an inguinal hernia is between 6% and 18% throughout childhood years, and two thirds of incarcerated hernias occur in the 1st yr of life. The greatest risk is in infants younger than 6 mo of age, with reported incidences of incarceration between 25% and 30%. Reports vary, but many believe a history of prematurity imparts an increased risk of incarceration in the 1st yr of life.

Although incarceration may be tolerated in adults for years, most nonreducible inguinal hernias in children, unless treated, rapidly progress to *strangulation* with potential infarction of the hernia contents or intestinal obstruction. Initially, pressure on the herniated viscera leads to impaired lymphatic and venous drainage. This leads to swelling of the herniated viscera, which further increases the compression in the inguinal canal, ultimately resulting in total occlusion of the arterial supply to the trapped viscera. Progressive ischemic changes take place, culminating in gangrene and/or perforation of the herniated viscera. The testis is at risk of ischemia because of compression of the testicular blood vessels by the strangulated hernia. In females, herniation/incarceration of the ovary places it at risk of torsion with resultant ischemia.

The symptoms of an incarcerated hernia are irritability, feeding intolerance, and abdominal distention in the infant; pain presents in the older child. Within a few hours, the infant becomes inconsolable; lack of flatus or stool signals complete intestinal obstruction. A somewhat tense, nonfluctuant mass is present in the inguinal region and can extend down into the scrotum or labia. The mass is well defined, firm, and does not reduce. With the onset of ischemic changes, the pain intensifies, and the vomiting becomes bilious or feculent. Blood may be noted in the stools. The mass is typically markedly tender, and there is often edema and erythema of the overlying skin. The testes may be normal, demonstrate a reactive hydrocele, or may be swollen and hard on the affected side because of venous congestion resulting from compression of the spermatic veins and lymphatic channels at the inguinal ring by the tightly strangulated hernia mass. Abdominal radiographs demonstrate features of partial or complete intestinal obstruction, and gas within the incarcerated bowel segments may be seen below the inguinal ligament or within the scrotum.

Ambiguous Genitalia

Infants with disorders of sexual development commonly present with inguinal hernias, often containing a gonad, and require special consideration. In female infants with inguinal hernias, particularly if the presentation is bilateral inguinal masses, **testicular feminization syndrome** should be suspected (>50% of patients with testicular feminization have an inguinal hernia; see Chapter 606). Conversely, the true incidence of testicular feminization in all female infants with inguinal hernias is difficult to determine but is approximately 1%. In phenotypic females, if the diagnosis of testicular feminization is suspected preoperatively, the child should be screened with a buccal smear for Barr bodies and appropriate genetic evaluation before proceeding with the hernia repair. The diagnosis of testicular feminization is occasionally made at the time of operation by identifying an abnormal gonad (testis) within the hernia sac or absence of the uterus on laparoscopy or rectal exam. In the normal female infant, the uterus is easily palpated as a distinct midline structure beneath the symphysis pubis on rectal examination. Preoperative diagnosis of testicular feminization syndrome or other disorders of sexual development such as mixed gonadal dysgenesis and selected pseudohermaphrodites enables the family to receive genetic counseling, and gonadectomy can be accomplished at the time of the hernia repair if indicated.

Indications for Surgery

The presence of an inguinal hernia in the pediatric age group constitutes the indication for operative repair. An inguinal hernia does not resolve spontaneously, and prompt repair eliminates the risk of incarceration and the associated potential complications, particularly in the 1st 6-12 mo of life. The timing of operative repair depends on several factors, including age, general condition of the patient, and comorbid conditions. In full-term, healthy infants (younger than 1 yr) with an inguinal hernia, repair should proceed promptly (within 2-3 wk) following diagnosis because as many as 70% of incarcerated inguinal hernias requiring emergency operation occur in infants younger than 11 mo. In addition, the incidence of complications associated with elective hernia repair (intestinal injury, testicular atrophy, recurrent hernia, wound infection) are low (≈1%), but rise to as high as 18–20% when repair is performed emergently at the time of incarceration. The incidence of testicular atrophy after incarceration in infants younger than 3 mo of age has been reported as high as 30%. Therefore, an approach emphasizing prompt elective repair in infants is warranted; anesthetic risks must be considered when determining timing of elective surgery for inguinal hernia repair. The risk factors for apnea following general anesthesia include prematurity, multiple congenital anomalies, history of apnea and bradycardia, chronic lung disease, postconceptual age <60 wk at the time of surgery, and anemia. Unfortunately, while this group of patients would be ideal for inguinal hernia repair under regional (spinal/caudal) anesthesia, inguinal hernia repair in this group is often remarkably technically challenging even for experienced pediatric surgeons, and success is elusive under regional techniques. The outcome advantage of a regional technique is lost if additional intravenous sedation is required. Full-term infants <3 mo of age and preterm infants <60 wk postconceptual age should be observed following repair for a minimum of 12 hr postoperatively and potentially overnight following general anesthesia for the development of apnea and bradycardia.

In children older than 1 yr, the risk of incarceration is less, and the repair can be scheduled with less urgency. For the routine reducible hernia, the operation should be carried out electively shortly after diagnosis. Elective inguinal hernia repair in healthy children can be safely performed in an outpatient setting with an expectation for full recovery within 48 hr. A regional caudal block or local inguinal nerve block using local anesthetic is useful to diminish perioperative pain and optimize recovery. Prophylactic antibiotics are not routinely used except for associated conditions, such as congenital heart disease or the presence of a ventriculoperitoneal shunt. *The operation should be performed at a facility with the ability to admit the patient to an inpatient unit as needed should concerns or complications arise.*

There is controversy as to the optimal timing of inguinal herniorrhaphy in preterm and low-birth-weight infants. In the past 2 decades, most pediatric surgeons have planned hernia repair shortly before discharge from the neonatal intensive care unit. This group has a high rate of incarceration, but also a high risk of anesthesia related postoperative complications with elective surgery, such as apnea, bradycardia, inability to extubate, hemodynamic instability (5–10%), and even cardiopulmonary arrest. In addition, this group also has an increased rate of postoperative surgical-related complications such as wound infection (5–10%) and recurrent hernia (10%). At present, studies to develop evidence-based data for timing of inguinal hernia repair in premature infants are ongoing, but there is a lack of consensus and patients should be individualized, with important consultation with both neonatology and pediatric anesthesia. The operation for inguinal hernia repair is most often performed under general anesthesia, but it can be performed under spinal/caudal anesthesia in selected high-risk infants in whom avoidance of intubation is preferable (e.g., because of chronic lung disease or bronchopulmonary dysplasia). In this setting, open repair (OH) is preferable to the laparoscopic approach, as it can be performed under local/regional techniques.

An incarcerated, irreducible hernia without evidence of strangulation in a clinically stable patient should initially be managed nonoperatively, unless there is evidence of bowel obstruction, peritonitis, or hemodynamic instability, because 70–95% of incarcerated inguinal hernias are successfully reduced. Manual reduction is performed using a surgical technique called taxis, first with traction caudad and posteriorly to free the mass from the external inguinal ring, and then upward to reduce the contents back into the peritoneal cavity. Reduction attempts usually require sedation (intravenous) and analgesics, and thus appropriate experience with monitoring and airway management are critical concerns. In addition, if reduction of the incarcerated hernia is successful, the infant may rapidly become somnolent and apneic, requiring important supportive measures by skilled personnel. Other techniques advocated to assist in the nonoperative reduction of an incarcerated inguinal hernia include elevation of the lower torso and legs. Ice packs should be avoided in infants because of the risk of hypothermia but may be used for brief periods in the older child. If reduction is successful but difficult, the patient should be observed (several hours) to ensure that feedings are tolerated and there is no concern that necrotic intestine was reduced; fortunately, this is an uncommon occurrence. Given the risk of early recurrent incarceration after a successful reduction, it is recommended that herniorrhaphy be performed following a brief period (1-4 days), by which time there is less edema, handling of the sac is easier, and the risk of complications is reduced.

If the inguinal hernia is unable to be reduced, or there is concern for an incomplete reduction, then operative reduction should be performed emergently. In addition, for any patient who presents with a prolonged history of incarceration of an inguinal hernia, signs of peritoneal irritation, or small bowel obstruction, surgery and operative reduction and repair of the hernia should be urgently performed. Initial management includes nasogastric intubation, intravenous fluids, and administration of broad-spectrum antibiotics. When fluid and electrolyte imbalance has been corrected and the child's condition is satisfactory, exploration is undertaken. In current practice, the laparoscopic approach may have advantages, as the abdominal cavity insufflation expands the internal ring, potentially aiding reduction of the incarcerated viscera as well as enabling visualization of the viscera for possible ischemic injury and/or perforation. The risk of postoperative complications such as testicular atrophy, bowel ischemia, wound infections, and recurrence of hernia is increased following emergency inguinal hernia repair, 4.5–33% compared with 1% in elective hernia repairs in healthy, full-term infants.

A common presentation in female patients is an irreducible ovary in the inguinal hernia in an otherwise asymptomatic patient. The inguinal mass is soft and nontender to gentle exam, and there is no swelling or edema; thus there are no findings suggesting strangulation. This represents a *sliding* hernia with the fallopian tube and ovary fused to the wall of the hernia sac preventing reduction to the abdominal cavity. Overzealous attempts to reduce the hernia are unwarranted and potentially harmful to the tube and ovary. The risk that incarceration, most often resulting from torsion of the ovary in this setting, will lead to strangulation is not known. Most pediatric surgeons recommend elective repair of the hernia within 24-48 hr.

The appearance of necrotic ovaries and testes at the time of operation does not consistently evidence irreversible damage or predict future functionality. Multiple studies report that even when ovaries appear persistently ischemic after relief of incarceration and detorsion, most ovaries, if preserved, will recover and demonstrate evidence of follicular development. Similarly, ischemic appearing testes following relief of incarceration survive in as much as 50% of cases. Testicular atrophy occurs in 2.5–15% of incarcerated hernias. Given the potential for retained functionality, the current recommendation is to avoid testicular resection unless there is frank necrosis present.

Open Inguinal Hernia Repair

The open technique for elective inguinal hernia repair in infants and children has been the standard of care since its introduction more than 50 yr ago. The operation is performed through a small (2-3 cm) inguinal skin crease incision. The procedure involves the opening of the inguinal canal, reduction of the contents of the hernia sac if present, careful separation of the hernia sac from the cremasteric muscle fibers, spermatic cord vessels, and vas deferens to avoid injury to these structures in the inguinal canal, division of the hernia sac, and high ligation of the hernia sac at the internal ring, thus preventing protrusion of abdominal contents into the inguinal canal. A communicating hydrocele is approached with the same technique, separation of the spermatic cord structures from the hernia sac, high ligation of the proximal portion of the hernia sac, and opening of the distal sac to relieve the hydrocele. In older children with a noncommunicating hydrocele, the approach may be through a scrotal incision with avoidance of manipulation of the spermatic cord vessels and vas deferens. Open inguinal hernia repair has a low rate of recurrence, vas deferens injury, and testicular atrophy (~1–2%).

In females, surgical repair is technically simpler because the hernia sac and round ligament can be ligated without concern for injury to the ovary and its blood supply, which generally remain within the abdomen. The hernia sac and round ligament are divided from their distal attachment in the labia majora, proximal dissection away from the cremasteric muscle fibers to the internal ring, and high ligation at the internal ring. In female infants, opening of the sac to visualize the ovary and fallopian tube may help avoid injury to these structures during suture ligation of the sac and also rule out testicular feminization syndrome. If the ovary and fallopian tube are within the sac and not reducible, the sac is suture ligated distal to these structures, and the internal ring is closed after reducing the sac and its contents to the abdominal cavity.

Laparoscopic Inguinal Hernia Repair

Although the classic open inguinal hernia repair is most commonly performed, laparoscopic repair (LH) is used by most pediatric surgeons. There are several techniques described, both transperitoneal and pre-peritoneal, depending on surgeon preference. Like the open technique, the laparoscopic technique is fundamentally a high ligation of the indirect inguinal hernia sac (PV) at the internal ring to prevent protrusion of abdominal viscera into the inguinal canal. The laparoscopic technique affords confirmation of the diagnosis, as well as inspection of the contralateral side for the presence of a hernia or a patent PV (potential hernia). Reported advantages of laparoscopic repair (LR) compared with open repair (OH) include better cosmesis, shorter length of stay (LOS), faster recovery, and greater ability to visualize and repair a contralateral hernia.

In LH, the inguinal canal is not explored, and the spermatic cord structures are not manipulated, which may portend reduced risk to the testicular blood supply or vas deferens, particularly in younger patients. Disadvantages of LH in infants and younger children are the increased risk associated with general anesthesia, the potential hemodynamic effects of abdominal insufflation (acidosis), and technical challenges of the LH technique. Operative times have been similar for the OH and LH approaches; however, there is wide variability with the LH technique based on the experience of the surgeon and surgical team. Laparoscopic procedures in infants should always be performed expeditiously and with low insufflations pressure to avoid the risk of cardiorespiratory compromise and development of acidosis. Postoperative pain in both techniques is managed with oral acetaminophen for 24-48 hr; older children may require a brief period of postoperative narcotics. In a prospective, randomized study, the laparoscopic approach was associated with decreased pain, parental perception of faster recovery, and parental perception of better wound cosmesis. At present, outcomes, recurrence rates, recovery metrics, complications, and family satisfaction appears similar for both approaches (OH and LH), and evidence is lacking to recommend one approach over the other.

Contralateral Inguinal Exploration

Most children (85%) present with a unilateral inguinal hernia. Controversy exists regarding when to proceed with contralateral groin exploration. The only purpose of contralateral exploration is to avoid the occurrence of a hernia on that side at a later date. The advantages of contralateral exploration include avoidance of parental anxiety and possibly a 2nd anesthesia, the cost of additional surgery, and the risk of contralateral incarceration. The disadvantages of exploration include potential injury to the spermatic cord vessels, vas deferens, and testis; increased operative and anesthesia time; and the fact that, in many infants, it is an unnecessary procedure.

With the introduction of minimally invasive techniques and laparoscopy, much of the debate over contralateral inguinal exploration has been resolved, as laparoscopy enables assessment of the contralateral side without risk of injury to the spermatic cord structures or testis. When performing OH repair, the laparoscope can be introduced through an umbilical incision or by passing a 30-degree or 70-degree oblique scope through the OH sac prior to ligation of the hernia sac on the involved side. If patency of the contralateral side is demonstrated, the surgeon can proceed with bilateral hernia repair, and if the contralateral side is properly obliterated, exploration and potential complications are avoided. When performing LH, visualization of the contralateral side is easily performed. The downside of this approach includes the risks associated with laparoscopy, and that laparoscopy cannot differentiate between a patent PV and a true hernia (Figs. 373.2 and 373.3). Infants and children with risk factors for development of an inguinal hernia or with medical conditions that increase the risk of general anesthesia should be approached with a low threshold for routine contralateral exploration.

Direct Inguinal Hernia

Direct inguinal hernias are rare in children, approximately 0.5–1%. Direct hernias appear as groin masses that extend toward the femoral vessels with exertion or straining. The etiology is from a muscular defect or weakness in the floor of the inguinal canal *medial* to the epigastric vessels. Thus direct inguinal hernias in children are generally considered an acquired problem. In one third of cases, the patient has a history of a prior indirect hernia repair on the side of the direct hernia, which suggests a possible missed direct hernia at the initial surgery, or injury to the floor muscles of the inguinal canal at the time of the 1st herniorrhaphy. Patients with **connective tissue disorders** such as Ehlers-Danlos syndrome or Marfan syndrome and mucopolysaccharidosis such as Hunter-Hurler syndrome are at increased risk for the development of direct inguinal hernias either independently or after indirect inguinal hernia repair.

Operative repair of a direct inguinal hernia involves strengthening of the floor of the inguinal canal, and many standard techniques have been described, similar to repair techniques used in adults. The repair can be performed through a single limited incision, and therefore LR does not offer significant advantage. Recurrence after repair, in contrast to that in adults, is extraordinarily rare. Because typically the area of muscular weakness is small and pediatric tissues have greater elasticity, primary repair is usually possible. Prosthetic material (mesh) for direct hernia repair or other approaches, such as preperitoneal repair, are rarely required in the pediatric age group. The older child with a direct inguinal hernia and a connective tissue disorder may be the exception, and a laparoscopic approach and prosthetic material in such a case can be useful for repair.

Femoral Hernia

Femoral hernias are rare in children (<1% of groin hernias in children). They are more common in females than males, (2 : 1 ratio). They are extremely rare in infancy and occur typically in older children, believed to most often be an acquired defect. Femoral hernias represent a protrusion through the femoral canal. The bulge of a femoral hernia is located below the inguinal ligament and typically projects on the medial aspect of the proximal thigh. Femoral hernias are more often missed clinically than direct hernias on physical examination or at the time of indirect hernia repair. Repair of a femoral hernia involves closure of the defect at the femoral canal, generally suturing the inguinal ligament to the pectineal ligament/fascia.

Complications

Complications after elective inguinal hernia repair are uncommon (≈1.5%) but significantly higher in association with incarceration (≈10%). The major risk of elective inguinal hernia repair in infants and children relates to the need for general anesthesia, and spinal/caudal anesthesia should be considered based on the experience of the surgeon and anesthesia team. Surgical complications can be related to technical factors (recurrence, iatrogenic cryptorchidism or *trapped testicle* , inadvertent injury to the vas deferens or spermatic vessels), or to the underlying process, such as bowel ischemia, gonadal infarction, and testicular atrophy following incarceration. The most critical surgical complication of inguinal hernia repair involves injury to the testicular vessels, vas deferens, testicular atrophy, or iatrogenic cryptorchidism (trapped testicle). Since LH repair generally does not involve inguinal exploration or manipulation of the testicular vessels or vas deferens, the risk of injury is potentially lower, but supportive data are unavailable at present.

Wound Infection

Wound infection occurs in <1% of elective inguinal hernia repairs in infants and children, but the incidence increases to 5–7% in association with incarceration and emergent repair. The patient typically develops fever and irritability 3-5 days after the surgery, and the wound demonstrates warmth, erythema, and fluctuance. Management consists of opening and draining the wound, a short course of antibiotics, and a daily wound dressing. The most common organisms are Gram-positive (*Staphylococcus* and *Streptococcus* spp.), and consideration should be given to coverage of methicillin-resistant *Staphylococcus aureus*. The wound generally heals in 1-2 wk with low morbidity and a good cosmetic result.

Recurrent Hernia

The recurrence rate of inguinal hernias after elective inguinal hernia repairs is generally reported as 0.5–1.0%, with rates as high as 2% for premature infants. The rate of recurrence after emergency repair of an incarcerated hernia is much higher, reported as 3–6% in most large series. The true incidence of recurrence is most certainly even higher, given the problem of accurate long-term follow-up. In the group of patients who develop recurrent inguinal hernia, the recurrence occurs in 50% within 1 yr of the initial repair and in 75% by 2 yr. Recurrence of an indirect hernia may be the result of a technical problem in the original procedure, such as failure to identify the sac properly, failure to perform high ligation of the sac at the level of the internal ring, or a tear in the sac that leaves a strip of peritoneum along the cord structures. Recurrence as a direct hernia can result from injury to the inguinal floor (transversalis fascia) during the original procedure or, more likely, failure to identify a direct hernia during the original exploration. Patients with *connective tissue disorders* (collagen deficiency) or conditions that cause *increased intraabdominal pressure* (ventriculoperitoneal shunts, ascites, chronic lung disease, peritoneal dialysis) are at increased risk for recurrence.

Iatrogenic Cryptorchidism (Trapped Testicle)

Iatrogenic cryptorchidism describes malposition of the testis after inguinal hernia repair. This complication is usually related to disruption of the testicular attachment in the scrotum at the time of hernia repair or failure to recognize an undescended testis during the original procedure, allowing the testes to retract, typically to the region of the external ring. At the completion of inguinal hernia repair, the testis should be placed in a dependent intrascrotal position. If the testis will not remain in this position, proper fixation in the scrotum should be performed at the time of the hernia repair.

Incarceration

Incarceration of an inguinal hernia can result in injury to the intestines, the fallopian tube and ovary, or the ipsilateral testis. The incidence of incarceration of a congenital indirect inguinal hernia is reported as 6–18% throughout childhood and as high as 30% for infants younger than 6 mo of age. Intestinal injury requiring bowel resection is uncommon, occurring in only 1–2% of incarcerated hernias. In cases of incarceration in which the hernia is reduced nonoperatively, the likelihood of intestinal injury is low; however, these patients should be observed closely for 6-12 hr following reduction of the hernia persistent for signs and symptoms of intestinal obstruction, such as fever, vomiting, abdominal distention, or bloody stools. Laparoscopy affords the opportunity to inspect the reduced viscera for injury or necrosis in select cases.

The reported incidence of testicular infarction and subsequent testicular atrophy with incarceration is 4–12%, with higher rates among the irreducible cases requiring emergency operative reduction and repair. The testicular insult can be caused by compression of the gonadal vessels by the incarcerated hernia mass or as a result of damage incurred during operative repair. Young infants are at highest risk, with testicular infarction rates reported as high as 30% in infants younger than 2-3 mo of age. These problems underscore the need for prompt reduction of incarcerated hernias and early repair once the diagnosis is known to avoid repeat episodes of incarceration.

Injury to the Vas Deferens and Male Fertility

Similar to the gonadal vessels, the vas deferens can be injured as a consequence of compression from an incarcerated hernia or during operative repair. This injury is almost certainly underreported because it is unlikely to be recognized until adulthood and, even then, possibly only if the injury is bilateral. Although the vulnerability of the vas deferens has been documented in many studies, no good data exist as to the actual incidence of this complication. One review reported an incidence of injury to the vas deferens of 1.6% based on pathology demonstrating segments of the vas deferens in the hernia sac specimen; this may be overstated, because others have shown that small glandular inclusions found in the hernia sac can represent müllerian duct remnants and are of no clinical importance. The relationship between male fertility and previous inguinal hernia repair is also unknown. There appears to be an association between infertile males with testicular atrophy and abnormal sperm count and a previous hernia repair. A relationship has also been reported between infertile males with spermatic autoagglutinating antibodies and previous inguinal hernia repair. The proposed etiology is that operative injury to the vas deferens during inguinal hernia repair might result in obstruction of the vas with diversion of spermatozoa to the testicular lymphatics, and this breach of the blood–testis barrier produces an antigenic challenge, resulting in formation of spermatic autoagglutinating antibodies.

Embryology, Anatomy, and Physiology of the Pancreas

Steven L. Werlin, Michael Wilschanski

The human pancreas develops from the ventral and dorsal domains of the primitive duodenal endoderm beginning at about the 5th wk of gestation (Fig. 374.1). The larger dorsal anlage, which develops into the tail, body, and part of the head of the pancreas, grows directly from the duodenum. The smaller ventral anlage develops as 1 or 2 buds from the primitive liver and eventually forms the major portion of the head of the pancreas. At about the 17th wk of gestation, the dorsal and ventral anlagen fuse as the buds develop and the gut rotates. The ventral duct forms the proximal portion of the major pancreatic duct of Wirsung, which opens into the ampulla of Vater. The dorsal duct forms the distal portion of the duct of Wirsung and the accessory duct of Santorini, which empties independently in approximately 5% of people. Variations in fusion might account for pancreatic developmental anomalies. Pancreatic agenesis has been associated with a base pair deletion in the insulin promoter factor 1-*HOX* gene, *PDX1 (PAGEN1)* , *PTF1A (PAGEN 2), GATA 6 haploinsufficiency* and *FS123TER* genes. Other genes involved in pancreatic organogenesis include the *IHH* , *SHH* or sonic hedgehog gene, *SMAD2* , and transforming growth factor-1β genes.

FIG. 374.1 **Development of the exocrine pancreas. A, Gestational age 6 wk. B, Gestational age 7-8 wk. The ventral pancreas has rotated but has not yet fused with the dorsal pancreas. C, The ventral and dorsal pancreatic ductal systems have fused. (From Werlin SL: The exocrine pancreas. In Kelly VC, editor: *Practice of pediatrics,* vol 3, Hagerstown, MD, 1980, Harper and Row, Fig. 16.1.)**

The pancreas lies transversely in the upper abdomen between the duodenum and the spleen in the retroperitoneum (Fig. 374.2). The head, which rests on the vena cava and renal vein, is adherent to the C loop of the duodenum and surrounds the distal common bile duct. The tail of the pancreas reaches to the left splenic hilum and passes above the left kidney. The lesser sac separates the tail of the pancreas from the stomach.

By the 13th wk of gestation, exocrine and endocrine cells can be identified. Primitive acini containing immature zymogen granules are found by the 16th wk. Mature zymogen granules containing amylase, trypsinogen, chymotrypsinogen, and lipase are present at the 20th wk. Centroacinar and duct cells, which are responsible for water, electrolyte, and bicarbonate secretion, are also found by the 20th wk. The final 3-dimensional structure of the pancreas consists of a complex series of branching ducts surrounded by grape-like clusters of epithelial cells. Cells containing glucagon are present at the 8th wk. Islets of Langerhans appear between the 12th and 16th wk.

374.1

Pancreatic Anatomic Abnormalities

Steven L. Werlin, Michael Wilschanski

Complete or partial **pancreatic agenesis** is a rare condition. Complete agenesis is associated with severe neonatal diabetes and usually death at an early age (see Chapter 607). Partial or dorsal pancreatic agenesis is often asymptomatic but may be associated with diabetes, congenital heart disease, polysplenia, and recurrent pancreatitis. Pancreatic agenesis is also associated with malabsorption.

An **annular pancreas** results from incomplete rotation of the left (ventral) pancreatic anlage, which may be a result of recessive mutations in the *IHH* or *SHH* genes. Patients usually present in infancy with symptoms of complete or partial bowel obstruction or in the 4th or 5th decade. There is often a history of maternal polyhydramnios. Other congenital anomalies, such as Down syndrome, tracheoesophageal fistula, intestinal atresia, imperforate anus, malrotation and cardiorenal abnormalities, and pancreatitis may be associated with annular pancreas. Some children present with chronic vomiting, pancreatitis, or biliary colic. The treatment of choice is duodenojejunostomy. Division of the pancreatic ring is not attempted because a duodenal diaphragm or duodenal stenosis often accompanies annular pancreas.

Ectopic pancreatic rests in the stomach or small intestine occur in approximately 3% of the population. Most cases (70%) are found in the upper intestinal tract. Recognized on barium contrast studies by their typical umbilicated appearance, they are rarely of clinical importance. On endoscopy, they are irregular, yellow nodules 2-4 mm in diameter. A pancreatic rest may rarely be the lead point of an intussusception, produce hemorrhage, or cause bowel obstruction.

Pancreas divisum , which occurs in 5–15% of the population, is the most common pancreatic developmental anomaly. As the result of failure of the dorsal and ventral pancreatic anlagen to fuse, the tail, body, and part of the head of the pancreas drain through the small accessory duct of Santorini rather than the main duct of Wirsung. Some researchers believe that this anomaly may be associated with recurrent pancreatitis when there is relative obstruction of the outflow of the ventral pancreas. Diagnosis is made by endoscopic retrograde cholangiopancreatography or by magnetic resonance cholangiopancreatography. Pancreatitis in patients with pancreas divisum is associated with mutations in the *CFTR* gene. Sphincterotomy is not recommended unless other anomalies are present or the patient has classic pancreatobiliary-type pain, recurrent pancreatitis, or chronic pancreatitis and no other etiology is found.

Choledochal cysts are dilations of the biliary tract and usually cause biliary tract symptoms, such as jaundice, pain, and fever. On occasion, the presentation may be pancreatitis. The diagnosis is usually made with ultrasonography, CT or biliary scanning, or magnetic resonance cholangiopancreatography. Similarly, a choledochocele—an intraduodenal choledochal cyst—may manifest with pancreatitis. The diagnosis can be difficult and require magnetic resonance cholangiopancreatography, endoscopic retrograde cholangiopancreatography, or endoscopic ultrasound.

A number of rare conditions, such as Ivemark (mutation in GDF gene) and Johanson-Blizzard (mutation in UBR1 gene) syndromes, include pancreatic dysgenesis or dysfunction among their features. Many of these syndromes include renal and hepatic dysgenesis along with the pancreatic anomalies.

374.2

Pancreatic Physiology

Steven L. Werlin, Michael Wilschanski

The acinus is the functional unit of the exocrine pancreas. Acinar cells are arrayed in a semicircle around a lumen. Ducts that drain the acini are lined by centroacinar and ductular cells. This arrangement allows the secretions of the various cell types to mix.

The acinar cell synthesizes, stores, and secretes more than 20 enzymes, which are stored in zymogen granules, some in inactive forms. The relative concentration of the various enzymes in pancreatic juice is affected and perhaps controlled by the diet, probably by regulating the synthesis of specific messenger RNA. The main enzymes involved in digestion include *amylase* , which splits starch into maltose, isomaltose, maltotriose; dextrins; and *trypsin* and *chymotrypsin* , endopeptidases secreted by the pancreas as inactive proenzymes. Trypsinogen is activated in the gut lumen by enterokinase, a brush-border enzyme. Trypsin can then activate trypsinogen, chymotrypsinogen, and procarboxypeptidase into their respective active forms. Pancreatic lipase requires *colipase* , a coenzyme also found in pancreatic fluid, for activity. Lipase liberates fatty acids from the 1 and 3 positions of triglycerides, leaving a monoglyceride.

The stimuli for exocrine pancreatic secretion are neural and hormonal. Acetylcholine mediates the cephalic phase; cholecystokinin (CCK) mediates the intestinal phase. CCK is released from the duodenal mucosa by luminal amino acids and fatty acids. Feedback regulation of pancreatic secretion is mediated by pancreatic proteases in the duodenum. Secretion of CCK is inhibited by the digestion of a trypsin-sensitive, CCK-releasing peptide released in the lumen of the small intestine or by a monitor peptide released in pancreatic fluid.

Centroacinar and duct cells secrete water and bicarbonate. Bicarbonate secretion is under feedback control and is regulated by duodenal intraluminal pH. The stimulus for bicarbonate production is secretin in concert with CCK. Secretin cells are abundant in the duodenum.

Although normal pancreatic function is required for digestion, maldigestion occurs only after considerable reduction in pancreatic function; lipase and colipase secretion must be decreased by 90–98% before fat maldigestion occurs.

Although amylase and lipase are present in the pancreas early in gestation, secretion of both amylase and lipase is low in the infant. Adult levels of these enzymes are not reached in the duodenum until late in the 1st yr of life. Digestion of the starch found in many infant formulas depends in part on the low levels of salivary amylase that reach the duodenum. This explains the diarrhea that may be seen in infants who are fed formulas high in glucose polymers or starch. Neonatal secretion of trypsinogen and chymotrypsinogen is at approximately 70% of the level found in the 1 yr old infant. The low levels of amylase and lipase in duodenal contents of infants may be partially compensated by salivary amylase and lingual lipase. This explains the relative starch and fat intolerance of premature infants.

CHAPTER 375

Pancreatic Function Tests

Michael Wilschanski, Steven L. Werlin

Pancreatic function can be measured by direct and indirect methods. An indirect test, the measurement of *fecal elastase* , which has become the standard screening test for pancreatic insufficiency, has a sensitivity and specificity >90%. When compared to a 72-hr fecal fat content in both pancreatic insufficient and sufficient patients, an elastase value of 100 µg/g stool has a 99% predictive value in ruling out pancreatic insufficiency based on an abnormal fecal fat finding. Falsely abnormal results can occur in many enteropathies and when the stool is very loose. The activity of other pancreatic enzymes in stool is rarely measured.

Direct Test

Classically, a triple-lumen tube was used to isolate the pancreatic secretions in the duodenum. Measurement of bicarbonate concentration and enzyme activity (*trypsin* , *chymotrypsin* , *lipase* , and *amylase*) is performed on the aspirated secretions. This test is cumbersome and infrequently used. The most commonly used direct test is collection of pancreatic juice at endoscopy after stimulation with secretin and/or cholecystokinin. A 72-hr stool collection for quantitative analysis of fat content is the gold standard for the diagnosis of malabsorption. The collection is usually performed at home, and the parent is asked to keep a careful dietary record, from which fat intake is calculated. A pre-weighed, sealable plastic container is used, which the parent keeps in the freezer. Freezing helps to preserve the specimen and reduce odor. Infants are dressed in disposable diapers with the plastic side facing the skin so that the complete sample can be transferred to the container. Normal fat absorption is >93% of intake. The presence of fat malabsorption does not differentiate between pancreatic dysfunction and enteropathies, such as celiac disease. Qualitative examination of the stool for microscopic fat globules can give false-positive and false-negative results.

CHAPTER 376

Disorders of the Exocrine Pancreas

Steven L. Werlin, Michael Wilschanski

Disorders Associated With Pancreatic Insufficiency

Other than cystic fibrosis (CF), conditions that cause pancreatic insufficiency are very rare in children. They include Shwachman-Diamond syndrome (SDS), Johanson-Blizzard syndrome, Ivemark syndrome, Pearson syndrome, isolated enzyme deficiencies, enterokinase deficiency (see Chapter 364), chronic pancreatitis, protein-calorie malnutrition (see Chapters 57 and 364), and IMNEPD (infantile onset multisystem neurologic, endocrine, and pancreatic disease).

Cystic Fibrosis (see Chapter 432)

By the end of the 1st yr of life, 85–90% of children with CF have pancreatic insufficiency, which, if untreated, will lead to malnutrition. Treatment of the associated pancreatic insufficiency leads to improvement in absorption, better growth, and more normal stools. Pancreatic function can be monitored in children with CF with serial measurements of fecal elastase. Ten to 15% of children present with a neonatal intestinal obstruction called meconium ileus; in later life a common intestinal complication is distal intestinal obstruction syndrome which is unique to CF. Ten percent of CF patients develop severe liver disease. Ten to 15% of CF patients are pancreatic sufficient and their presentation tends to be later in life, including recurrent pancreatitis, male infertility, and chronic bronchiectasis. CF is part of the newborn screen in every state in the United States and in most countries in the Western world.

Shwachman-Diamond Syndrome (see Chapter 157)

SDS is an autosomal recessive syndrome (1/20,000 births) caused by a mutation of the Shwachman-Bodian-Diamond syndrome *(SBDS)* gene on chromosome 7, which causes ribosomal dysfunction in 90–95% of patients. Signs and symptoms of SDS include pancreatic insufficiency; neutropenia, which may be cyclic; neutrophil chemotaxis defects; metaphyseal dysostosis; failure to thrive; and short stature. Some patients with SDS have liver or kidney involvement, dental disease, or learning difficulty. SDS is a common cause of congenital neutropenia.

Patients typically present in infancy with poor growth and steatorrhea. More varied phenotypes have been described including absence of pancreatic lipomatosis on imaging, normal fecal elastase levels, and normal skeletal survey. These children can be readily differentiated from those with CF by their normal sweat chloride levels, lack of mutations in the CF gene, characteristic metaphyseal lesions, and fatty pancreas characterized by a hypodense appearance on CT and MRI scans (Fig. 376.1).

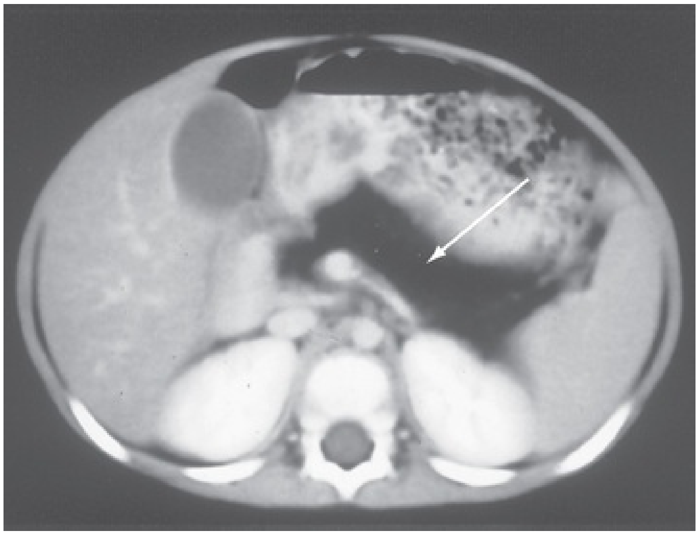

FIG. 376.1 **CT appearance of the pancreas in a patient with Shwachman-Diamond syndrome. Note that the pancreas *(arrow)* retains a typical size and shape, but it is highly fatty and therefore appears as a very low-density structure. (Courtesy Prof. Peter Durie, Hospital for Sick Children, Toronto, Ontario.)**

Despite adequate pancreatic replacement therapy and correction of malabsorption, poor growth commonly continues. Pancreatic insufficiency is often transient, and steatorrhea frequently spontaneously improves with age. Recurrent pyogenic infections (otitis media, pneumonia, osteomyelitis, dermatitis, sepsis) are frequent and are a common cause of death. Thrombocytopenia is found in 70% of patients and anemia in 50%. Development of aplastic anemia or a *myelodysplastic syndrome* can occur, with transformation to *acute myeloid leukemia* in 24%. The pancreatic acini are replaced by fat with little fibrosis. Islet cells and ducts are normal. Bone marrow transplant is the treatment of choice in patients who develop acute myeloid leukemia.

Pearson Syndrome

Pearson (marrow-pancreas) syndrome is caused by a contiguous mitochondrial gene depletion involving several mitochondrial genes affecting oxidative phosphorylation, that manifests in infants with severe **macrocytic anemia** and **variable thrombocytopenia** . The bone marrow demonstrates vacuoles in erythroid and myeloid precursors as well as ringed sideroblasts. In addition to its role in severe bone marrow failure, pancreatic insufficiency contributes to growth failure. Mitochondrial DNA mutations are transmitted through maternal inheritance to both sexes or are sporadic.

Johanson-Blizzard Syndrome

The features of Johanson-Blizzard syndrome include exocrine pancreatic deficiency, aplasia or hypoplasia of the alae nasi, congenital deafness, hypothyroidism, developmental delay, short stature, ectodermal scalp defects, absence of permanent teeth, urogenital malformations, and imperforate anus. This syndrome is caused by a mutation in the *UBR1* gene found on chromosome 15. The UBR1 protein acts as a ubiquitin ligase.

Isolated Enzyme Deficiencies

Isolated deficiencies of trypsinogen, enterokinase, lipase, and colipase have been reported. Although enterokinase is a brush-border enzyme, deficiency causes pancreatic insufficiency because enterokinase is required to activate trypsinogen to trypsin in the duodenum. Deficiencies of trypsinogen or enterokinase manifest with failure to thrive, hypoproteinemia, and edema. Isolated amylase deficiency is typically developmental and resolves by age 2-3 yr.

Other Syndromes Associated With Pancreatic Insufficiency

Pancreatic agenesis, congenital pancreatic hypoplasia, and congenital rubella are rare causes of pancreatic insufficiency. Pancreatic insufficiency has also been reported in duodenal atresia and stenosis and may also be seen in infants with familial or nonfamilial hyperinsulinemic hypoglycemia, who require 95–100% pancreatectomy to control hypoglycemia. Mutations in at least 6 genes have been described. Pancreatic insufficiency, which may be found in children with celiac disease and undernutrition, recovers with nutritional rehabilitation.

IMNEPD is a rare disease due to mutations in the *PTRH2* gene. Neurologic features dominate the phenotype (microcephaly, intellectual disability, cerebellar atrophy, deafness, and neuropathy), but pancreatic insufficiency is seen in most patients.

CHAPTER 377

Treatment of Pancreatic Insufficiency

Michael Wilschanski, Steven L. Werlin

The most important treatment of pancreatic insufficiency (PI) is pancreatic enzyme replacement therapy (PERT). In modern enzyme capsules the enzymes are enterically coated to protect the enzymes from degradation by gastric acid and from autodigestion in the small intestine. It is common for patients to change from one product to another using a 1 : 1 lipase ratio and then titrating for maximum efficacy (Table 377.1).

Table 377.1

FDA-Approved Pancreatic Enzyme Replacement Products for Exocrine Pancreatic Insufficiency[*]

DRUG	AVAILABLE STRENGTHS	COST ($)[†]
IMMEDIATE-RELEASE–		
Viokace (Allergan)[‡,§,‖]	10,440 or 20,880 units of lipase[¶]	8.80
DELAYED-RELEASE–		
Creon (Abbvie)	3,000, 6,000, 12,000, 24,000, or 36,000 USP units of lipase[¶,**]	8.20
Pancreaze (Janssen)	2,600, 4,200, 10,500, 16,800, or 21,000 units of lipase[¶,**]	8.80
Pertzye (Digestive Care)	4,000, 8,000, 16,000, or 24,000 units of lipase[¶,**]	8.40
Zenpep (Allergan)	3,000, 5,000, 10,000, 15,000, 20,000, 25,000, or 40,000 units of lipase[¶,**]	9.60

[*] Pancrelipase products are not interchangeable. All of these products contain a combination of porcine-derived lipases, proteases, and amylases.

[†] Approximate WAC for one dose (as close as possible to 35,000 USP units of lipase using available formulations) for a 70-kg patient. WAC is wholesaler acquisition cost, or manufacturer's published price to wholesalers; WAC represents published catalogue or list prices and may not represent an actual transactional price.

[‡] Viokace is only approved for use in adults.

[§] Should be used in combination with a proton pump inhibitor to maximize absorption in the duodenum.

[||] FDA-approved only for treatment of adults with EPI due to chronic pancreatitis or pancreatectomy.

[¶] Should not be crushed or chewed.

[**] Capsules can be opened and contents sprinkled on soft acidic food (pH ≤ 4.5) such as applesauce.

The North American CF Foundation has published dosing guidelines based on age and fat ingestion (Table 377.2). Because these products contain excess protease compared with lipase, the dosage is estimated from the lipase requirement. The final dosage of PERT for children is often established by trial and error. An adequate dose is one that is followed by resumption of normal growth and the return of stools to normal fat content, which, when desired, can be verified by a 72-hr fecal fat collection and normalization of stool consistency and color. Because there is no elastase in enzyme preparations, fecal elastase cannot be used to monitor appropriateness of PERT dosage. Enzyme replacement should be divided and given at the beginning of and during the meal. Enzymes should not be chewed, crushed, or dissolved in food, which would allow gastric acid to penetrate the enteric coating and destroy the enzymes. Enzymes must also be given with snacks which contain fat. Increasing enzyme supplements beyond the recommended dose does not improve absorption, might retard growth, and can cause fibrosing colonopathy (see below).

Table 377.2

Pancreatic Enzyme Replacement Therapy: North American CF Foundation Consensus Statement

Infants (up to 12 mo)	2,000-4,000 U lipase/120 mL breast milk or formula
12 mo to 4 yr	1,000 U lipase/kg/meal initially, then titrate per response
Children >4 yr and adults	500 U lipase/kg/meal initially, up to maximum of 2,500 U lipase/kg/meal or 10,000 U lipase/kg/day or 4,000 U lipase/g fat ingested per day

PLUS: one half the standard meal dose to be given with snacks.

A major concern has been the ingestion of enzymes by infants. The importance of correct enzyme ingestion in infants and children is obvious but there may be difficulty in feeding the infant microspheres however small they may be. Enterically coated microspheres can be mixed with apple sauce for oral use or crushed for use in tube feeding. Patients treated with this approach do achieve growth and weight gain. Pancreatic enzymes specifically prepared for infants and young children with smaller granules have been developed.

Treatment of exocrine PI by oral enzyme replacement usually corrects protein malabsorption, but steatorrhea is difficult to correct completely. Factors contributing to fat malabsorption include inadequate dosage, incorrect timing of doses in relation to food consumption or gastric emptying, lipase inactivation by gastric acid, and the observation that *chymotrypsin* in the enzyme preparation digests and thus inactivates *lipase* .

When adequate fat absorption is not achieved, gastric acid neutralization with an H_2 -receptor antagonist or, more commonly, a proton pump inhibitor, decreases enzyme inactivation by gastric acid and thus improves delivery of lipase into the intestine. Enteric coating also protects lipase from acid inactivation.

Untoward effects secondary to PERT include allergic reactions and kidney stones. Fibrosing colonopathy, consisting of colonic fibrosis and strictures, can occur 7-12 mo after severe overdose of PERT.

Fat-soluble vitamin supplements are required by PI patients due to the ongoing mild to moderate fat malabsorption that occurs despite PERT.

Pancreatitis

378.1

Acute Pancreatitis

Steven L. Werlin, Michael Wilschanski

Keywords

Acute pancreatitis
acute pancreatitis etiology
acute pancreatitis diagnosis
drug-induced pancreatitis
(serum) amylase
(serum) lipase

Acute pancreatitis (AP), the most common pancreatic disorder in children, is increasing in incidence, and 50 or more cases are usually seen in major pediatric centers per year. In children, blunt abdominal injuries, multisystem disease such as the hemolytic uremic syndrome and inflammatory bowel disease, biliary stones or microlithiasis (sludging), and drug toxicity are the most common etiologies. Although many drugs and toxins can induce AP in susceptible persons, in children, valproic acid, L -asparaginase, 6-mercaptopurine, and azathioprine are the most common causes of drug-induced pancreatitis. Alcohol should be considered in adolescents. Other cases follow organ transplantation or are caused by infections, metabolic disorders, or mutations in susceptibility genes (see Chapter 378.1). Only 10–20% of cases are idiopathic (Table 378.1).

Table 378.1

Etiology of Acute and Recurrent Pancreatitis in Children

DRUGS AND TOXINS
• Acetaminophen overdose • Alcohol • L -Asparaginase • Azathioprine • Cannabis • Carbamazepine • Cimetidine • Corticosteroids • Cytosine arabinoside • Dapsone • Didanosine • Enalapril • Erythromycin • Estrogen • Furosemide • Glucagon-like peptide-1 agents • Interferon α • Isoniazid • Lamivudine • Lisinopril • 6-Mercaptopurine • Methyldopa • Mesalamine • Metronidazole • Octreotide • Organophosphate poisoning • Pentamidine • Procainamide • Retrovirals: DDC (dideoxycytidine), DDI (dideoxyinosine), tenofovir • Rifampin • Sulfonamides: mesalamine, 5-aminosalicytates, sulfasalazine, trimethoprim-sulfamethoxazole • Sulindac • Tetracycline • Thiazides • Valproic acid • Venom (spider, scorpion, Gila monster lizard) • Vincristine • Volatile hydrocarbons
GENETIC
• Cationic trypsinogen gene *(PRSS1)* • Chymotrypsin C gene *(CTRC)* • Cystic fibrosis gene *(CFTR)* • Trypsin inhibitor gene *(SPINK1)*
INFECTIOUS

- Transplantation: bone marrow, heart, liver, kidney, pancreas
- Vasculitis

TRAUMATIC

- Blunt injury
- Burns
- Child abuse
- Hypothermia
- Surgical trauma
- Total-body cast

After an initial insult, such as ductal disruption or obstruction, there is premature activation of trypsinogen to trypsin within the acinar cell. Trypsin then activates other pancreatic proenzymes, leading to autodigestion, further enzyme activation, and release of active proteases. Lysosomal hydrolases colocalize with pancreatic proenzymes within the acinar cell. Pancreastasis (similar in concept to cholestasis) with continued synthesis of enzymes occurs. Lecithin is activated by phospholipase A_2 into the toxic lysolecithin. Prophospholipase is unstable and can be activated by minute quantities of trypsin. After the insult, cytokines and other proinflammatory mediators are released.

The healthy pancreas is protected from autodigestion by pancreatic proteases that are synthesized as inactive proenzymes; digestive enzymes that are segregated into secretory granules at pH 6.2 by low calcium concentration, which minimizes trypsin activity; the presence of protease inhibitors both in the cytoplasm and zymogen granules; and enzymes that are secreted directly into the ducts.

Histopathologically, interstitial edema appears early. Later, as the episode of pancreatitis progresses, localized and confluent necrosis, blood vessel disruption leading to hemorrhage, and an inflammatory response in the peritoneum can develop.

The diagnosis of pancreatitis in children is made when 2 of 3 of the following are present: abdominal pain; serum amylase and/or lipase activity at least 3 times greater than the upper limit of normal; and imaging findings characteristic of, or compatible with, AP.

Clinical Manifestations

The severity of AP in children has been defined by a consensus committee.

Mild Acute Pancreatitis: AP that is not associated with organ failure, local or systemic complications, and usually resolves within the 1st wk after presentation. This is the most common form of pediatric AP.

The patient with mild AP has moderate to severe abdominal pain, persistent vomiting, and possibly fever. The pain is epigastric or in either upper quadrant, steady, often resulting in the child's assuming an antalgic position with hips and knees flexed, sitting upright, or lying on the side. The child is uncomfortable, irritable, and appears acutely ill. The abdomen may be distended and tender and a mass may be palpable. The pain can increase in intensity for 24-48 hr, during which time vomiting may increase and the patient can require hospitalization for fluid and electrolyte therapy and analgesia. There is no organ failure, and imaging does not demonstrate peri- or pancreatic necrosis. The prognosis for complete recovery in the acute uncomplicated case after 4-7 days is excellent.

Moderately Severe Acute Pancreatitis : AP with either transient organ failure/dysfunction (lasting <48 hr) or development of local or systemic complications, such as exacerbation of previously diagnosed comorbid disease (such as lung or kidney disease). Imaging may reveal sterile (peri-) pancreatic necrosis. The prognosis for these patients is also excellent but recovery may be prolonged.

Severe Acute Pancreatitis*:* AP with development of organ dysfunction that persists longer than 48 hr. Persistent organ failure may be single or multiple. Severe AP is uncommon in children. In this life-threatening condition, the patient is acutely ill with severe nausea, vomiting, and abdominal pain. Shock, high fever, jaundice, ascites, hypocalcemia, and pleural effusions can occur. A bluish discoloration may be seen around the umbilicus (Cullen sign) or in the flanks (Grey Turner sign). The pancreas is necrotic and can be transformed into an inflammatory hemorrhagic mass. The mortality rate, which is approximately 20%, is related to the systemic inflammatory response syndrome with multiple organ dysfunction, shock, renal failure, acute respiratory distress syndrome, disseminated intravascular coagulation, gastrointestinal bleeding, and systemic or intra-abdominal infection. The percentage of necrosis seen on CT and failure of pancreatic tissue to enhance on CT (suggesting necrosis) predicts the severity of the disease.

Diagnosis

AP is usually diagnosed by measurement of serum lipase and amylase activities. Serum lipase is considered the test of choice for AP, as it is more specific than amylase for acute inflammatory pancreatic disease and should be determined when pancreatitis is suspected. The serum lipase rises by 4-8 hr, peaks at 24-48 hr, and remains elevated 8-14 days longer than serum amylase. Serum lipase greater than 7 times the upper limit of normal obtained within 24 hr of presentation may predict a severe course. Serum lipase can be elevated in nonpancreatic diseases. The serum amylase level is typically elevated for up to 4 days. A variety of other conditions can also cause hyperamylasemia without pancreatitis (Table 378.2). Elevation of salivary amylase can mislead the clinician to diagnose pancreatitis in a child with abdominal pain. The laboratory can separate amylase isoenzymes into pancreatic and salivary fractions. Initially serum amylase levels are normal in 10–15% of patients.

Table 378.2

Differential Diagnosis of Hyperamylasemia

PANCREATIC PATHOLOGY
• Acute or chronic pancreatitis • Complications of pancreatitis (pseudocyst, ascites, abscess) • Factitious pancreatitis
SALIVARY GLAND PATHOLOGY
• Parotitis (mumps, *Staphylococcus aureus* , cytomegalovirus, HIV, Epstein-Barr virus) • Sialadenitis (calculus, radiation) • Eating disorders (anorexia nervosa, bulimia)
INTRAABDOMINAL PATHOLOGY
• Biliary tract disease (cholelithiasis) • Peptic ulcer perforation • Peritonitis • Intestinal obstruction • Appendicitis
SYSTEMIC DISEASES
• Metabolic acidosis (diabetes mellitus, shock) • Renal insufficiency, transplantation • Burns • Pregnancy • Drugs (morphine) • Head injury • Cardiopulmonary bypass

Other laboratory abnormalities that may be present in AP include hemoconcentration, coagulopathy, leukocytosis, hyperglycemia, glucosuria, hypocalcemia, elevated γ-glutamyl transpeptidase, and hyperbilirubinemia.

X-ray of the chest and abdomen might demonstrate nonspecific findings such as atelectasis, basilar infiltrates, elevation of the hemidiaphragm, left- (rarely right-) sided pleural effusions, pericardial effusion, and pulmonary edema. Abdominal x-rays might demonstrate a sentinel loop, dilation of the transverse colon (cutoff sign), ileus, pancreatic calcification (if recurrent), blurring of the left psoas margin, a pseudocyst, diffuse abdominal haziness (ascites), and peripancreatic extraluminal gas bubbles.

CT has a major role in the diagnosis and follow-up of children with pancreatitis. Findings can include pancreatic enlargement; a hypoechoic, sonolucent edematous pancreas; pancreatic masses; fluid collections; and abscesses (Fig. 378.1). Normal imaging studies at the time of diagnosis are not uncommon. In adults, CT findings are the basis of a widely accepted prognostic system (Table 378.3). Ultrasonography is more sensitive than CT for the diagnosis of biliary stones. Magnetic resonance cholangiopancreatography and endoscopic retrograde cholangiopancreatography are essential in the investigation of recurrent pancreatitis, nonresolving pancreatitis, and disease associated with gallbladder pathology. Endoscopic ultrasonography also helps visualize the pancreaticobiliary system. Complications of AP are noted in Table 378.4 .

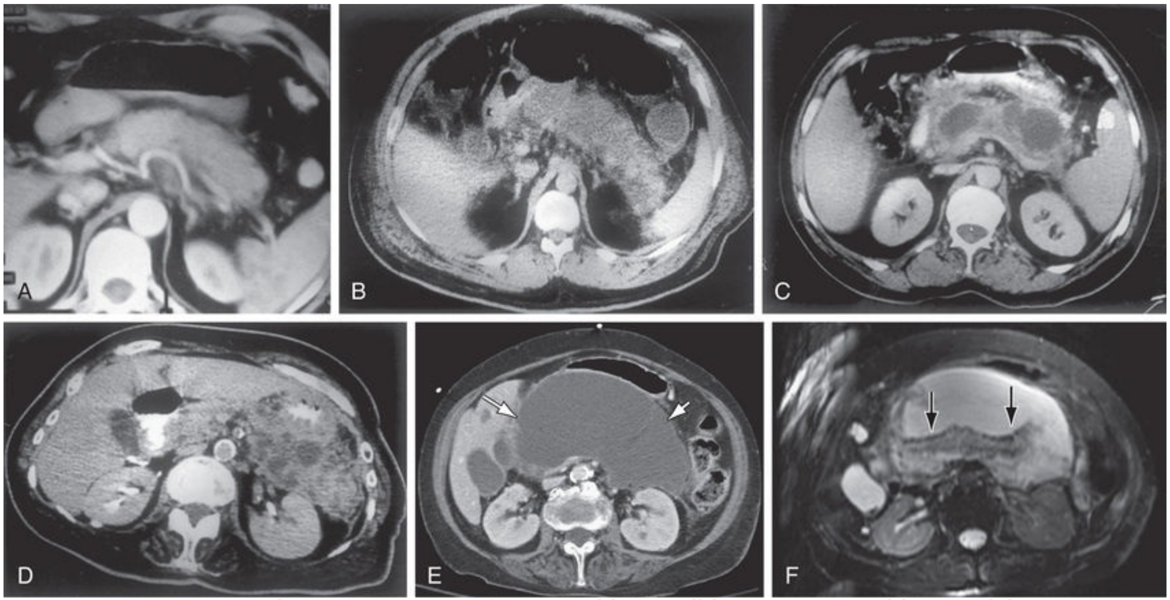

FIG. 378.1 **CT and MRI appearance of pancreatitis. A, Mild acute pancreatitis. Arterial phase spiral CT. Diffuse enlargement of pancreas without fluid accumulation. B, Severe acute pancreatitis. Lack of enhancement of the pancreatic parenchyma due to the necrosis of the entire pancreatic gland. C, Pancreatic pseudocyst. A round fluid collection with thin capsule is seen within the lesser sac. D, Acute severe pancreatitis and peripancreatic abscess formation. Peripancreatic abscess formation is observed within the peripancreatic and the left anterior pararenal space. E, Pancreatic necrosis. A well-defined fluid attenuation collection in the pancreatic bed *(white arrows)* seen on contrast-enhanced CT imaging. F, The same collection is more complex appearing on the corresponding T2-weighted MR image. The internal debris and necrotic tissue are better appreciated because of the superior soft-tissue contrast of MRI *(black arrows)* . Table 378.3

Revised Definitions of Morphologic Features of Acute Pancreatitis

INTERSTITIAL EDEMATOUS PANCREATITIS
Acute inflammation of the pancreatic parenchyma and peripancreatic tissues, but without recognizable tissue necrosis
• CECT criteria • Pancreatic parenchyma enhancement by intravenous contrast agent • No peripancreatic necrosis
NECROTIZING PANCREATITIS
Inflammation associated with pancreatic parenchymal necrosis and/or peripancreatic necrosis
• CECT criteria • Lack of pancreatic parenchymal enhancement by intravenous contrast agent • Presence of findings of peripancreatic necrosis
ACUTE PANCREATITIS FLUID COLLECTION
Peripancreatic fluid associated with interstitial edematous pancreatitis with no associated peripancreatic necrosis. Applies only to areas of peripancreatic fluid seen within the first 4 wk after onset of interstitial edematous pancreatitis and without the features of a pseudocyst.
• CECT criteria • Occurs in the setting of interstitial edematous pancreatitis • Homogeneous collection with fluid density • Confined by normal peripancreatic fascial planes • No definable wall encapsulating the collection • Adjacent to pancreas (no intrapancreatic extension)
PANCREATIC PSEUDOCYST
An encapsulated collection of fluid with a well-defined inflammation wall, usually outside the pancreas, with little or no necrosis. Usually occurs more than 4 wk after onset of interstitial edematous pancreatitis.
• CECT criteria • Well circumscribed; usually round or oval • Homogeneous fluid density • No nonliquid component • Well-defined wall that is wholly encapsulated • Maturation usually needs >4 wk after onset of acute pancreatitis; occurs after interstitial edematous pancreatitis
ACUTE NECROTIC COLLECTION
A collection containing variable amounts of both fluid and necrosis associated with necrotizing pancreatitis; the necrosis can include the pancreatic parenchyma and/or the peripancreatic tissue.
• CECT criteria • Occurs only in the setting of acute necrotizing pancreatitis • Heterogeneous and nonliquid density of varying degrees in different locations (some seem homogeneous early in their course) • No definable wall encapsulating the collection • Intrapancreatic and/or extrapancreatic
WALLED-OFF NECROSIS
A mature, encapsulated collection of pancreatic and/or peripancreatic necrosis that has developed a well-defined inflammatory wall. Usually occurs >4 wk after onset of necrotizing pancreatitis.
• CECT criteria • Heterogeneous with liquid and nonliquid density, with varying locations (some can seem homogeneous)

• Well-defined wall that is wholly encapsulated
• Intrapancreatic and/or extrapancreatic
• Maturation usually needs 4 wk after onset of acute necrotizing pancreatitis

CECT, contrast-enhanced CT.

Table 378.4

Complications of Acute Pancreatitis

LOCAL
Pseudocyst Sterile necrosis Infected necrosis Abscess GI bleeding • Pancreatitis-related • Splenic artery or splenic artery pseudoaneurysm rupture • Splenic vein rupture • Portal vein rupture • Splenic vein thrombosis leading to gastroesophageal variceal bleeding • Pseudocyst or abscess hemorrhage • Postnecrosectomy bleeding Nonpancreatitis-related • Mallory-Weiss tear • Alcoholic gastropathy • Stress-related mucosal gastropathy Splenic complications • Infarction • Rupture • Hematoma • Splenic vein thrombosis Fistulization to or obstruction of the small intestine or colon Hydronephrosis
SYSTEMIC
Respiratory failure Renal failure Shock Hyperglycemia Hypocalcemia Disseminated intravascular coagulation Fat necrosis (subcutaneous nodules) Retinopathy
PSYCHOSIS

From Tenner S, Steinberg WM: Acute pancreatitis. In Feldman M, Friedman LS, Brandt LJ, editors: *Sleisenger and Fordtran's gastrointestinal and liver disease,* ed 10, Philadelphia, 2016, Elsevier (Box 58.7, p. 991).

Treatment

The aims of medical management are to relieve pain and restore metabolic homeostasis. Analgesia should be given in adequate doses. Fluid, electrolyte, and mineral balance should be restored and maintained. Nasogastric suction is useful in patients who are vomiting. Early refeeding decreases the complication rate and length of stay. While he or she is vomiting, the patient should be maintained with nothing by mouth. Recovery is usually complete within 4-5 days.

Prophylactic antibiotics are not recommended, but antibiotics are used to treat infected necrosis. Gastric acid secretion is suppressed with proton pump inhibitors. Enteral alimentation by mouth, nasogastric tube, or nasojejunal tube (in severe cases or for those intolerant of oral or nasogastric feedings) within 2-3 days of onset reduces the length of hospitalization, complication rate, and survival in patients with severe AP. In children, surgical therapy of nontraumatic AP is rarely required but may include drainage of necrotic material or abscesses. Endotherapy for common bile duct stones, ductal strictures, and for drainage of fluid collections is the standard of care when indicated.

Prognosis

Children with mild AP do well and recover within 4-5 days. When pancreatitis is associated with trauma or systemic disease, the prognosis is typically related to the associated medical conditions.

autoimmune pancreatitis
PRSS1 gene
CTRC gene
CFTR gene
SPINK1 gene
tropical pancreatitis

Acute recurrent pancreatitis (ARP) is defined as ≥2 distinct episodes of AP with intervening return of enzymes to baseline. Chronic pancreatitis (CP) is defined as the presence of typical abdominal pain plus characteristic imaging findings including pancreatic calcifications, inflammation and fibrosis, or exocrine insufficiency plus imaging findings, or endocrine insufficiency plus imaging findings. Most children with CP describe a history of ARP and tend to be older at the time of diagnosis compared with children with ARP, suggesting that ARP and CP are a disease continuum.

ARP and CP in children are often due to genetic mutations or due to congenital anomalies of the pancreatic or biliary ductal system (Tables 378.5 and 378.6). Mutations in the *PRSS1* gene (cationic trypsinogen) located on the long arm of chromosome 7, *SPINK1* gene (pancreatic trypsin inhibitor) located on chromosome 5, in the cystic fibrosis gene *(CFTR)* , and chymotrypsin C *(CTRC)* may all lead to CP (Fig. 378.2).

From Majumder S, Chari ST: Chronic pancreatitis, *Lancet* 387:1957–1966, 2016 (Fig 1, p. 1958).

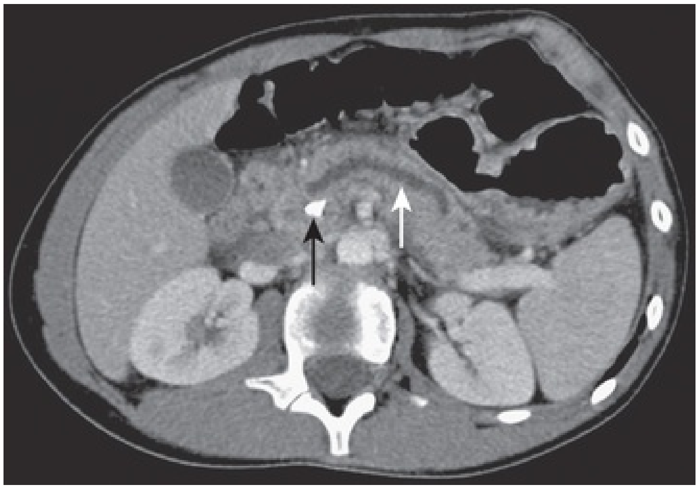

FIG. 378.2 **Chronic pancreatitis. Computed tomogram showing calcification in the head of the pancreas *(black arrow)* and dilated pancreatic duct *(white arrow)* in a 12 yr old patient. (Courtesy Dr. Janet Reid. From Wyllie R, Hyams JS, editors: *Pediatric gastrointestinal and liver disease,* ed 3, Philadelphia, 2006, WB Saunders.)**

Cationic trypsinogen has a trypsin-sensitive cleavage site. Loss of this cleavage site in the abnormal protein permits uncontrolled activation of trypsinogen to trypsin, which leads to autodigestion of the pancreas. Mutations in *PRSS1* act in an autosomal dominant fashion with incomplete penetrance and variable expressivity. Symptoms often begin in the first decade but are usually mild at the onset. Although spontaneous recovery from each attack occurs in 4-7 days, episodes become progressively more severe. Hereditary pancreatitis may be diagnosed by the presence of the disease in successive generations of a family. An evaluation during symptom-free intervals may be unrewarding until calcifications, pseudocysts, or pancreatic exocrine and endocrine insufficiency develop (Fig. 378.3 ; see Fig. 378.2). CP is a risk factor for the development of pancreatic cancer. Multiple mutations of the *PRSS1* gene associated with hereditary pancreatitis have been described.

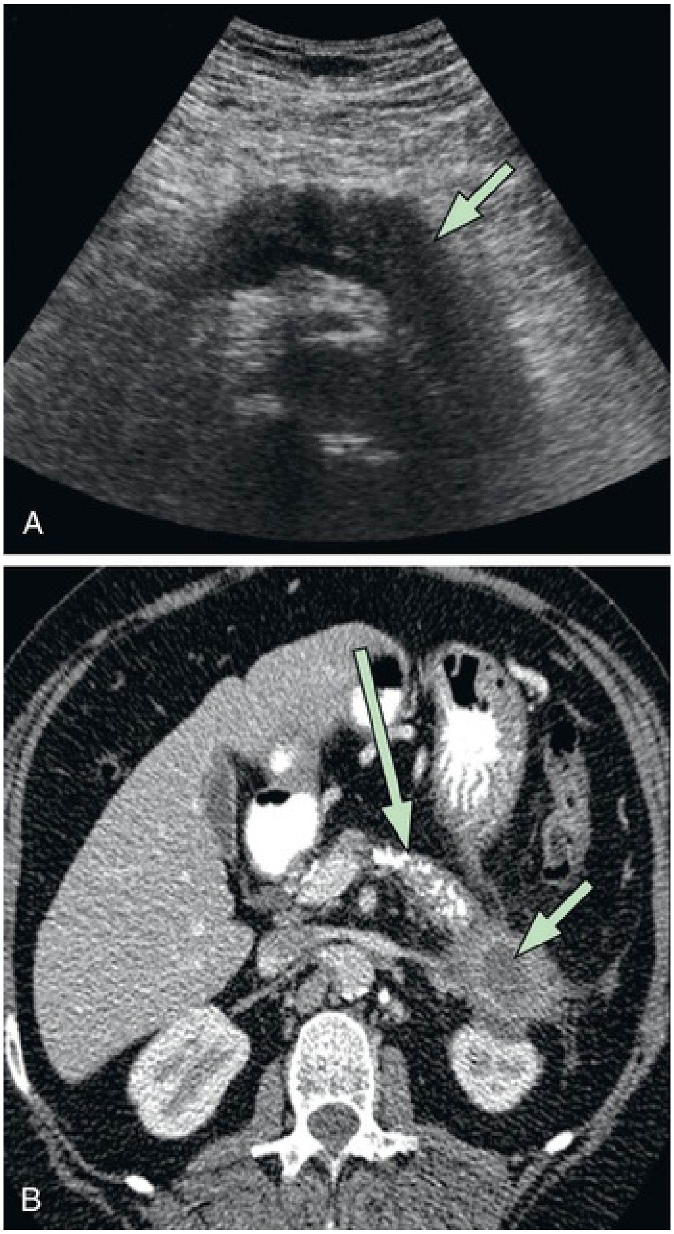

FIG. 378.3 **Examples of ultrasound and multidetector images in patients with chronic pancreatitis. A, Transabdominal ultrasound scan showing a uniformly swollen, hypoechoic pancreas *(arrow)* typical of autoimmune pancreatitis. B, Multidetector CT showing pancreatic calculi in an atrophic pancreas *(long arrow)* and a pseudocyst at the tail of the pancreas *(short arrow)* . (From Braganza JM, Lee SH, McCloy RF, McMahon MJ: Chronic pancreatitis, *Lancet* 377:1184–1197, 2011, Fig. 5, p 1191.)**

Trypsin inhibitor acts as a fail-safe mechanism to prevent uncontrolled autoactivation of trypsin. Mutations in the *SPINK1* gene have been associated with recurrent or CP. In *SPINK1* mutations, this fail-safe mechanism is lost; this gene may be a modifier gene and not the direct etiologic factor.

Mutations of the cystic fibrosis gene *(CFTR)* , associated with pancreatic sufficiency or which do not typically produce pulmonary disease, can cause CP, possibly due to ductal obstruction. Patients with genotypes associated with mild phenotypic effects have a greater risk of developing pancreatitis than those with genotypes associated with moderate to severe phenotypes.

Mutations in the chymotrypsin C gene, which cause a loss of function, may also cause recurrent pancreatitis. Indications for genetic testing include recurrent episodes of AP, CP, a family history of pancreatitis, or unexplained pancreatitis in children.

Other conditions associated with chronic, relapsing pancreatitis are hyperlipidemia (types I, IV, and V), hyperparathyroidism, and ascariasis. Previously, most cases of recurrent pancreatitis in childhood were considered idiopathic; with the discovery of gene families associated with recurrent pancreatitis, this has changed. Congenital anomalies of the ductal systems, such as pancreas divisum, are more common than previously recognized.

Autoimmune pancreatitis (AIP) typically manifests with jaundice, abdominal pain, and weight loss. The pancreas is typically enlarged and is hypodense on CT. The pathogenesis is unknown. **Type 1** is a systemic disease and is associated with high serum IgG4. In addition to pancreatitis in type 1 disease, the patient may have retroperitoneal fibrosis, orbital inflammation, aortitis, sclerosing cholangitis, cutaneous vasculitis, pulmonary fibrosis, and sialoadenitis. These extrapancreatic features may also be present in the absence of pancreatitis (Table 378.7). Tissue biopsy shows fibrosis, plasmacytosis, and positive staining for IgG4; serum IgG4 levels are not always elevated.

Table 378.7

Conditions Classification of Chronic Disorders Now Recognized to Be Part of IgG4-Related Disease

Autoimmune pancreatitis (lymphoplasmacytic sclerosing pancreatitis)
Eosinophilic angiocentric fibrosis (affecting the orbits and upper respiratory tract)
Fibrosing mediastinitis
Hypertrophic pachymeningitis
Idiopathic hypocomplementaemic tubulointerstitial nephritis with extensive tubulointerstitial deposits
Inflammatory pseudotumor (affecting the orbits, lungs, kidneys, and other organs)
Küttner tumor (affecting the submandibular glands)
Mikulicz disease (affecting the salivary and lacrimal glands)
Multifocal fibrosclerosis (commonly affecting the orbits, thyroid gland, retroperitoneum, mediastinum, and other tissues and organs)
Periaortitis and periarteritis
Inflammatory aortic aneurysm
Retroperitoneal fibrosis (Ormond disease)

Riedel thyroiditis
Sclerosing mesenteritis
Conditions once regarded as individual disorders now recognized to be part of IgG4-related disease

From Kamisawa T, Zen Y, Pillai S, Stone JH: IgG4-related disease, *Lancet* 385:1460–1471, 2015 (Panel 1, p. 1461).

Type 2 is limited to diffuse or focal involvement of just the pancreas. IgG4 levels are normal. *Both types respond to steroids* . Children with AIP typically have type 2.

Juvenile tropical pancreatitis is the most common form of CP in developing equatorial countries. The highest prevalence is in the Indian state of Kerala. Tropical pancreatitis occurs during late childhood or early adulthood, manifesting with abdominal pain and irreversible pancreatic insufficiency followed by diabetes mellitus within 10 years. The pancreatic ducts are obstructed with inspissated secretions, which later calcify. This condition is associated with mutations in the *SPINK* gene in 50% of cases.

A thorough diagnostic evaluation of every child with more than one episode of pancreatitis is indicated. Serum lipid, calcium, and phosphorus levels are determined. Stools are evaluated for ascaris, and a sweat test is performed. Plain abdominal films are evaluated for the presence of pancreatic calcifications. Abdominal ultrasound or CT scanning is performed to detect the presence of a pseudocyst. The biliary tract is evaluated for the presence of stones. After genetic counseling, evaluation of *PRSS1*, *SPINK1*, *CFTR* , and *CRTC* genotypes can be measured. Electrophysiologic tests such as nasal potential difference testing may be recommended when the diagnosis of cystic fibrosis (CF) is uncertain.

Magnetic resonance cholangiopancreatography (MRCP) and Endoscopic retrograding cholangiopancreatography (ERCP) are techniques that can be used to define the anatomy of the gland and are mandatory if surgery is considered. MRCP is the test of choice when endotherapy is not being considered and should be performed as part of the evaluation of any child with idiopathic, nonresolving, or recurrent pancreatitis and in patients with a pseudocyst before drainage. In these cases a previously undiagnosed anatomic defect that may be amenable to endoscopic or surgical therapy may be detected. Endoscopic treatments include sphincterotomy, stone extraction, drainage on pseudocysts, and insertion of pancreatic or biliary endoprosthetic stents. These treatments allow the successful nonsurgical management of conditions previously requiring surgical intervention. In patients with intractable pain, total pancreatectomy and islet cell transfusion is performed in specialist centers.

CHAPTER 379

Pancreatic Fluid Collections

Michael Wilschanski, Steven L. Werlin

Pancreatic pseudocyst formation is an uncommon sequela to acute or chronic pancreatitis.

A pancreatic pseudocyst is a circumscribed collection of fluid rich in pancreatic enzymes, blood, and necrotic tissue, typically located in the lesser sac of the abdomen. Pancreatic pseudocysts are usually complications of pancreatitis, although in children they frequently occur following abdominal trauma. They can enlarge or extend in almost any direction, thus producing a wide variety of symptoms (see Fig. 378.1*C*).

A pancreatic pseudocyst is suggested when an episode of pancreatitis fails to resolve or when a mass develops after an episode of pancreatitis. Clinical features usually include pain, nausea, and vomiting, but many patients are asymptomatic. The most common signs are a palpable mass in 50% of patients and jaundice in 10%. Other findings include ascites and pleural effusions (usually left-sided).

Pancreatic pseudocysts can be detected by transabdominal ultrasonography, CT scanning, magnetic resonance cholangiopancreatography (MRCP), endoscopic retrograde cholangiopancreatography (ERCP), and endoscopic ultrasound (EUS). Because of its ease, availability, and reliability, ultrasonography is the first choice. Sequential ultrasonography studies have demonstrated that most small pseudocysts (<6 cm) resolve spontaneously. It is recommended that the patient with acute pancreatitis undergo an ultrasonographic evaluation 4 wk after resolution of the acute episode for an evaluation of possible pseudocyst formation.

Treatment of Fluid Collections and

Necrosis

Percutaneous and endoscopic drainage of pseudocysts have replaced open surgical drainage, except for complicated or recurrent pseudocysts. Whereas a pseudocyst must be allowed to mature for 4-6 wk before surgical drainage is attempted, percutaneous or endoscopic drainage can be attempted earlier. In some cases, endoscopic creation of a cyst-gastrostomy is performed. When a surgical treatment is planned an MRCP or ERCP is performed to define anatomic abnormalities and aid the surgeon in planning his approach. EUS is helpful when an endoscopic approach is chosen.

Necrotizing pancreatitis includes both pancreatic gland necrosis and peripancreatic fat necrosis. In the initial phases, the necrotic collection is a mix of semisolid and solid tissue. Over a period of 4 wk or longer, the collection becomes more liquid and becomes encapsulated by a visible wall. At this point, the process is termed walled-off pancreatic necrosis. Sterile necrosis does not require therapy except in the rare case of a collection that obstructs a nearby viscus (e.g., duodenal, bile duct, or gastric obstruction).

The development of *infected* necrosis is the main indication for broad-spectrum antibiotic therapy. The development of fever, leukocytosis, and increasing abdominal pain suggests infection of the necrotic tissue. A CT scan may reveal evidence of air bubbles in the necrotic cavity.

CHAPTER 380

Pancreatic Tumors

Meghen B. Browning, Steven L. Werlin, Michael Wilschanski

Pancreatic tumors can be of either endocrine or nonendocrine origin. Tumors of endocrine origin include gastrinomas and insulinomas (Table 380.1). These and other functioning tumors occur in the autosomal dominantly inherited multiple endocrine neoplasia type 1 (MEN-1). Hypoglycemia accompanied by higher-than-expected insulin levels or refractory gastric ulcers (Zollinger-Ellison syndrome) indicates the possibility of a pancreatic tumor (see Chapter 372). Most gastrinomas arise outside of the pancreas. The treatment of choice is surgical removal. If the primary tumor cannot be found, or if it has metastasized, cure might not be possible. Treatment with a high dose of a proton pump inhibitor to inhibit gastric acid secretion is then indicated.

Table 380.1

Syndromes Associated With Pancreatic Neuroendocrine Tumors (pNETs)*

SYNDROME	INCIDENCE/10^6 /YEAR	MALIGNANCY (%)	HORMONE
Insulinoma	1-2	<10	Insulin
Gastrinoma (ZES)	0.5-1.5	60–90	Gastrin
VIPoma (Verner-Morrison syndrome, WDHA, pancreatic cholera)	0.05-0.2	>60	VIP
Glucagonoma	0.01-0.1	50–80	Glucagon
Somatostatinoma	Rare	>70	Somatostatin
GRFoma	Unknown	>30	GH-RF
ACTHoma	Uncommon	>95%	ACTH
pNET secreting PTH-rP	Rare	84%	PTH-rP
Pancreatic carcinoid tumor	Rare (<1% of all carcinoids)	77%	Serotonin, tachykinins
pNET secreting renin	Rare	Unknown	Renin
pNET secreting erythropoietin	Rare	Unknown	Erythropoietin

pNET secreting luteinizing hormone	Rare	Unknown	Luteinizing hormone
pNET secreting cholecystokinin (CCKoma)	Rare	Unknown	CCK

[*] These syndromes may also be caused by a GI-NET (carcinoid).

GH-RF , growth hormone–releasing factor; *PP* , pancreatic polypeptide; *PTH-rP* , parathyroid hormone–related protein; *VIP* , vasoactive intestinal polypeptide; *WDHA* , watery diarrhea, hypokalemia, achlorhydria.

From Jensen RT, Norton JA, Oberg K: Neuroendocrine tumors. In Feldman M, Friedman LS, Brandt LJ, editors: *Sleisenger and Fordtran's gastrointestinal and liver disease* , ed 10, Elsevier, 2016, Philadelphia, Table 33.1.

Insulinomas and persistent hyperinsulinemic hypoglycemia of infancy produce symptomatic hypoglycemia caused by mutations in a variety of genes, most commonly *GUUD1* and *KATP* . Massive subtotal or total pancreatectomy is the treatment of choice when medical treatment fails. These children might then develop pancreatic insufficiency and diabetes as a complication of surgery.

The **watery diarrhea–hypokalemia–acidosis syndrome** is usually produced by the secretion of vasoactive intestinal peptide by a non–α-cell tumor (VIPoma) (see Table 367.7). Vasoactive intestinal peptide levels are often, but not always, increased in the serum. Treatment is surgical removal of the tumor. When this is not possible, symptoms may be controlled by the use of octreotide acetate (cyclic somatostatin, Sandostatin), a synthetic analog of somatostatin. Pancreatic tumors secreting a variety of hormones, including glucagon, somatostatin, and pancreatic polypeptide, have also been described. The treatment is surgical resection when possible.

Pancreatoblastomas, pancreatic adenocarcinomas, cystadenomas, and sarcomas of the pancreas are rarely encountered. Pancreatoblastoma, a malignant embryonal tumor that secretes α-fetoprotein and can contain both endocrine and exocrine elements, is the most common pancreatic neoplasm in young children. Presurgical chemotherapy should be considered for lesions not primarily resectable. Resection can be curative; adjuvant chemotherapy has been used, but its effectiveness is not established.

Sarcomas are very rarely primary pancreatic but may include Ewing sarcoma, rhabdomyosarcoma, or undifferentiated soft tissue sarcomas. They are treated with multimodal therapy including chemotherapy and either resection or radiation.

Carcinoma of the exocrine pancreas is a major problem in adults, accounting for 2% of diagnoses and 5% of deaths from cancer. It is very rare in childhood. No definite causes are known. Several genetic syndromes including mutations in the *PRSS1* and *MEN-1* genes lead to an increased incidence of pancreatic cancer in adult life. The solid pseudopapillary tumor of the pancreas, also called Frantz tumor, is a more indolent pancreatic carcinoma usually found in adolescent/young adult females. Typical presenting symptoms are abdominal pain, mass, or jaundice. The treatment of choice is total surgical removal. Prognosis is very good.

Pancreatic lesions in **von Hippel-Lindau disease** are usually benign and cystic. Cystadenomas, familial adenocarcinomas, and islet cell tumors are less common. Metastases have been reported, but adjuvant therapy after surgical excision cannot yet be recommended. The diagnosis is suggested by CT scan.

Prognosis is good for completely resected endocrine tumors but very poor for sarcomas and carcinomas, excepting rare subtypes. Children who survive partial or complete pancreatectomy may have decreased pancreatic exocrine and endocrine reserve.

CHAPTER 381

Morphogenesis of the Liver and Biliary System

Stacey S. Huppert, William F. Balistreri

During the early embryonic process of gastrulation, the 3 embryonic germ layers (endoderm, mesoderm, and ectoderm) are formed. The liver and biliary system arises from cells of the ventral foregut endoderm; their development can be divided into 3 distinct processes (Fig. 381.1). First, through unknown mechanisms, the ventral foregut endoderm acquires *competence* to receive signals arising from the cardiac mesoderm. These mesodermal signals, in the form of various fibroblast growth factors and bone morphogenetic proteins, lead to *specification* of cells that have the potential to form the liver and activate liver-specific genes. During this period of hepatic fate decision, “pioneer” transcription factors, including *Foxa* and *Gata4* , bind to specific binding sites in compacted chromatin, open the local chromatin structure, and mark genes as competent. However, these will be expressed only if they are correctly induced by additional transcription factors. Newly specified cells then delaminate from the ventral foregut endoderm and migrate in a cranial ventral direction into the septum transversum in the 4th wk of human gestation to initiate liver *morphogenesis.*

FIG. 381.1 Processes involved in early liver development. A, The ventral foregut endoderm acquires *competence* to receive signals arising from the cardiac mesoderm. B, Specific cells of the ventral foregut endoderm undergo *specification* and activation of liver-specific genes under the influence of mesodermal signals. C, Liver *morphogenesis* is initiated as the newly specified cells migrate into the septum transversum under the influence of signaling molecules and extracellular matrix released by septum transversum mesenchymal cells and of primitive endothelial cells. (From Zaret K7S: Liver specification and early morphogenesis, *Mech Dev* 92:83–88, 2000.)

The growth and development of the newly budded liver require interactions with endothelial cells. Certain proteins are important for liver development in animal models (Table 381.1). In addition to these proteins, microRNAs, which consist of small noncoding, single-stranded RNAs, have a functional role in the regulation of gene expression and hepatobiliary development in zebrafish and mouse models.

Table 381.1

Selected Growth Factors, Receptors, Protein Kinases, and Transcription Factors Required for Normal Liver Development in Animal Models

INDUCTION OF HEPATOCYTE FATE THROUGH CARDIAC MESODERM

SPECIFICATION OF HEPATOCYTE LINEAGE

• HGF • Transforming growth factor-β and its downstream effectors Smad 2, Smad 3 • Hepatocyte nuclear factors (HNFs) 1α, 4α, 6
SPECIFICATION OF CHOLANGIOCYTE LINEAGE
• Jagged 1 (Notch ligand) and Notch receptors 1, 2 • HNF6, HNF1β • Wnt signaling pathway, β-catenin • Vacuolar sorting protein Vps33b

Within the ventral mesentery, proliferation of migrating cells form anastomosing hepatic cords, with the network of primitive liver cells, sinusoids, and septal mesenchyme establishing the basic architectural pattern of liver lobule (Fig. 381.2). The solid *cranial* portion of the hepatic diverticulum (pars hepatis) eventually forms the hepatic parenchyma and the intrahepatic bile ducts. The hepatic lobules are identifiable in the 6th wk of human gestation. The bile canalicular structures, including microvilli and junctional complexes, are specialized loci of the liver cell membrane; these appear very early in gestation, and large canaliculi bounded by several hepatocytes are seen by 6-7 wk.

lobule as present in the newborn. (From Andres JM, Mathis RK, Walker WA: Liver disease in infants. Part I: developmental hepatology and mechanisms of liver dysfunction, *J Pediatr* 90:686–697, 1977.)

Hepatocytes and bile duct cells (cholangiocytes) originate from hepatoblasts as common precursors. Notch signaling, which is impaired in Alagille syndrome, promotes hepatoblast differentiation into biliary epithelium, whereas hepatocyte growth factor antagonizes differentiation. The development of the intrahepatic bile ducts is determined by the development and branching pattern of the portal vein. Around the 8th wk of gestation, starting at the hilum of the liver, primitive hepatoblasts adjacent to the mesenchyme around the portal vein branches form a cylindrical sleeve, termed the *ductal plate.* From 12 wk of gestation onward, a remodeling of the ductal plate occurs, with some segments of the ductal plate undergoing tubular dilation and excess ductal plate cells gradually disappearing. The ramification of the biliary tree continues throughout human fetal life and at the time of birth the most peripheral branches of the portal veins are still surrounded by ductal plates; these require 4 more wk to develop into definitive portal ducts. Lack of remodeling of the ductal plate results in persistence of primitive ductal plate configurations, an abnormality called *ductal plate malformation* . This histopathologic lesion has been observed in liver biopsies of a variety of liver conditions, including congenital hepatic fibrosis, Caroli disease, and biliary atresia.

The *caudal* part (pars cystica) of the hepatic diverticulum becomes the gallbladder, cystic duct, and common bile duct. The distal portions of the right and left hepatic ducts develop from the extrahepatic ducts, whereas the proximal portions develop from the first intrahepatic ductal plates. The extrahepatic bile ducts and the developing intrahepatic biliary tree maintain luminal continuity and patency from the beginning of organogenesis (see Fig. 381.2*C*).

Fetal hepatic blood flow is derived from the hepatic artery and from the portal and umbilical veins, which form the portal sinus. The portal venous inflow is directed mainly to the right lobe of the liver and umbilical flow primarily to the left. The ductus venosus shunts blood from the portal and umbilical veins to the hepatic vein, bypassing the sinusoidal network. After birth, the ductus venosus becomes obliterated when oral feedings are initiated. The fetal oxygen saturation is lower in portal than in umbilical venous blood; accordingly, the right hepatic lobe has lower oxygenation and greater hematopoietic activity than the left hepatic lobe.

The transport and metabolic activities of the liver are facilitated by the structural arrangement of liver cell cords, which are formed by rows of hepatocytes, separated by sinusoids that converge toward the tributaries of the hepatic vein (the central vein) located in the center of the lobule (see Fig. 381.2*D*). This establishes the pathways and patterns of flow for substances to and from the liver. In addition to arterial input from the systemic circulation, the liver also receives venous input from the gastrointestinal tract via the portal system. The products of the hepatobiliary system are released by 2 different paths: through the hepatic vein and through the biliary system back into the intestine. Plasma proteins and other plasma components are secreted by the liver. Absorbed and circulating nutrients arrive through the portal vein or the hepatic artery and pass through the sinusoids and past the hepatocytes to the systemic circulation at the central vein. Biliary components are transported via the series of enlarging channels from the bile canaliculi through the bile ductule to the common bile duct.

Bile secretion is first noted at the 12th wk of human gestation. The major components of bile vary with stage of development. Near term, cholesterol and phospholipid content is relatively low. Low concentrations of bile acids, the absence of bacterially derived (secondary) bile acids, and the presence of unusual bile acids reflect low rates of bile flow and immature bile acid synthetic pathways.

The liver reaches a peak relative size of approximately 10% of the fetal weight at the 9th wk. Early in development, the liver is a primary site of hematopoiesis. In the 7th wk, hematopoietic cells outnumber functioning hepatocytes in the hepatic anlage. These early hepatocytes are smaller than at maturity (~20 µm vs. 30-35 µm) and contain less glycogen. Near term, the hepatocyte mass expands to dominate the organ, as cell size and glycogen content increase. Hematopoiesis is virtually absent by the 2nd postnatal mo in full-term infants. As the density of hepatocytes increases with gestational age, the relative volume of the sinusoidal network decreases. The liver constitutes 5% of body weight at birth but only 2% in an adult.

Several metabolic processes are immature in a healthy newborn infant, owing in part to the fetal patterns of activity of various enzymatic processes. Many fetal hepatic functions are carried out by the maternal liver, which provides nutrients and serves as a route of elimination of metabolic end products and toxins. Fetal liver metabolism is devoted primarily to the production of proteins required for growth. Toward term, primary functions become production and storage of essential nutrients, excretion of bile, and establishment of processes of elimination. Extrauterine adaptation requires de novo enzyme synthesis. Modulation of these processes depends on substrate and hormonal input via the placenta and on dietary and hormonal input in the postnatal period.

Hepatic Ultrastructure

Hepatocytes exhibit various ultrastructural features that reflect their biologic functions (Fig. 381.3). Hepatocytes, like other epithelial cells, are polarized, meaning that their structure and function are directionally oriented. One result of this polarity is that various regions of the hepatocyte plasma membrane exhibit specialized functions. Bidirectional transport occurs at the *sinusoidal* surface, where materials reaching the liver via the portal system enter and compounds secreted by the liver leave the hepatocyte. *Canalicular* membranes of adjacent hepatocytes form bile canaliculi, which are bounded by tight junctions, preventing transfer of secreted compounds back into the sinusoid. Within hepatocytes, metabolic and synthetic activities are contained within a number of different cell organelles. The oxidation and metabolism of heterogeneous classes of substrates, fatty acid oxidation, key processes in gluconeogenesis, and the storage and release of energy occur in the abundant mitochondria.

The endoplasmic reticulum, a continuous network of rough- and smooth-surfaced tubules and cisternae, is the site of various processes, including protein and triglyceride synthesis and drug metabolism. Low fetal activity of endoplasmic reticulum–bound enzymes accounts for a relative inefficiency of xenobiotic (drug) metabolism. The Golgi apparatus is active in protein packaging and possibly in bile secretion. Hepatocyte peroxisomes are single membrane–limited cytoplasmic organelles that contain enzymes such as oxidases and catalase and those that have a role in lipid and bile acid metabolism. Lysosomes contain numerous hydrolases that have a role in intracellular digestion. The hepatocyte cytoskeleton, composed of actin and other filaments, is distributed throughout the cell and concentrated near the plasma membrane. Microfilaments and microtubules have a role in receptor-mediated endocytosis, in bile secretion, and in maintaining hepatocyte architecture and motility.

Metabolic Functions of the Liver

Carbohydrate Metabolism

The liver regulates serum glucose levels closely via several processes, including storage of excess carbohydrate as glycogen, a polymer of glucose readily hydrolyzed to glucose during fasting. To maintain serum glucose levels, hepatocytes produce free glucose by either glycogenolysis or gluconeogenesis. Immediately after birth, an infant is dependent on hepatic glycogenolysis. Gluconeogenic activity is present at a low level in the fetal liver and increases rapidly after birth. Fetal glycogen synthesis begins at about the 9th wk of gestation, with glycogen stores most rapidly accumulated near term, when the liver contains 2-3 times the amount of glycogen of adult liver. Most of this stored glycogen is used in the immediate postnatal period. Reaccumulation is initiated at about the 2nd wk of postnatal life, and glycogen stores reach adult levels at approximately the 3rd wk in healthy full-term infants. In preterm infants, serum glucose levels fluctuate in part because efficient regulation of the synthesis, storage, and degradation of glycogen develops only near the end of full-term gestation. Dietary carbohydrates such as galactose are converted to glucose, but there is a substantial dependence on gluconeogenesis for glucose in early life, especially if glycogen stores are limited.

Protein Metabolism

During the rapid fetal growth phase, specific decarboxylases that are rate limiting in the biosynthesis of physiologically important polyamines have higher activities than in the mature liver. The rate of synthesis of albumin and secretory proteins in the developing liver parallels the quantitative changes in endoplasmic reticulum. Synthesis of albumin appears at approximately the 7th-8th wk in the human fetus and increases in inverse proportion to that of α-fetoprotein, which is the dominant fetal protein. By the 3rd-4th mo of gestation, the fetal liver is able to produce fibrinogen, transferrin, and low-density lipoproteins. From this period on, fetal plasma contains each of the major protein classes at concentrations considerably below those achieved at maturity.

The *postnatal* patterns of protein synthesis vary with the class of protein. Lipoproteins of each class rise abruptly in the 1st wk after birth to reach levels that vary little until puberty. Albumin concentrations are low in a neonate (~2.5 g/dL), reaching adult levels (~3.5 g/dL) after several mo. Levels of ceruloplasmin and complement factors increase slowly to adult values in the 1st yr. In contrast, transferrin levels at birth are similar to those of an adult, decline for 3-5 mo, and rise thereafter to achieve their final concentrations. Low levels of activity of specific proteins have implications for the nutrition of an infant. A low level of cystathionine γ-lyase (cystathionase) activity impairs the *trans* -sulfuration pathway by which dietary methionine is converted to cysteine. Consequently, the latter must be supplied in the diet. Similar dietary requirements might exist for other sulfur-containing amino acids, such as taurine.

Lipid Metabolism

Fatty acid oxidation provides a major source of energy in early life, complementing glycogenolysis and gluconeogenesis. Newborn infants are relatively intolerant of prolonged fasting, owing in part to a restricted capacity for hepatic ketogenesis. Rapid maturation of the ability of the liver to oxidize fatty acid occurs in the 1st few days of life. Milk provides the major source of calories in early life; this high-fat, low-carbohydrate diet mandates active gluconeogenesis to maintain blood glucose levels. When the glucose supply is limited, ketone body production from endogenous fatty acids can provide energy for hepatic gluconeogenesis and an alternative fuel for brain metabolism. When carbohydrates are in excess, the liver produces triglycerides. Metabolic processes involving lipids and lipoproteins are predominantly hepatic; liver immaturity or disease affects lipid concentrations and lipoproteins.

Biotransformation

Newborn infants have a decreased capacity to metabolize and detoxify certain drugs, owing to underdevelopment of the hepatic microsomal component that is the site of the specific oxidative, reductive, hydrolytic, and conjugation reactions required for these biotransformations. The major components of the monooxygenase system, such as cytochrome P450, cytochrome-*c* reductase, and the reduced form of nicotinamide-adenine dinucleotide phosphate, are present in low concentrations in fetal microsomal preparations. In full-term infants, hepatic uridine diphosphate glucuronosyltransferase and enzymes involved in the oxidation of polycyclic aromatic hydrocarbons are expressed at very low levels.

Age-related differences in pharmacokinetics vary from compound to compound. The half-life of acetaminophen in a newborn is similar to that of an adult, whereas theophylline has a half-life of approximately 100 hr in a premature infant, as compared with 5-6 hr in an adult. These differences in metabolism, as well as factors such as binding to plasma proteins and renal clearance, determine appropriate drug dosage to maximize effectiveness and to avoid toxicity. Dramatic examples of the susceptibility of newborn infants to drug toxicity are the responses to chloramphenicol (the *gray baby* syndrome) or to benzoyl alcohol and its metabolic products, which involve ineffective glucuronide and glycine conjugation, respectively. The low concentrations of antioxidants (vitamin E, superoxide dismutase, glutathione peroxidase) in the fetal and early newborn liver lead to increased susceptibility to deleterious effects of oxygen toxicity and oxidant injury through lipid peroxidation.

Conjugation reactions, which convert drugs or metabolites into water-soluble forms that can be eliminated in bile, are also catalyzed by hepatic microsomal enzymes. Newborn infants have decreased activity of hepatic uridine diphosphate glucuronosyltransferase, which converts unconjugated bilirubin to the readily excreted glucuronide conjugate and is the rate-limiting enzyme in the excretion of bilirubin. There is rapid postnatal development of transferase activity irrespective of gestational age, which suggests that birth-related, rather than age-related, factors are of primary importance in the postnatal development of activity of this enzyme. Microsomal activity can be stimulated by administration of phenobarbital, rifampin, or other inducers of cytochrome P450. Alternatively, drugs such as cimetidine can inhibit microsomal P450 activity.

Hepatic Excretory Function

Hepatic excretory function and bile flow are closely related to hepatic *bile acid* excretion and enterohepatic recirculation. Bile acids, the major products of cholesterol degradation, are incorporated into mixed micelles with cholesterol and phospholipid. These micelles act as an efficient vehicle for solubilization and intestinal absorption of lipophilic compounds, such as dietary fats and fat-soluble vitamins. Secretion of bile acids by the liver cells is the major determinant of bile flow in the mature animal. Accordingly, maturity of bile acid metabolic processes affects overall hepatic excretory function, including biliary excretion of endogenous and exogenous compounds.

In humans, the 2 primary bile acids, cholic acid and chenodeoxycholic acid, are synthesized in the liver. Before excretion, they are conjugated with glycine and taurine. In response to a meal, contraction of the gallbladder delivers bile acids to the intestine to assist in fat digestion and absorption. After mediating fat digestion, the bile acids themselves are reabsorbed from the terminal ileum through specific active transport processes. They return to the liver via portal blood, are taken up by liver cells, and are reexcreted in bile. In an adult, this enterohepatic circulation involves 90–95% of the circulating bile acid pool. Bile acids that escape ileal reabsorption reach the colon, where the bacterial flora, through dihydroxylation and deconjugation, produce the secondary bile acids, deoxycholate and lithocholate. In an adult, the composition of bile reflects the excretion of the primary and also the secondary bile acids, which are reabsorbed from the distal intestinal tract.

Intraluminal concentrations of bile acids are low in newborn infants and increase rapidly after birth. The expansion of the bile acid pool is critical because bile acids are required to stimulate bile flow and absorb lipids, a major component of the diet of a newborn. Nuclear receptors, such as farnesoid X receptor, control intrahepatic bile acid homeostasis through several mechanisms, including regulation of expression of the genes encoding 2 key proteins, cholesterol 7α-hydroxylase (CYP7A1) and bile salt export pump (BSEP). These proteins are critical for bile acid synthesis and canalicular secretion, respectively. Neonatal expression of these nuclear receptors varies depending on the studied animal model and is largely unknown for humans.

Because of inefficient ileal reabsorption of bile acids and the low rate of hepatic clearance of bile acids from portal blood, serum concentrations of bile acids are commonly elevated in healthy newborns, often to levels that would suggest liver disease in older persons. Transient phases of physiologic cholestasis and physiologic steatorrhea can often be observed in low birthweight infants and in full-term infants following perinatal stress, such as hypoxia or infection, but are otherwise uncommon in healthy full-term newborns.

Many of the processes related to immaturity of the newborn in liver morphogenesis and function, as discussed earlier, are implied in the increased susceptibility of infants to liver disease associated with parenteral nutrition. The reduced bile salt pool, hepatic glutathione depletion, and deficient sulfation contribute to production of toxic lithocholic bile acids and cholestasis, whereas deficiencies of essential amino acids, including taurine and cysteine, and excessive lipid infusion can lead to hepatic steatosis in these infants. Beyond the neonatal period, disturbances in bile acid metabolism may be responsible for diverse effects on hepatobiliary and intestinal function (Table 381.2).

Table 381.2

Causes of Impaired Bile Acid Metabolism and Enterohepatic Circulation

DEFECTIVE BILE ACID SYNTHESIS OR TRANSPORT
• Inborn errors of bile acid synthesis (reductase deficiency, isomerase deficiency) • Progressive familial intrahepatic cholestasis (PFIC1, PFIC2, PFIC3) • Intrahepatic cholestasis (neonatal hepatitis) • Acquired defects in bile acid synthesis secondary to severe liver disease
ABNORMALITIES OF BILE ACID DELIVERY TO THE BOWEL
• Celiac disease (sluggish gallbladder contraction) • Extrahepatic bile duct obstruction (e.g., biliary atresia, gallstones)
LOSS OF ENTEROHEPATIC CIRCULATION OF BILE ACIDS
• External bile fistula • Cystic fibrosis • Small bowel bacterial overgrowth syndrome (with bile acid precipitation, increased jejunal absorption, and “short-circuiting”) • Drug-induced entrapment of bile acids in intestinal lumen (e.g., cholestyramine)
BILE ACID MALABSORPTION
• Primary bile acid malabsorption (absent or inefficient ileal active transport) • Secondary bile acid malabsorption • Ileal disease or resection • Cystic fibrosis
DEFECTIVE UPTAKE OR ALTERED INTRACELLULAR METABOLISM
• Parenchymal disease (acute hepatitis, cirrhosis) • Regurgitation from cells • Portosystemic shunting • Cholestasis

CHAPTER 382

Manifestations of Liver Disease

James E. Squires, William F. Balistreri

Pathologic Manifestations

Congenital and acquired alterations in hepatic structure and function (acute or chronic) can be manifest by varying patterns of reaction of the liver to cell injury. Hepatocyte injury can be caused by viral infection, drugs or toxins, hypoxia, immunologic and structural disorders, or inborn errors of metabolism. The injury results in inflammatory cell infiltration and cell death (necrosis), which may be followed by a healing process of scar formation (fibrosis) and, potentially, nodule formation (regeneration). Cirrhosis is the end result of any progressive fibrotic liver disease.

Cholestasis is an alternative or concomitant response to injury caused by extrahepatic or intrahepatic obstruction to bile flow. Substances that are normally excreted in bile, such as bile acids, conjugated bilirubin, cholesterol, and trace elements, accumulate in serum. Bile pigment accumulation in liver parenchyma can be seen in liver biopsy specimens. In *extrahepatic* obstruction, bile pigment may be visible in the intralobular bile ducts or throughout the parenchyma as bile lakes or infarcts. In *intrahepatic* cholestasis, an injury to hepatocytes or an alteration in hepatic physiology leads to a reduction in the rate of secretion of solute and water. Causes include alterations in enzymatic or canalicular transporter activity, permeability of the bile canalicular apparatus, organelles responsible for bile secretion, or ultrastructure of the cytoskeleton of the hepatocyte. The end result may be clinically indistinguishable from obstructive cholestasis.

Cirrhosis, defined histologically by the presence of bands of fibrous tissue that link central and portal areas and form parenchymal nodules, is an end stage of any acute or chronic liver disease. Cirrhosis can be *macronodular* , with nodules of various sizes (up to 5 cm) separated by broad septa, or *micronodular* , with nodules of uniform size (<1 cm) separated by fine septa; mixed forms occur. The progressive scarring results in altered hepatic blood flow, with further impairment of liver cell function. Increased intrahepatic resistance to portal blood flow leads to portal hypertension.

The liver can be secondarily involved in neoplastic (metastatic) and non-neoplastic (storage diseases, fat infiltration) processes, as well as a number of systemic conditions and infectious processes. The liver can be affected by chronic passive congestion (congestive heart failure) or acute hypoxia, with hepatocellular damage.

Clinical Manifestations

Hepatomegaly

Enlargement of the liver can be caused by several mechanisms (Table 382.1). Normal liver size estimations are based on age-related clinical indices, such as the degree of extension of the liver edge below the costal margin, the span of dullness to percussion, or the length of the vertical axis of the liver, as estimated from imaging techniques. In children, the normal liver edge can be felt up to 2 cm below the right costal margin. In a newborn infant, extension of the liver edge more than 3.5 cm below the costal margin in the right midclavicular line suggests hepatic enlargement. Measurement of liver span is carried out by percussing the upper margin of dullness and by palpating the lower edge in the right midclavicular line. This may be more reliable than an extension of the liver edge alone. The 2 measurements may correlate poorly.

Table 382.1

Mechanisms of Hepatomegaly

INCREASE IN THE NUMBER OR SIZE OF THE CELLS INTRINSIC TO THE LIVER
Storage
Fat: malnutrition, obesity, metabolic liver disease (diseases of fatty acid oxidation and Reye syndrome–like illnesses), lipid infusion (total parenteral nutrition), cystic fibrosis, medication related, pregnancy Specific lipid storage diseases: Gaucher, Niemann-Pick, Wolman disease Glycogen: glycogen storage diseases (multiple enzyme defects); total parenteral nutrition; infant of diabetic mother, Beckwith syndrome, poorly controlled type 1 diabetes mellitus (Mauriac syndrome) Miscellaneous: α_1 -antitrypsin deficiency, Wilson disease, hypervitaminosis A
Inflammation

- Hepatocyte enlargement (hepatitis)
  - Viral: acute and chronic
  - Bacterial: sepsis, abscess, cholangitis
  - Toxic: drugs
  - Autoimmune
- Kupffer cell enlargement
  - Sarcoidosis
  - Systemic lupus erythematosus
  - Hemophagocytic lymphohistiocytosis
  - Macrophage activating syndrome

INFILTRATION OF CELLS

Primary Liver Tumors: Benign

- Hepatocellular
  - Focal nodular hyperplasia
  - Nodular regenerative hyperplasia
  - Hepatocellular adenoma
- Mesodermal
  - Infantile hemangioendothelioma
  - Mesenchymal hamartoma
- Cystic masses
  - Choledochal cyst
  - Hepatic cyst
  - Hematoma
  - Parasitic cyst
  - Pyogenic or amebic abscess

Primary Liver Tumors: Malignant

- Hepatocellular
  - Hepatoblastoma
  - Hepatocellular carcinoma
- Mesodermal
  - Angiosarcoma
  - Undifferentiated embryonal sarcoma
- Secondary or metastatic processes
  - Lymphoma
  - Leukemia
  - Lymphoproliferative disease
  - Langerhans cell histiocytosis
  - Neuroblastoma
  - Wilms tumor

INCREASED SIZE OF VASCULAR SPACE

- Intrahepatic obstruction to hepatic vein outflow
  - Venoocclusive disease
  - Hepatic vein thrombosis (Budd-Chiari syndrome)
  - Hepatic vein web
- Suprahepatic
  - Congestive heart failure
- Pericardial disease/tamponade/constrictive pericarditis
- Post-Fontan procedure
- Hematopoietic: sickle cell anemia, thalassemia

INCREASED SIZE OF BILIARY SPACE

- Congenital hepatic fibrosis
- Caroli disease
- Extrahepatic obstruction

IDIOPATHIC

- Various

- Riedel lobe
- Normal variant
- Downward displacement of diaphragm

The liver span increases linearly with body weight and age in both sexes, ranging from approximately 4.5-5.0 cm at 1 wk of age to approximately 7-8 cm in boys and 6.0-6.5 cm in girls by 12 yr of age. The lower edge of the right lobe of the liver extends downward (Riedel lobe) and can normally be palpated as a broad mass in some people. An enlarged left lobe of the liver is palpable in the epigastrium of some patients with cirrhosis. Downward displacement of the liver by the diaphragm (hyperinflation) or thoracic organs can create an erroneous impression of hepatomegaly.

Examination of the liver should note the consistency, contour, tenderness, and presence of any masses or bruits, as well as assessment of spleen size, along with documentation of the presence of ascites and any stigmata of chronic liver disease.

Ultrasound is useful in assessment of liver size and consistency, as well as gallbladder size. Gallbladder length normally varies from 1.5-5.5 cm (average: 3 cm) in infants to 4-8 cm in adolescents; width ranges from 0.5-2.5 cm for all ages. Gallbladder distention may be seen in infants with sepsis. The gallbladder is often absent in infants with biliary atresia.

Jaundice (Icterus)

Yellow discoloration of the sclera, skin, and mucous membranes is a sign of hyperbilirubinemia (see Chapter 123.3). Clinically apparent jaundice in children and adults occurs when the serum concentration of bilirubin reaches 2-3 mg/dL (34-51 µmol/L); the neonate might not appear jaundiced until the bilirubin level is >5 mg/dL (>85 µmol/L). Jaundice may be the earliest and only sign of hepatic dysfunction. Liver disease must be suspected in the infant who appears only mildly jaundiced but has dark urine or acholic (light-colored) stools. Immediate evaluation to establish the cause is required.

Measurement of the total serum bilirubin concentration allows quantitation of jaundice. Bilirubin occurs in plasma in 4 forms: *unconjugated* bilirubin tightly bound to albumin; *free* or *unbound bilirubin* (the form responsible for kernicterus, because it can cross cell membranes); *conjugated bilirubin* (the only fraction to appear in urine); and *δ fraction* (bilirubin covalently bound to albumin), which appears in serum when hepatic excretion of conjugated bilirubin is impaired in patients with hepatobiliary disease. The δ fraction permits conjugated bilirubin to persist in the circulation and delays resolution of jaundice. Although the terms *direct* and *indirect* bilirubin are used equivalently with *conjugated* and *unconjugated* bilirubin, this is not quantitatively correct, because the direct fraction includes both conjugated bilirubin and δ bilirubin.

Investigation of jaundice in an infant or older child must include determination of the accumulation of both unconjugated and conjugated bilirubin. Unconjugated hyperbilirubinemia might indicate increased production, hemolysis, reduced hepatic removal, or altered metabolism of bilirubin (Table 382.2). Conjugated hyperbilirubinemia reflects decreased excretion by damaged hepatic parenchymal cells or disease of the biliary tract, which may be a result of obstruction, sepsis, toxins, inflammation, and genetic or metabolic disease (Table 382.3).

Table 382.2

Differential Diagnosis of Unconjugated Hyperbilirubinemia

INCREASED PRODUCTION OF UNCONJUGATED BILIRUBIN FROM HEME
Hemolytic Disease (Hereditary or Acquired)
Isoimmune hemolysis (neonatal; acute or delayed transfusion reaction; autoimmune) • Rh incompatibility • ABO incompatibility • Other blood group incompatibilities Congenital spherocytosis Hereditary elliptocytosis Infantile pyknocytosis Erythrocyte enzyme defects Hemoglobinopathy • Sickle cell anemia • Thalassemia • Others Sepsis Microangiopathy • Hemolytic-uremic syndrome • Hemangioma • Mechanical trauma (heart valve) Ineffective erythropoiesis Drugs Infection Enclosed hematoma Polycythemia • Diabetic mother • Fetal transfusion (recipient) • Delayed cord clamping
DECREASED DELIVERY OF UNCONJUGATED BILIRUBIN (IN PLASMA) TO HEPATOCYTE
Right-sided congestive heart failure Portacaval shunt
DECREASED BILIRUBIN UPTAKE ACROSS HEPATOCYTE MEMBRANE

Presumed enzyme transporter deficiency Competitive inhibition • Breast milk jaundice • Lucey-Driscoll syndrome • Drug inhibition (radiocontrast material) Miscellaneous • Hypothyroidism • Hypoxia • Acidosis
DECREASED STORAGE OF UNCONJUGATED BILIRUBIN IN CYTOSOL (DECREASED Y AND Z PROTEINS)
Competitive inhibition Fever
DECREASED BIOTRANSFORMATION (CONJUGATION)
Neonatal jaundice (physiologic) Inhibition (drugs) Hereditary (Crigler-Najjar) • Type I (complete enzyme deficiency) • Type II (partial deficiency) Gilbert disease Hepatocellular dysfunction
ENTEROHEPATIC RECIRCULATION
Breast milk jaundice Intestinal obstruction • Ileal atresia • Hirschsprung disease • Cystic fibrosis • Pyloric stenosis Antibiotic administration

Table 382.3

Differential Diagnosis of Neonatal and Infantile Cholestasis

INFECTIOUS
Generalized bacterial sepsis Viral hepatitis • Hepatitides A, B, C, D, E • Cytomegalovirus • Rubella virus • Herpesviruses: herpes simplex, human herpesvirus 6 and 7 • Varicella virus • Coxsackievirus • Echovirus • Reovirus type 3 • Parvovirus B19 • HIV • Adenovirus Others • Toxoplasmosis • Syphilis • Tuberculosis • Listeriosis

• Urinary tract infection
TOXIC
Sepsis Parenteral nutrition related Drug, dietary supplement, herbal related
METABOLIC
Disorders of amino acid metabolism • Tyrosinemia Disorders of lipid metabolism • Wolman disease • Niemann-Pick disease (type C) • Gaucher disease Cholesterol ester storage disease Disorders of carbohydrate metabolism • Galactosemia • Fructosemia • Glycogenosis IV Disorders of bile acid biosynthesis Other metabolic defects • α_1 -Antitrypsin deficiency • Cystic fibrosis • Hypopituitarism • Hypothyroidism • Zellweger (cerebrohepatorenal) syndrome
• Wilson disease • Gestational alloimmune liver disease (previously *neonatal iron storage disease*) • Indian childhood cirrhosis/infantile copper overload • Congenital disorders of glycosylation • Mitochondrial hepatopathies • Citrin deficiency
GENETIC OR CHROMOSOMAL
Trisomies 17, 18, 21
INTRAHEPATIC CHOLESTASIS SYNDROMES
“Idiopathic” neonatal hepatitis Alagille syndrome Intrahepatic cholestasis (progressive familial intrahepatic cholestasis [PFIC]) • FIC-1 deficiency • Bile salt export pump (BSEP) deficiency • MDR3 deficiency • Tight junction protein 2 deficiency • Farnesoid X receptor (FXR) mutations Familial benign recurrent cholestasis associated with lymphedema (Aagenaes syndrome) ARC (arthrogryposis, renal dysfunction, and cholestasis) syndrome Caroli disease (cystic dilation of intrahepatic ducts)
EXTRAHEPATIC DISEASES
Biliary atresia Sclerosing cholangitis Bile duct stricture/stenosis Choledochal–pancreaticoductal junction anomaly Spontaneous perforation of the bile duct Choledochal cyst Mass (neoplasia, stone) Bile/mucous plug (“inspissated bile”)
MISCELLANEOUS
Shock and hypoperfusion

Associated with enteritis
Associated with intestinal obstruction
Neonatal lupus erythematosus
Myeloproliferative disease (trisomy 21)
Hemophagocytic lymphohistiocytosis (HLH)
COACH syndrome (coloboma, oligophrenia, ataxia, cerebellar vermis hypoplasia, hepatic fibrosis)
Cholangiocyte cilia defects

Pruritus

Intense generalized itching can occur in patients with chronic liver disease often in association with cholestasis (conjugated hyperbilirubinemia). Symptoms can be generalized or localized (commonly to palms and soles), are usually worse at night, are exacerbated with stress and heat, and are relieved by cool temperatures. Pruritus is unrelated to the degree of hyperbilirubinemia; deeply jaundiced patients can be asymptomatic.

The pathogenesis of pruritus remains unknown, however, multiple suspected pruritogens have been reported including bile acids, histamine, serotonin, progesterone metabolites, endogenous opioids, the potent neuronal activator lysophosphatidic acid (LPA), and the LPA-forming enzyme, autotaxin (ATX). Ultimately, a multifactorial process is suspected as evidenced by the symptomatic relief of pruritus after administration of various therapeutic agents including bile acid-binding agents (cholestyramine), choleretic agents (ursodeoxycholic acid), opiate antagonists, antihistamines, serotonin reuptake inhibitors (sertraline), and antibiotics. Plasmapheresis, molecular adsorbent recirculating system therapy, and surgical diversion of bile (partial and total biliary diversion) have been used in attempts to provide relief for medically refractory pruritus.

Spider Angiomas

Vascular spiders *(telangiectasias)* , characterized by central pulsating arterioles from which small, wiry venules radiate, may be seen in patients with chronic liver disease. These are usually most prominent in the superior vena cava distribution area (on the face and chest). Their size varies between 1 and 10 mm and they exhibit central clearing with pressure. They presumably reflect altered estrogen metabolism in the presence of hepatic dysfunction.

Palmar Erythema

Blotchy erythema, most noticeable over the thenar and hypothenar eminences and on the tips of the fingers, is also noted in patients with chronic liver disease. Abnormal serum estradiol levels and regional alterations in peripheral circulation have been identified as possible causes.

Xanthomas

The marked elevation of serum cholesterol levels (to >500 mg/dL) associated with some forms of chronic cholestasis, especially Alagille syndrome, can cause the deposition of lipid in the dermis and subcutaneous tissue. Brown nodules can develop, first over the extensor surfaces of the extremities; rarely, xanthelasma of the eyelids develops.

Portal Hypertension

Portal hypertension occurs when there is increased portal resistance and/or increased portal flow. The portal system drains the splanchnic area (abdominal portion of the gastrointestinal tract, pancreas, and spleen) into the hepatic sinusoids. Normal portal pressure is between 1 and 5 mm Hg. Portal hypertension is defined as a portal pressure greater than or equal to 6 mm Hg. Clinically significant portal hypertension exists when pressure exceeds a threshold of 10-12 mm Hg. Portal hypertension is the main complication of cirrhosis, directly responsible for 2 of the most common and potentially lethal complications: ascites and variceal hemorrhage.

Ascites

Ascites is a consequence of increased hydrostatic and osmotic pressures within the hepatic and mesenteric capillaries resulting in transfer of fluid from the blood vessels to the lymphatics that overcomes the drainage capacity of the lymphatic system. Ascites can also be associated with nephrotic syndrome and other urinary tract abnormalities, metabolic diseases (such as lysosomal storage diseases), congenital or acquired heart disease, and hydrops fetalis. Factors favoring the intraabdominal accumulation of fluid include decreased plasma colloid (albumin) osmotic pressure, increased capillary hydrostatic pressure, increased ascitic colloid osmotic fluid pressure, and decreased ascitic fluid hydrostatic pressure. Abnormal renal sodium retention plays a central role.

Gastrointestinal Bleeding

Chronic liver disease may manifest as gastrointestinal hemorrhage. Bleeding may result from portal hypertensive gastropathy, gastric antral vascular ectasia, or varix rupture. Variceal hemorrhage is classically from an esophageal origin but may be caused by gastric, duodenal, peristomal, or rectal varices. Variceal hemorrhage results from increased pressure within the varix, which leads to changes in the diameter of the varix and increased wall tension. When the variceal wall strength is exceeded, physical rupture of the varix results. Given the high blood flow and pressure in the portosystemic collateral system, coupled with the lack of a natural mechanism to tamponade variceal bleeding, the rate of hemorrhage can be striking.

Encephalopathy

Hepatic encephalopathy can be manifest as any neurologic dysfunction, but it is most likely to present in subtle forms such as deterioration of school performance, sleep disturbances, depression, or emotional outbursts. It can be recurrent and precipitated by intercurrent illness, drugs, bleeding, or electrolyte and acid-base disturbances. The appearance of hepatic encephalopathy depends on the presence of portosystemic shunting, alterations in the blood–brain barrier, and the interactions of toxic metabolites with the central nervous system. Postulated causes include altered ammonia metabolism, synergistic neurotoxins, decreased cerebral oxygen metabolism and blood flow, or false neurotransmitters with plasma amino acid imbalance.

Endocrine Abnormalities

Endocrine abnormalities are more common in older adolescents and adults with hepatic disease than in children. They reflect alterations in hepatic synthetic, storage, and metabolic functions, including those concerned with hormonal metabolism in the liver. Proteins that bind hormones in plasma are synthesized in the liver, and steroid hormones are conjugated in the liver and excreted in the urine; failure of such functions can have clinical consequences. Endocrine abnormalities can also result from malnutrition or specific deficiencies.

Renal Dysfunction

Systemic disease or toxins can affect the liver and kidneys simultaneously, or parenchymal liver disease can produce secondary impairment of renal function. In hepatobiliary disorders, there may be renal alterations in sodium and water economy, impaired renal concentrating ability, and alterations in potassium metabolism. Ascites in patients with cirrhosis may be related to inappropriate retention of sodium by the kidneys and expansion of plasma volume, or it may be related to sodium retention mediated by diminished effective plasma volume.

Hepatorenal syndrome is defined as functional renal failure in patients with end-stage liver disease. The pathophysiology of hepatorenal syndrome is related to splanchnic vasodilation, mesenteric angiogenesis, and decreased effective blood volume with resulting decreased renal perfusion. The hallmark is intense renal vasoconstriction (mediated by hemodynamic, humoral, or neurogenic mechanisms) with coexistent systemic vasodilation. The diagnosis is supported by the findings of oliguria (<1 mL/kg/day), a characteristic pattern of urine electrolyte abnormalities (urine sodium <10 mEq/L, fractional excretion of sodium of <1%, urine: plasma creatinine ratio <10, and normal urinary sediment), absence of hypovolemia, and exclusion of other kidney pathology. The best treatment of hepatorenal syndrome is timely liver transplantation, with complete renal recovery expected.

Pulmonary Involvement

Hepatopulmonary syndrome (HPS) is characterized by the typical triad of hypoxemia, intrapulmonary vascular dilations, and liver disease. There is intrapulmonic right-to-left shunting of blood resulting from enlarged pulmonary vessels that prevents adequate exposure to oxygen-rich alveoli of red blood cells traveling through the center of the vessel. Shunting of vasodilatory mediators from the mesentery away from the liver is thought to contribute. HPS should be suspected and investigated in the child with chronic liver disease with history of shortness of breath or exercise intolerance and clinical examination findings of cyanosis (particularly of the lips and fingers), digital clubbing, and oxygen saturations <96%, particularly in the upright position. Treatment is timely liver transplantation; resolution of pulmonary involvement usually follows.

Portopulmonary hypertension is a condition characterized by an increase in the resistance to pulmonary arterial blood flow in the setting of portal hypertension. It is defined by a pulmonary arterial pressure >25 mm Hg at rest and above 30 mm Hg with exercise, elevated pulmonary vascular resistance with pulmonary arterial occlusion pressure, or a left-ventricular end-diastolic pressure of <15 mm Hg. Although the pathophysiology is unclear, deficiency in endothelial prostacyclin synthase and increased circulating endothelin-1 have been implicated as a cause for the vasculopathy. Autopsy studies have demonstrated the coexistence of portal hypertension, microscopic pulmonary artery thromboembolism, endothelial and smooth muscle proliferation, and platelet aggregates contributing to portopulmonary hypertension development. Symptoms suggesting a diagnosis include exertional dyspnea, fatigue, syncope, palpitations, and chest pain. Pulmonary artery directed therapy is the cornerstone of management, along with consideration of liver transplant.

Recurrent Cholangitis

Ascending infection of the biliary system is often seen in pediatric cholestatic disorders, most commonly because of Gram-negative enteric organisms such as *Escherichia coli*, *Klebsiella*, *Pseudomonas*, and *Enterococcus*. Liver transplantation is the definitive treatment for recurrent cholangitis, especially when medical therapy is not effective.

Miscellaneous Manifestations of Liver Dysfunction

Nonspecific signs of acute and chronic liver disease include anorexia, which often affects patients with anicteric hepatitis and with cirrhosis associated with chronic cholestasis; abdominal pain or distention resulting from ascites, spontaneous peritonitis, or visceromegaly; malnutrition and growth failure; and bleeding, which may be a result of altered synthesis of coagulation factors (biliary obstruction with vitamin K deficiency or excessive hepatic damage) or to portal hypertension with hypersplenism. In the presence of hypersplenism, there can be decreased synthesis of specific clotting factors, production of qualitatively abnormal proteins, or alterations in platelet number and function. Altered drug metabolism can prolong the biologic half-life of commonly administered medications.

382.1

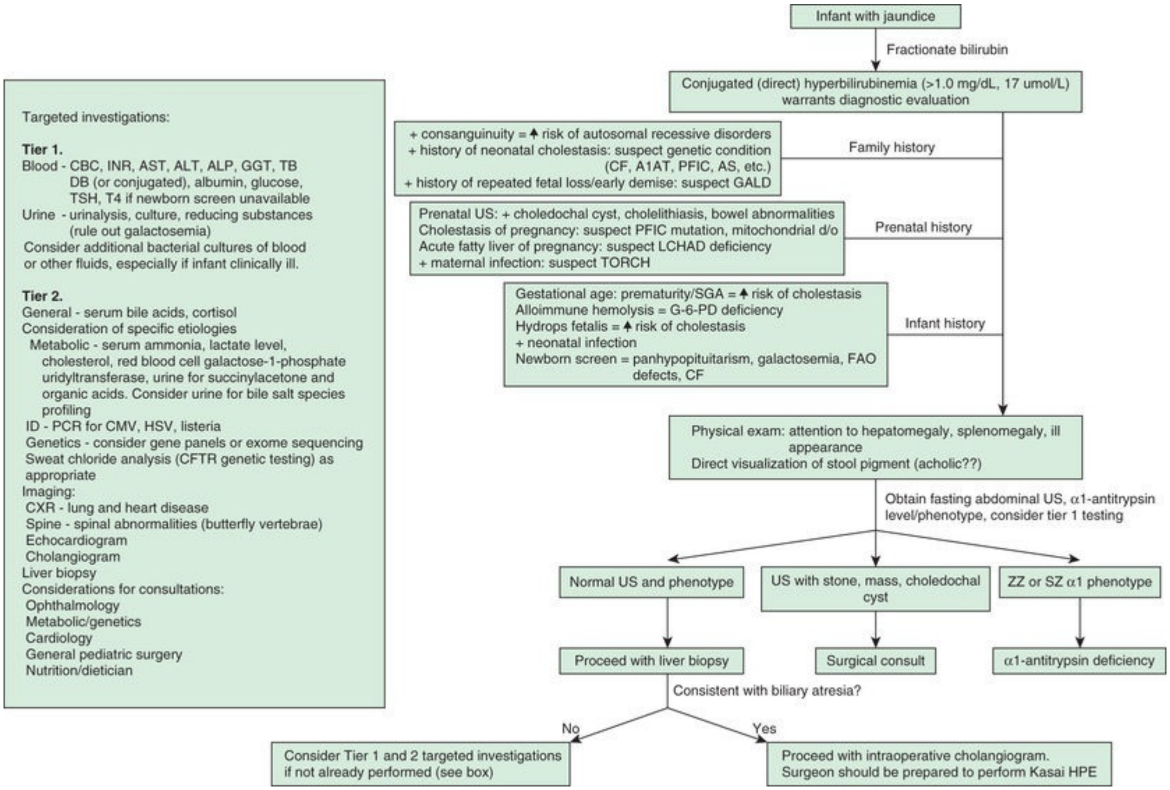
Evaluation of Patients With Possible Liver Dysfunction

James E. Squires, William F. Balistreri

Keywords

liver disease
liver biochemistries
liver function studies
liver biopsy
hepatic imaging

Adequate evaluation of an infant, child, or adolescent with suspected liver disease begins with an appropriate and accurate history, a carefully performed physical examination, and skillful interpretation of signs and symptoms. Further evaluation is aided by judicious selection of diagnostic tests, followed by the use of imaging modalities and/or a liver biopsy (Fig. 382.1). Most of the so-called liver “function” tests *do not* measure any specific hepatic function: a rise in serum aminotransferase levels reflects liver cell *injury* , an increase in immunoglobulin levels reflects an immunologic response to injury, or an elevation in serum bilirubin levels can reflect any of several disturbances of bilirubin metabolism (see Table 382.2). Any single biochemical assay provides limited information, which must be placed in the context of the entire clinical picture. The most cost-efficient approach is to become familiar with the rationale, implications, and limitations of a selected group of tests so that specific questions can be answered. Young infants with cholestatic jaundice should be evaluated promptly to identify patients needing specific medical treatment or surgical intervention.



Infant with jaundice
Fractionate bilirubin
Conjugated (direct) hyperbilirubinemia (>1.0 mg/dL, 17 umol/L) warrants diagnostic evaluation
+ consanguinity = ↑ risk of autosomal recessive disorders
+ history of neonatal cholestasis: suspect genetic condition (CF, A1AT, PFIC, AS, etc.)
+ history of repeated fetal loss/early demise: suspect GALD
Family history
Prenatal US: + choledochal cyst, cholelithiasis, bowel abnormalities
Cholestasis of pregnancy: suspect PFIC mutation, mitochondrial d/o
Acute fatty liver of pregnancy: suspect LCHAD deficiency
+ maternal infection: suspect TORCH
Prenatal history
Gestational age: prematurity/SGA = ↑ risk of cholestasis
Alloimmune hemolysis = G-6-PD deficiency
Hydrops fetalis = ↑ risk of cholestasis
+ neonatal infection
Newborn screen = panhypopituitarism, galactosemia, FAO defects, CF
Infant history
Targeted investigations:
Tier 1.
Blood - CBC, INR, AST, ALT, ALP, GGT, TB DB (or conjugated), albumin, glucose, TSH, T4 if newborn screen unavailable
Urine - urinalysis, culture, reducing substances (rule out galactosemia)
Consider additional bacterial cultures of blood or other fluids, especially if infant clinically ill.
Tier 2.
General - serum bile acids, cortisol
Consideration of specific etiologies
Metabolic - serum ammonia, lactate level, cholesterol, red blood cell galactose-1-phosphate uridyltransferase, urine for succinylacetone and organic acids. Consider urine for bile salt species profiling
ID - PCR for CMV, HSV, listeria
Genetics - consider gene panels or exome sequencing
Sweat chloride analysis (CFTR genetic testing) as appropriate
Imaging:
CXR - lung and heart disease
Spine - spinal abnormalities (butterfly vertebrae)
Echocardiogram
Cholangiogram
Liver biopsy
Considerations for consultations:
Ophthalmology
Metabolic/genetics
Cardiology
General pediatric surgery
Nutrition/dietician
Physical exam: attention to hepatomegaly, splenomegaly, ill appearance
Direct visualization of stool pigment (acholic??)
Obtain fasting abdominal US, α1-antitrypsin level/phenotype, consider tier 1 testing
Normal US and phenotype
US with stone, mass, choledochal cyst
ZZ or SZ α1 phenotype
Proceed with liver biopsy
Surgical consult
α1-antitrypsin deficiency
Consistent with biliary atresia?
No
Yes
Consider Tier 1 and 2 targeted investigations if not already performed (see box)
Proceed with intraoperative cholangiogram. Surgeon should be prepared to perform Kasai HPE

FIG. 382.1 Treatment algorithm for a 2-8 wk-old with cholestasis, based on clinical practice guidelines. *A1AT* , alpha one antitrypsin deficiency; *ALP* , alkaline phosphatase; *ALT* , alanine aminotransferase; *AS* , Alagille syndrome; *AST* , aspartate aminotransferase; *CBC* , complete blood count; *CF* , cystic fibrosis; *CFTR* , cystic fibrosis transmembrane receptor; *CMV* , cytomegalovirus; *CXR* , chest x-ray; *DB* , direct bilirubin; *FAO* , fatty acid oxidation; *GALD* , gestational alloimmune liver disease; *GGT* , gamma glutamyl transpeptidase; *HSV* , herpes simplex virus; *INR* , International normalized ratio; *LCHAD* , long-chain 3-hydroxyacyl-coenzyme A dehydrogenase deficiency; *PCR* , polymerase chain reaction; *PFIC* , progressive familial intrahepatic cholestasis; *SGA* , small for gestational age; *TB* , total bilirubin; *TSH* , thyroid stimulating hormone; *US* , ultrasound. (Data from Fawaz R, Baumann U, Ekong U, et al: Guideline for the evaluation of cholestatic jaundice in infants: joint recommendations of the North American Society for pediatric gastroenterology, hepatology, and nutrition and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition, *J Pediatr Gastroenterol Nutr* 64(1):154–168, 2017; and from Feldman AG, Mack CL: Biliary atresia: clinical lessons learned, *J Pediatr Gastroenterol Nutr* 61(2):167–75, 2015.)

For a patient with suspected liver disease, evaluation addresses the following issues in sequence: Is liver disease present? If so, what is its nature? What is its severity? Is specific treatment available? How can we monitor the response to treatment? What is the prognosis?

Biochemical Tests

Laboratory tests commonly used to screen for or to confirm a suspicion of liver disease include measurements of serum aminotransferase (Table 382.4), bilirubin (total and fractionated), alkaline phosphatase (AP) and gamma glutamyl-transpeptidase (GGT) levels, as well as determinations of prothrombin time (PT) or international normalized ratio (INR) and serum albumin level. These tests are complementary, provide an estimation of synthetic and excretory functions, and might suggest the nature of the disturbance (inflammation or cholestasis).

Table 382.4

Causes of Elevated Serum Aminotransferase Levels*

CHRONIC, MILD ELEVATIONS, ALT > AST (<150 U/L OR 5 × NORMAL)
Hepatic Causes
α_1 -Antitrypsin deficiency Autoimmune hepatitis Chronic viral hepatitis (B, C, and D) Hemochromatosis Medications and toxins Steatosis and steatohepatitis Wilson disease
Nonhepatic Causes
Celiac disease Hyperthyroidism
SEVERE, ACUTE ELEVATIONS, ALT > AST (>1,000 U/L OR >20-25 × NORMAL)
Hepatic Causes
Acute bile duct obstruction Acute Budd-Chiari syndrome Acute viral hepatitis Autoimmune hepatitis Drugs and toxins Hepatic artery ligation Ischemic hepatitis Wilson disease
SEVERE, ACUTE ELEVATIONS, AST > ALT (>1,000 U/L OR >20-25 × NORMAL)
Hepatic Cause
Medications or toxins in a patient with underlying alcoholic liver injury
Nonhepatic Cause
Acute rhabdomyolysis
CHRONIC, MILD ELEVATIONS, AST > ALT (<150 U/L, <5 × NORMAL)
Hepatic Causes
Alcohol-related liver injury (AST/ALT > 2 : 1, AST nearly always <300 U/L) Cirrhosis
Nonhepatic Causes

Hypothyroidism Macro-AST Myopathy Strenuous exercise
CHRONIC, MILD ELEVATIONS, ALT > AST (<150 U/L OR 5 × NORMAL)

[*] Virtually any liver disease can cause moderate aminotransferase elevations (5-15 × normal).

The severity of the liver disease may be reflected in clinical signs or biochemical alterations. Clinical signs include encephalopathy, variceal hemorrhage, worsening jaundice, apparent shrinkage of liver mass owing to massive necrosis, or onset of ascites. Biochemical alterations reflective of severity include hypoglycemia, acidosis, hyperammonemia, electrolyte imbalance, continued hyperbilirubinemia, marked hypoalbuminemia, or a prolonged PT or INR that is unresponsive to parenteral administration of vitamin K.

Acute liver cell injury (parenchymal disease) caused by viral hepatitis, drug- or toxin-induced liver disease, shock, hypoxemia, or metabolic disease is best suggested by a marked increase in serum aminotransferase levels. Cholestasis (obstructive disease) involves regurgitation of bile components into serum; the serum levels of total and conjugated bilirubin and serum bile acids are elevated. Elevations in serum AP, 5′ nucleotidase, and GGT levels are also sensitive indicators of obstruction or inflammation of the biliary tract. Fractionation of the total serum bilirubin level into conjugated and unconjugated bilirubin fractions helps to distinguish between elevations caused by processes such as hemolysis and those caused by hepatic dysfunction. A predominant elevation in the conjugated bilirubin level provides a relatively sensitive index of hepatocellular disease or hepatic excretory dysfunction.

Alanine aminotransferase (ALT, serum glutamate pyruvate transaminase) is *liver* specific, whereas aspartate aminotransferase (AST, serum glutamic-oxaloacetic transaminase) is derived from other organs in addition to the liver. The most marked rises of AST and ALT levels can be noted in patients with acute hepatocellular injury; a several thousand–fold elevation can result from acute viral hepatitis, toxic injury (e.g., acetaminophen), hypoxia, or hypoperfusion (see Table 382.4). After blunt abdominal trauma, parallel elevations in aminotransferase levels can provide an early clue to hepatic injury. A differential rise or fall in AST and ALT levels sometimes provides useful information. In acute hepatitis, the rise in ALT may be greater than the rise in AST. In alcohol-induced liver injury, fulminant echovirus infection, and various metabolic diseases, more predominant rises in the AST level are reported. In chronic liver disease or in intrahepatic and extrahepatic biliary obstruction, AST and ALT elevations may be less marked. Elevated serum aminotransferase levels are seen in patients with nonalcoholic fatty liver disease and nonalcoholic steatohepatitis (NASH).

Hepatic synthetic function is reflected in serum albumin and protein levels and in the PT or INR. Examination of serum globulin concentration and of the relative amounts of the globulin fractions may be helpful. Patients with autoimmune hepatitis often have high γ-globulin levels and increased titers of anti–smooth muscle, antinuclear, and anti–liver-kidney-microsome antibodies. Antimitochondrial antibodies may also be found in patients with autoimmune hepatitis. A resurgence in α-fetoprotein levels can suggest hepatoma, hepatoblastoma, or hereditary tyrosinemia. Hypoalbuminemia caused by depressed synthesis can complicate severe liver disease and serve as a prognostic factor. Deficiencies of factor V and of the vitamin K–dependent factors (II, VII, IX, and X) can occur in patients with severe liver disease or fulminant hepatic failure. If the PT or INR is prolonged as a result of intestinal malabsorption of vitamin K (resulting from cholestasis) or decreased nutritional intake of vitamin K, parenteral administration of vitamin K should correct the coagulopathy, leading to normalization within 12-24 hr. *Unresponsiveness to parenteral vitamin K suggests severe hepatic disease* . Persistently low levels of factor VII are evidence of a poor prognosis in patients with fulminant liver disease.

Interpretation of results of biochemical tests of hepatic structure and function must be made in the context of age-related changes. The activity of AP varies considerably with age. Normal growing children have significant elevations of serum AP activity originating from influx into serum of the isoenzyme that originates in bone, particularly in rapidly growing adolescents. An isolated increase in AP does not indicate hepatic or biliary disease if other liver tests are normal. Other enzymes such as 5′ nucleotidase and GGT are increased in cholestatic conditions and may be more specific for hepatobiliary disease. 5′ nucleotidase is not found in bone. GGT exhibits high enzyme activity in early life that declines rapidly with age. Cholesterol concentrations increase throughout life but may be markedly elevated in patients with intra- or extrahepatic cholestasis and decreased in severe acute liver disease such as hepatitis.

Interpretation of serum ammonia values must be carried out with caution because of variability in their physiologic determinants and the inherent difficulty in laboratory measurement.

Liver Biopsy

Liver biopsy combined with clinical data can suggest a cause for hepatocellular injury or cholestatic disease in most cases. Specimens of liver tissue can be used to determine a precise histologic diagnosis in patients with neonatal cholestasis, chronic hepatitis, nonalcoholic fatty liver disease or NASH, metabolic liver disease, intrahepatic cholestasis, congenital hepatic fibrosis, or undefined portal hypertension. The sample may be subjected to enzyme analysis to detect inborn errors of metabolism and to analysis of stored material such as iron, copper, or specific metabolites. Liver biopsies can monitor responses to therapy or detect complications of treatment with potentially hepatotoxic agents, such as aspirin, antiinfectives (minocycline, ketoconazole, isoniazid), antimetabolites, antineoplastics, or anticonvulsant agents.

In infants and children, needle biopsy of the liver is easily accomplished percutaneously. The amount of tissue obtained, even in small infants, is usually sufficient for histologic interpretation and for biochemical analyses, if the latter are deemed necessary. Percutaneous liver biopsy can be performed safely in infants as young as 1 wk of age. Contraindications to the percutaneous approach include prolonged PT or INR; thrombocytopenia; suspicion of a vascular, cystic, or infectious lesion in the path of the needle; and severe ascites. If administration of fresh-frozen plasma or of platelet transfusions fails to correct a prolonged PT, INR, or thrombocytopenia, a tissue specimen can be obtained via alternative techniques. Considerations include either the open laparotomy (wedge) approach by a general surgeon or the transjugular approach under ultrasound and fluoroscopic guidance by an experienced pediatric interventional radiologist in an appropriately equipped fluoroscopy suite. The risk of development of a complication such as hemorrhage, hematoma, creation of an arteriovenous fistula, pneumothorax, or bile peritonitis is small.

Hepatic Imaging Procedures

Various techniques help define the size, shape, and architecture of the liver and the anatomy of the intrahepatic and extrahepatic biliary trees. Although imaging might not provide a precise histologic and biochemical diagnosis, specific questions can be answered, such as whether hepatomegaly is related to accumulation of fat or glycogen or is caused by a tumor or cyst. These studies can direct further evaluation such as percutaneous biopsy and make possible prompt referral of patients with biliary obstruction to a surgeon. Choice of imaging procedure should be part of a carefully formulated diagnostic approach, with avoidance of redundant demonstrations by several techniques.

A *plain x-ray study* can suggest hepatomegaly, but a carefully performed physical examination gives a more reliable assessment of liver size. The liver might appear less dense than normal in patients with fatty infiltration or denser with deposition of heavy metals such as iron. A hepatic or biliary tract mass can displace an air-filled loop of bowel. Calcifications may be evident in the liver (parasitic or neoplastic disease), in the vasculature (portal vein thrombosis), or in the gallbladder or biliary tree (gallstones). Collections of gas may be seen within the liver (abscess), biliary tract, or portal circulation (necrotizing enterocolitis).

Ultrasound provides information about the size, composition, and blood flow to the liver. Increased echogenicity is observed with fatty infiltration; mass lesions as small as 1-2 cm may be shown. Ultrasound has replaced cholangiography in detecting stones in the gallbladder or biliary tree. Even in neonates, ultrasound can accurately assess gallbladder size, detect dilation of the biliary tract, and define a choledochal cyst. In infants with biliary atresia, ultrasound findings might include small or absent gallbladder; nonvisualization of the common duct; and presence of the triangular cord sign, a triangular or tubular-shaped echogenic density in the bifurcation of the portal vein, representing fibrous remnants at the porta hepatis. Hyperechogenic hepatic parenchyma can be seen with metabolic disease (glycogen storage disease) or fatty liver (obesity, malnutrition, parenteral alimentation, corticosteroids). In patients with portal hypertension, Doppler ultrasound can evaluate patency of the portal vein, demonstrate collateral circulation, and assess size of spleen and amount of ascites. Relatively small amounts of *ascitic fluid* can also be detected. The use of Doppler ultrasound has been helpful in determining vascular patency after liver transplantation. In patients with liver lesions, newer intravenous agents consisting of insoluble gas bubbles with a lipoprotein shell have enabled contrast-enhanced ultrasonographic lesion characterization without the associated risks often accompanied by more traditional imaging modalities such as CT scan (radiation, contrast-induced renal injury) and *magnetic resonance imaging* (MRI; sedation).

CT scanning provides information similar to that obtained by ultrasound but is less suitable for use in patients younger than 2 yr of age because of the small size of structures, the paucity of intraabdominal fat for contrast, and the need for heavy sedation or general anesthesia. CT scan may be more accurate than ultrasound in detecting focal lesions such as tumors, cysts, and abscesses. When enhanced by contrast medium, CT scanning can reveal a neoplastic mass density only slightly different from that of a normal liver. When a hepatic tumor is suspected, CT scanning is currently considered the best method to define anatomic extent, solid or cystic nature, and vascularity. CT scanning can also reveal subtle differences in density of liver parenchyma, the average liver attenuation coefficient being reduced with fatty infiltration.

MRI is a useful alternative that limits radiation exposure. Magnetic resonance cholangiography can be of value in differentiating biliary tract lesions. MRI with Eovist (gadoxetate disodium) can assist in the detection and characterization of known or suspected focal liver lesions. In differentiating obstructive from nonobstructive cholestasis, CT scanning or MRI identifies the precise level of obstruction more often than ultrasound. Either CT scanning or ultrasound may be used to guide percutaneously placed fine needles for biopsies, aspiration of specific lesions, or cholangiography.

Elastography is a novel noninvasive method to assess for liver *stiffness* , a measure of the development of hepatic fibrosis in patients with liver disease. Both ultrasound and MR methods have been developed. These noninvasive techniques allow for monitoring fibrosis progression and development of cirrhosis, improved characterization of hepatic tumors, and prognostic stratification of diseases such as nonalcoholic fatty liver disease and NASH.

Radionuclide scanning relies on selective uptake of a radiopharmaceutical agent. Commonly used agents include technetium-99m–labeled sulfur colloid, which undergoes phagocytosis by Kupffer cells; ^{99m} Tc-iminodiacetic acid agents, which are taken up by hepatocytes and excreted into bile in a fashion similar to bilirubin; and gallium-67, which is concentrated in inflammatory and neoplastic cells. The anatomic resolution possible with hepatic scintiscans is generally less than that obtained with CT scanning, MRI, or ultrasound.

The ^{99m} Tc-sulfur colloid scan can detect focal lesions (tumors, cysts, abscesses) >2-3 cm in diameter. This modality can help to evaluate patients with possible cirrhosis and with patchy hepatic uptake and a shift of colloid uptake from liver to bone marrow.

Cholangiography , direct visualization of the intrahepatic and extrahepatic biliary tree after injection of opaque material, may be required in some patients to evaluate the cause, location, or extent of biliary obstruction. Percutaneous transhepatic cholangiography with a fine needle is the technique of choice in infants and young children. The likelihood of opacifying the biliary tract is excellent in patients in whom CT scanning, MRI, or ultrasound demonstrates dilated ducts. Percutaneous transhepatic cholangiography has been used to outline the biliary ductal system.

Endoscopic retrograde cholangiopancreatography is an alternative method of examining the bile ducts in older children. The papilla of Vater is cannulated under direct vision through a fiberoptic endoscope, and contrast material is injected into the biliary and pancreatic ducts to outline the anatomy. The advantage of endoscopic retrograde cholangiopancreatography is that it allows therapeutic interventions of the extrahepatic biliary tree (stone extraction, stent placement).

Selective angiography of the celiac, superior mesenteric, or hepatic artery can be used to visualize the hepatic or portal circulation. Both arterial and venous circulatory systems of the liver can be examined. Angiography is often required to define the blood supply of tumors before surgery and is useful in the study of patients with known or presumed portal hypertension. The patency of the portal system, the extent of collateral circulation, and the caliber of vessels under consideration for a shunting procedure can be evaluated. MRI can provide similar information.

Diagnostic Approach to Infants With Jaundice

Well-appearing infants can have cholestatic jaundice. Biliary atresia and neonatal hepatitis are the most common causes of cholestasis in early infancy. Biliary atresia portends a poor prognosis unless it is identified early. The best outcome for this disorder is with early surgical reconstruction (45-60 days of age). History, physical examination, and the detection of a conjugated hyperbilirubinemia via examination of total and direct bilirubin are the first steps in evaluating the jaundiced infant (see Fig. 382.1). Consultation with a pediatric gastroenterologist should be sought early in the course of the evaluation.

CHAPTER 383

Cholestasis

383.1

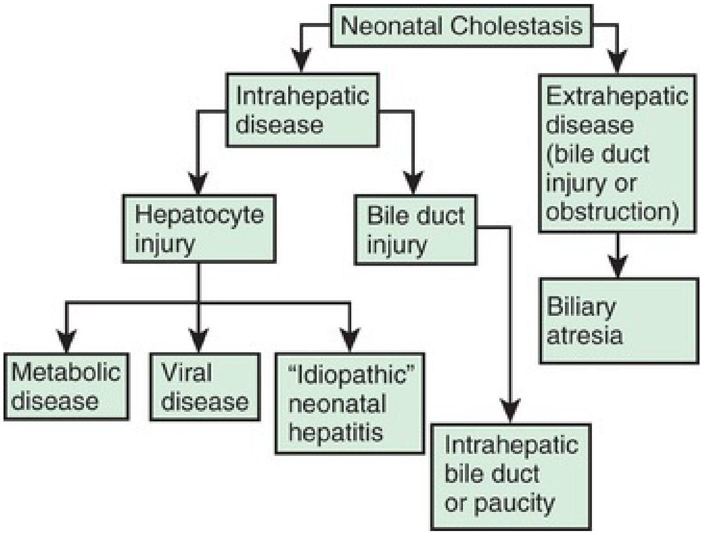
Neonatal Cholestasis

H. Hesham Abdel-Kader Hassan, William F. Balistreri

Neonatal cholestasis is defined biochemically as prolonged elevation of the serum levels of conjugated bilirubin beyond the first 14 days of life. Jaundice that appears after 2 wk of age, continues to progress, or does not resolve by this age should be evaluated and a conjugated bilirubin level determined.

Cholestasis in a newborn can be caused by infectious, genetic, metabolic, or undefined abnormalities giving rise to *mechanical* obstruction of bile flow or to *functional impairment* of hepatic excretory function and bile secretion (see Table 383.1). Mechanical lesions include stricture or obstruction of the common bile duct; biliary atresia is the prototypic obstructive abnormality. Functional impairment of bile secretion can result from congenital defects or damage to liver cells or to the biliary secretory apparatus.

Neonatal cholestasis can be divided into extrahepatic and intrahepatic disease (Fig. 383.1). The clinical features of any form of cholestasis are similar. In an affected neonate, the diagnosis of certain entities, such as galactosemia, cystic fibrosis, sepsis, or hypothyroidism, is relatively simple and a part of most neonatal screening programs. In most cases, the cause of cholestasis is more obscure. Differentiation among biliary atresia and idiopathic neonatal hepatitis is particularly difficult.



Neonatal Cholestasis
Intrahepatic disease
Extrahepatic disease (bile duct injury or obstruction)
Hepatocyte injury
Bile duct injury
Biliary atresia
Metabolic disease
Viral disease
"Idiopathic" neonatal hepatitis
Intrahepatic bile duct or paucity

FIG. 383.1 **Neonatal cholestasis. Conceptual approach to the group of diseases presenting as cholestasis in the neonate. There are areas of overlap. Patients with biliary atresia might have some degree of intrahepatic injury. Patients with "idiopathic" neonatal hepatitis might, in the future, be determined to have a primary metabolic or viral disease.**

Mechanisms

Metabolic liver disease caused by inborn errors of bile acid synthesis or transport is associated with accumulation of atypical toxic bile acids and failure to produce normal choleretic and trophic bile acids. The clinical and histologic manifestations are nonspecific and are similar to those noted in other forms of neonatal hepatobiliary injury. Autoimmune mechanisms may also be responsible for some of the enigmatic forms of neonatal liver injury.

Some of the histologic manifestations of hepatic injury in early life are not seen in older patients. Giant cell transformation of hepatocytes occurs commonly in infants with cholestasis and can occur in any form of neonatal liver injury. It is more common and more severe in intrahepatic forms of cholestasis. The clinical and histologic findings of patients with neonatal hepatitis and those with biliary atresia are somewhat similar, but there are distinguishing features. The basic process common to both is an undefined initiating insult causing inflammation of the liver cells or of the cells within the biliary tract. If the bile duct epithelium is the predominant site of disease, cholangitis can result and lead to progressive sclerosis and narrowing of the biliary tree, the ultimate state being complete obliteration *(biliary atresia)* . Injury to liver cells can present the clinical and histologic picture of "neonatal hepatitis." This concept does not account for the precise mechanism, but it offers an explanation for well-documented cases of unexpected postnatal evolution of the disease processes; infants initially considered to have neonatal hepatitis, with a patent biliary system shown on cholangiography, can later manifest biliary atresia.

Functional abnormalities in the generation of bile flow can also cause neonatal cholestasis. Bile flow is directly dependent on effective hepatic bile acid excretion by the hepatocytes. During the phase of relatively inefficient bile acid transport and metabolism by the liver cell in early life, minor degrees of hepatic injury can further decrease bile flow and lead to production of atypical and potentially toxic bile acids. Selective impairment of a single step in the series of events involved in hepatic excretion produces the full expression of a cholestatic syndrome. Specific defects in bile acid synthesis are found in infants with various forms of intrahepatic cholestasis (Table 383.1). Severe forms of familial cholestasis are associated with neonatal hemochromatosis, an alloimmune-mediated gestational (maternal antibodies against fetal hepatocytes) disease responsive to maternal intravenous immunoglobulin. Sepsis is known to cause cholestasis, presumably mediated by an endotoxin produced by *Escherichia coli*.

Table 383.1

Proposed Subtypes of Intrahepatic Cholestasis

A. Disorders of membrane transport and secretion
  1. Disorders of canalicular secretion
    a. Bile acid transport: BSEP deficiency
      i. Persistent, progressive (PFIC type 2)
      ii. Recurrent, benign (BRIC type 2)
    b. Phospholipid transport: MDR3 deficiency (PFIC type 3)
    c. Ion transport: cystic fibrosis (CFTR)
    d. Tight junction defect (TJP2 deficiency)
  2. Complex or multiorgan disorders
    a. FIC1 deficiency
      i. Persistent, progressive (PFIC type 1, Byler disease)
      ii. Recurrent, benign (BRIC type 1)
    b. Neonatal sclerosing cholangitis *(CLDN1)*
    c. Arthrogryposis-renal dysfunction-cholestasis syndrome *(VPS33B)*
B. Disorders of bile acid biosynthesis, conjugation and regulation
  1. Δ^4 -3-Oxosteroid-5β- reductase deficiency
  2. 3β- hydroxy-5-C27-steroid dehydrogenase/isomerase deficiency
  3. Oxysterol 7α- hydroxylase deficiency
  4. Bile acid-CoA Ligase deficiency
  5. BAAT deficiency (familial hypercholanemia)
  6. Farnesoid X receptor (FXR) deficiency.
C. Disorders of embryogenesis
  1. Alagille syndrome (Jagged1 defect, syndromic bile duct paucity)

2. Ductal plate malformation (ARPKD, ADPLD, Caroli disease)
D. Unclassified (idiopathic “neonatal hepatitis”): mechanism unknown

Note: FIC1 deficiency, BSEP deficiency, and some of the disorders of bile acid biosynthesis are characterized clinically by low levels of serum GGT despite the presence of cholestasis. In all other disorders listed, the serum GGT level is elevated.

ADPLD, autosomal dominant polycystic liver disease (cysts in liver only); ARPKD, autosomal recessive polycystic kidney disease (cysts in liver and kidney); BAAT, bile acid transporter; BRIC, benign recurrent intrahepatic cholestasis; BSEP, bile salt export pump in; GGT, γ-glutamyl transpeptidase; PFIC, progressive familial intrahepatic cholestasis.

From Balistreri WF, Bezerra JA, Jansen P, et al: Intrahepatic cholestasis: summary of an American Association for the study of liver diseases single-topic conference, *Hepatology* 42(1):222–235, 2005.

Evaluation

Identification of cholestasis warrants a prompt effort to accurately diagnose the cause (Table 383.2). Although cholestasis in the neonate may be the initial manifestation of numerous and potentially serious disorders, the clinical manifestations are usually similar and provide few clues about the etiology. Affected infants have icterus, dark urine, light or acholic stools, and hepatomegaly, all resulting from decreased bile flow as a result of either hepatocyte injury or bile duct obstruction. Hepatic synthetic dysfunction can lead to hypoprothrombinemia and bleeding. Administration of vitamin K should be included in the initial treatment of cholestatic infants to prevent hemorrhage (intracranial).

Table 383.2

Value of Specific Tests in the Evaluation of Patients With Suspected Neonatal Cholestasis

TEST	RATIONALE
Serum bilirubin fractionation (i.e., assessment of the serum level of conjugated bilirubin)	Indicates cholestasis
Assessment of stool color (does the baby have pigmented or acholic stools?)	Indicates bile flow into intestine
Urine and serum bile acid measurement	Confirms cholestasis; low level indicates inborn error of bile acid biosynthesis
Hepatic synthetic function (albumin, coagulation profile)	Indicates severity of hepatic dysfunction
α_1 -Antitrypsin phenotype	Suggests (or excludes) protease inhibitor ZZ phenotype
Thyroxine and thyroid-stimulating hormone	Suggests (or excludes) endocrinopathy
Lysosomal acid lipase enzyme activity	Suggests (or excludes) lysosomal acid lipase deficiency

Sweat chloride and mutation analysis	Suggests (or excludes) cystic fibrosis
Urine and serum amino acids and urine reducing substances	Suggests (or excludes) metabolic liver disease
Ultrasonography	Suggests (or excludes) choledochal cyst; might detect the triangular cord sign, suggesting biliary atresia
Liver biopsy	Distinguishes biliary atresia; suggests alternative diagnosis

In contrast to unconjugated hyperbilirubinemia, which can be physiologic, cholestasis (conjugated bilirubin elevation of any degree) in the neonate is **always pathologic** and prompt differentiation of the cause is imperative. The top priority is to recognize conditions that cause cholestasis and for which specific therapy is available to prevent further damage and avoid long-term complications such as sepsis, an endocrinopathy (hypothyroidism, panhypopituitarism), nutritional hepatotoxicity caused by a specific metabolic illness (galactosemia), or other metabolic diseases (tyrosinemia).

Another potential treatable metabolic disease, lysosomal acid lipase deficiency (LAL-D), is a rare autosomal recessive lysosomal storage disease which results in a mutation in the lysosomal acid lipase *(LIPA)* gene. The mutation creates a decline in the LAL activity, resulting in accumulation of cholesteryl esters and, to a lesser degree, triglycerides in multiple organs, including the liver, spleen, adrenal glands, lymph nodes, intestinal mucosa, vascular endothelium, and skeletal muscle. Clinically, the disease can present in 2 major phenotypes: infantile-onset Wolman disease (WD) and later-onset cholesterol ester storage disease (CESD). LAL-D usually presents in infants with an acute-severe course progressing to liver failure. Sebelipase Alfa (recombinant human LAL enzyme) is approved for the treatment of patients with LAL-D.

Hepatobiliary disease can be the initial manifestation of homozygous α_1-antitrypsin deficiency or of cystic fibrosis. Neonatal liver disease can also be associated with congenital syphilis and specific viral infections, notably echovirus and herpes viruses including cytomegalovirus. These account for a small percentage of cases of neonatal hepatitis syndrome. The hepatitis viruses (A, B, C) rarely cause neonatal cholestasis.

Mitochondrial disorders may present with acute neonatal hepatic failure, or cholestasis; prominent among these disorders are respiratory chain defects and mitochondrial DNA depletion syndromes (Table 383.3).

Table 383.3

Phenotypic Classification of Primary Mitochondrial Hepatopathies

RC (electron transport) defects (OXPHOS)
- Neonatal liver failure
  - Complex I deficiency
  - Complex IV deficiency (*SCO1* mutations)
  - Complex III deficiency (*BCS1L* mutations)
  - Co-enzyme Q deficiency
  - Multiple complex deficiencies (transfer and elongation factor mutations)
  - mtDNA depletion syndrome (*DUGOK* , *MPV17* , *POLG* , *SUCLG1* , *C10orf2/Twinkle* mutations)
- Later-onset liver dysfunction or failure
  - Alpers-Huttenlocher disease (*POLG* mutations)
  - Pearson's marrow pancreas syndrome (mtDNA deletion)
  - Mitochondrial neurogastrointestinal encephalopathy (*TYMP* mutations)
  - NNH (*MPV17* mutations)

Fatty acid oxidation defects
- Long-chain 3 hydroxyacyl-coenzyme A dehydrogenase
- Carnitine palmitoyltransferase I and II deficiencies
- Carnitine-acylcarnitinetranslocase deficiency

Urea cycle enzyme deficiencies
Electron transfer flavoprotein and electron transfer flavoprotein dehydrogenase deficiencies
Phosphoenol pyruvate carboxykinase (mitochondrial) deficiency; nonketotic hyperglycemia
Citrin deficiency; neonatal intrahepatic cholestasis caused by citrin deficiency (*SLC25A13* mutations)

NN, Navajo neurohepatopathy; OXPHOS, oxidative phosphorylation; RC, respiratory chain.

From Lee WS, Sokol RJ: Mitochondrial hepatopathies: advances in genetics, therapeutic approaches, and outcomes, *J Pediatr* 163[4]:942–948, 2013, Table 1, p. 943.

The final and critical step in evaluating neonates with cholestasis is to differentiate extrahepatic biliary atresia from neonatal hepatitis.

Intrahepatic Cholestasis

Neonatal Hepatitis

The term *neonatal hepatitis* implies intrahepatic cholestasis (see Fig. 383.1), which has various forms (see Tables 383.1 and 383.4).

Table 383.4

Molecular Defects Causing Liver Disease

GENE	PROTEIN	FUNCTION, SUBSTRATE	DISORDER
ATP8B1	FIC1	P-type ATPase; aminophospholipid translocase that flips phosphatidylserine and phosphatidylethanolamine from the outer to the inner layer of the canalicular membrane	PFIC 1 (Byler disease), BRIC 1, GFC
ABCB11	BSEP	Canalicular protein with ATP-binding cassette (ABC family of proteins); works as a pump transporting bile acids through the canalicular domain	PFIC 2, BRIC 2
ABCB4	MDR3	Canalicular protein with ATP-binding cassette (ABC family of	PFIC 3, ICP,

		proteins); works as a phospholipid flippase in canalicular membrane	cholelithiasis
AKR1D1	5β-Reductase	Δ^4 -3-Oxosteroid 5β-reductase gene; regulates bile acid synthesis	BAS: neonatal cholestasis with giant cell hepatitis
HSD3B7	C27-3β-HSD	3β-Hydroxy-5-C27-steroid oxido-reductase (C27-3β-HSD) gene; regulates bile acid synthesis	BAS: chronic intrahepatic cholestasis
CYP7BI	CYP7BI	Oxysterol 7α-hydroxylase; regulates the acidic pathway of bile acid synthesis	BAS: neonatal cholestasis with giant cell hepatitis
JAG1	JAG1	Transmembrane, cell-surface proteins that interact with Notch receptors to regulate cell fate during embryogenesis	Alagille syndrome
TJP2	Tight junction protein	Belongs to the family of membrane-associated guanylate kinase homologs that are involved in the organization of epithelial and endothelial intercellular junction; regulates paracellular permeability	Intrahepatic cholestasis
NR1H4	Nuclear hormone receptor	Farnesoid X receptor (FXR), a nuclear hormone receptor that regulates bile acid metabolism	Intrahepatic cholestasis
BAAT	BAAT	Enzyme that transfers the bile acid moiety from the acyl coenzyme A thioester to either glycine or taurine	FHC
EPHX1	Epoxide hydrolase	Microsomal epoxide hydrolase regulates the activation and detoxification of exogenous chemicals	FHC
ABCC2	MRP2	Canalicular protein with ATP-binding cassette (ABC family of proteins); regulates canalicular transport of GSH conjugates and arsenic	Dubin-Johnson syndrome
ATP7B	ATP7B	P-type ATPase; function as copper export pump	Wilson disease
CLDN1	Claudin 1	Tight junction protein	NSC
CIRH1A	Cirhin	Cell signaling?	NAICC
CFTR	CFTR	Chloride channel with ATP-binding cassette (ABC family of proteins); regulates chloride transport	Cystic fibrosis
PKHD1	Fibrocystin	Protein involved in ciliary function and tubulogenesis	ARPKD
PRKCSH	Hepatocystin	Assembles with glucosidase II α subunit in endoplasmic reticulum	ADPLD
VPS33B	Vascular protein sorting 33	Regulates fusion of proteins to cellular membrane	ARC

* Low GGT (PFIC types 1 and 2, BRIC types 1 and 2, ARC).

ADPLD, autosomal dominant polycystic liver disease; ARC, arthrogryposis–renal dysfunction–cholestasis syndrome* ; ARPKD, autosomal recessive polycystic kidney disease; ATP, adenosine triphosphate; BAAT, bile acid transporter; BAS, bile acid synthetic defect; BRIC, benign recurrent intrahepatic cholestasis; BSEP, bile salt export pump; CFTR, cystic fibrosis transmembrane conductance regulator; FHC, familial hypercholanemia; GFC, Greenland familial cholestasis; GSH, glutathione; ICP, intrahepatic cholestasis of pregnancy; NAICC, North American Indian childhood cirrhosis; NSC, neonatal sclerosing cholangitis with ichthyosis, leukocyte vacuoles, and alopecia; PFIC, progressive familial intrahepatic cholestasis.*

From Balistreri WF, Bezerra JA, Jansen P, et al: Intrahepatic cholestasis: summary of an American Association for the study of liver diseases single-topic conference, *Hepatology* 42(1):222–235, 2005.

Idiopathic neonatal hepatitis, which can occur in either a sporadic or familial form, is a disease of unknown cause. Patients with the sporadic form presumably have a specific yet undefined metabolic or viral disease. Familial forms, on the other hand, presumably reflect a genetic or metabolic aberration; in the past, patients with α-1 antitrypsin deficiency were included in this category.

Aagenaes syndrome is a form of idiopathic familial intrahepatic cholestasis associated with lymphedema of the lower extremities. The relationship between liver disease and lymphedema is not understood and may be attributable to decreased hepatic lymph flow or hepatic lymphatic hypoplasia. Affected patients usually present with episodic cholestasis with elevation of serum aminotransferase, alkaline phosphatase, and bile acid levels. Between episodes, the patients are usually asymptomatic and biochemical indices improve. Compared to other types of hereditary neonatal cholestasis, patients with Aagenaes syndrome have a relatively good prognosis. The locus for Aagenaes syndrome is mapped to a 6.6 cM interval on chromosome 15q.

Zellweger (cerebrohepatorenal) syndrome is a rare autosomal recessive genetic disorder marked by progressive degeneration of the liver and kidneys. The incidence is estimated to be 1 in 100,000 births; the disease is usually fatal by 6-12 mo of age. Affected infants have severe, generalized hypotonia and markedly impaired neurologic function with psychomotor retardation. Patients have an abnormal head shape and unusual facies, hepatomegaly, renal cortical cysts, stippled calcifications of the patellas and greater trochanter, and ocular abnormalities. Hepatic cells on ultrastructural examination show an absence of peroxisomes. Prenatal diagnosis can be achieved through assays of peroxisomal enzymes activity (dihydroacetone-phosphate acyltransferase), peroxisomal metabolites, or molecular screening techniques. MRI performed in the third trimester can allow analysis of cerebral gyration and myelination, facilitating the prenatal diagnosis of Zellweger syndrome.

Neonatal iron storage disease (neonatal hemochromatosis, gestational alloimmune liver disease) is a rapidly progressive disease characterized by increased iron deposition in the liver, heart, and endocrine organs without increased iron stores in the reticuloendothelial system. Patients have multiorgan failure and shortened survival. Familial cases are reported, and repeated affected neonates in the same family are common. This is an alloimmune disorder with maternal antibodies directed against the fetal liver. Liver injury results in decreased hepatic hepcidin expression and thus dysregulation of placental iron flux. Neonatal hemochromatosis (or fetal loss) seems to be a **gestational alloimmune disease** , and reoccurrence of severe neonatal hemochromatosis in at-risk pregnancies may be reduced by maternal treatment with weekly high-dose intravenous immunoglobulin (1 g/kg) beginning gestational age 18 wk.

Laboratory findings include hypoglycemia, hyperbilirubinemia, hypoalbuminemia, elevated ferritin, and profound hypoprothrombinemia. Serum aminotransferase levels may be high initially but normalize with the progression of the disease. The diagnosis is usually confirmed by buccal mucosal biopsy or MRI demonstrating extrahepatic siderosis. The prognosis is poor; however, liver transplantation can be curative.

Although liver transplantation for infants with neonatal hemochromatosis has a high rate of graft loss and death, outcomes are equivalent to the same age-matched recipients with acute liver failure due to other causes. Immune therapy with exchange transfusion and intravenous immunoglobulin has been reported to improve the outcome and reduce the need for liver transplantation in patients with neonatal hemochromatosis. The differential diagnosis includes familial hemophagocytic lymphohistiocytosis.

Disorders of Transport, Secretion, Conjugation, and Biosynthesis of Bile Acids

Progressive familial intrahepatic cholestasis type 1 (PFIC 1) or FIC 1 disease (formerly known as **Byler disease**) is a severe form of intrahepatic cholestasis. The disease was initially described in the Amish kindred of Jacob Byler. Affected patients present with steatorrhea, pruritus, vitamin D-deficient rickets, gradually developing cirrhosis, and low γ-glutamyl transpeptidase (GGT) levels. **PFIC 1** (FIC-1 deficiency) has been mapped to chromosome 18ql2 and results from defect in the gene for FIC-1 (ATP8Bl; see Tables 383.4 and 383.5). FIC-1 is a P-type adenosine triphosphatase that functions as aminophospholipid flippase, facilitating the transfer of phosphatidyl serine and phosphatidyl ethanolamine from the outer to inner hemileaflet of the cellular membrane. FIC-1 might also play a role in intestinal bile acid absorption, as suggested by the high level of expression in the intestine. Defective FIC-1 might also result in another form of intrahepatic cholestasis: **benign recurrent intrahepatic cholestasis (BRIC) type I** . The disease is characterized by recurrent bouts of cholestasis, jaundice, and severe pruritus. The episodes vary from few episodes per year to 1 episode per decade but can profoundly affect the quality of life. Nonsense, frame shift, and deletional mutations cause PFIC type I; missense and split-type mutations result in BRIC type I. Typically, patients with BRIC type I have normal serum cholesterol and GGT levels.

Table 383.5

Progressive Familial Intrahepatic Cholestasis

	PFIC1	PFIC2	PFIC3
Transmission	Autosomal recessive	Autosomal recessive	Autosomal recessive
Chromosome	18q21-22	2q24	7q21
Gene	*ATP8B1/F1C1*	*ABCB11/BSEP*	*ABCB4/MDR3*
Protein	FIC1	BSEP	MDR3
Location	Hepatocyte, colon, intestine, pancreas; on apical membranes	Hepatocyte canalicular membrane	Hepatocyte canalicular membrane
Function	ATP-dependent aminophospholipid flippase; unknown effects on intracellular signaling	ATP-dependent bile acid transport	ATP-dependent phosphatidylcholine translocation
Phenotype	Progressive cholestasis, diarrhea, steatorrhea, growth failure, severe pruritus	Rapidly progressive cholestatic giant cell hepatitis, growth failure, pruritus	Later-onset cholestasis, portal hypertension, minimal pruritus, intraductal and gallbladder lithiasis
Histology	Initial bland cholestatic; coarse, granular canalicular bile on EM	Neonatal giant cell hepatitis, amorphous canalicular bile on EM	Proliferation of bile ductules, periportal fibrosis, eventually biliary cirrhosis
Biochemical features	Normal serum γGT; high serum, low biliary bile acid concentrations	Normal serum γGT; high serum, low biliary bile acid concentrations	Elevated serum γGT; low to absent biliary PC; absent serum LPX; normal biliary bile acid concentrations
Treatment	Biliary diversion, ileal exclusion, liver transplantation, but post-OLT diarrhea, steatorrhea, fatty liver	Biliary diversion, liver transplantation	UDCA if residual PC secretion; liver transplantation

ATP, adenosine triphosphate; BCEP, B-cell epitope peptide; BSEP, bile salt export pump; EM, electron microscopy; γGT, γ-glutamyl transpeptidase; LPX, lipoprotein X; OLT, orthotopic liver transplantation; PC, phosphatidylcholine; PFIC, progressive familial intrahepatic cholestasis; UDCA, ursodeoxycholic acid.

From Suchy FJ, Sokol RJ, Balistreri WF, editors: *Liver disease in children* , ed 4, New York, 2014, Cambridge University Press.

PFIC type 2 (BSEP deficiency) is mapped to chromosome 2q24 and is similar to PFIC 1. The disease results from defects in the canalicular adenosine triphosphate -dependent bile acid transporter BSEP (ABCB11). The progressive liver disease results from accumulation of bile acids secondary to reduction in canalicular bile acid secretion. Mutation in ABC11 is also described in another disorder, BRIC type 2, characterized by recurrent bouts of cholestasis.

In contrast to PFIC I and PFIC 2, patients with **PFIC type 3** *(MDR3 disease)* have *high* levels of GGT. The disease results from defects in a canalicular phospholipids flippase, MDR3 *(ABCB4),* which results in deficient translocation of phosphatidylcholine across the canalicular membrane. Mothers who are heterozygous for this gene can develop intrahepatic cholestasis during pregnancy.

Familial hypercholanemia is characterized by an elevated serum bile acid concentration, pruritus, failure to thrive, and coagulopathy. Familial hypercholanemia is a complex genetic trait associated with mutation of bile acid coenzyme A (CoA), amino acid N-acyltransferase (encoded by bile acid transporter *[BAAT]*) as well as mutations in tight junction protein 2 (encoded by *TJP 2,* also known as *ZO-2*). Mutation of BAAT, which is a bile acid-conjugating enzyme, abrogates the enzyme activity. Patients who are homozygous for this mutation have only unconjugated bile acids in their bile. Mutation of both BAAT and TJP 2 can disrupt bile acid transport and circulation. Patients with familial hypercholanemia usually respond to the administration of ursodeoxycholic acid.

Defective bile acid biosynthesis is postulated to be an initiating or perpetuating factor in neonatal cholestatic disorders; the hypothesis is that inborn errors in bile acid biosynthesis lead to absence of normal trophic or choleretic primary bile acids and accumulation of atypical (hepatotoxic) metabolites. Inborn errors of bile acid biosynthesis cause acute and chronic liver disease; early recognition allows institution of targeted bile acid replacement, which reverses the hepatic injury. Several specific defects have been described:

- **Deficiency of Δ^4 -3-oxosteroid-5β reductase** , the fourth step in the pathway of cholesterol degradation to the primary bile acids, manifests with significant cholestasis and liver failure developing shortly after birth, with coagulopathy and metabolic liver injury resembling tyrosinemia. Hepatic histology is characterized by lobular disarray with giant cells, pseudoacinar transformation, and canalicular bile stasis. Mass spectrometry will display increased urinary bile acid excretion and the predominance of oxo-hydroxy and oxo-dihydroxy cholenoic acids. The diagnosis can be established by screening for mutations in *SRD5B1 (AKR1D1)* , the gene encoding Δ4-3-oxosteroid 5β-reductase. Treatment with cholic acid and ursodeoxycholic acid is associated with normalization of biochemical, histologic, and clinical features.

- **Deficiency of 3β-hydroxy- Δ^5 -C^{27} -steroid oxidoreductase (3β-HSD),** the second step in bile acid biosynthesis from cholesterol, causes PFIC. Affected patients usually have jaundice with increased aminotransferase levels and hepatomegaly; GGT levels and serum cholylglycine levels are *normal* . The histology is variable, ranging from giant cell hepatitis to chronic hepatitis. The diagnosis, suggested by mass spectrometry detection of C^{24} bile acids in urine, which retain the 3β-hydroxy-Δ^5 structure, can be confirmed by genetic screening for mutations in *HSD3B7* , the gene encoding 3β-HSD. Primary bile acid therapy, administered orally to down regulate cholesterol 7α-hydroxylase activity, to limit the production of 3β-hydroxy-Δ^5 bile acids, and to facilitate hepatic clearance, has been effective in reversing hepatic injury.

Bile Acid-Coenzyme a Ligase Deficiency

Conjugation with the amino acids glycine and taurine is the final step in bile acid synthesis. Two enzymes catalyze the amidation of bile acids. In the first reaction, a CoA thioester is formed by the rate-limiting bile acid-CoA ligase. The other reaction involves the coupling of glycine or taurine and is catalyzed by a cytosolic bile acid-CoA:amino acid N-acyltransferase. Affected patients present with conjugated hyperbilirubinemia, growth failure, or fat-soluble vitamin deficiency, and are identified with mutation of the bile acid-CoA ligase gene. Administration of conjugates of the primary bile acid, glycocholic acid, may be beneficial and can correct the fat-soluble vitamin malabsorption and improve growth.

Disorders of Embryogenesis

Alagille syndrome (arteriohepatic dysplasia) is the most common syndrome with intrahepatic bile duct paucity. Bile duct *paucity* (often erroneously called *intrahepatic biliary atresia*) designates an absence or marked reduction in the number of interlobular bile ducts in the portal triads, with normal-size branches of portal vein and hepatic arteriole. Biopsy in early life often reveals an inflammatory process involving the bile ducts; subsequent biopsy specimens then show subsidence of the inflammation, with residual reduction in the number and diameter of bile ducts, analogous to the *disappearing bile duct syndrome* noted in adults with immune-mediated disorders. Serial assessment of hepatic histology often suggests progressive destruction of bile ducts.

Clinical manifestations of Alagille syndrome are expressed in various degrees and can be nonspecific; they include unusual facial characteristics (broad forehead; deep-set, widely spaced eyes; long, straight nose; and an underdeveloped mandible). There may also be ocular abnormalities (posterior embryotoxon, microcornea, optic disk drusen, shallow anterior chamber), cardiovascular abnormalities (usually peripheral pulmonic stenosis, sometimes tetralogy of Fallot, pulmonary atresia, ventricular septal defect, atrial septal defect, aortic coarctation), vertebral defects (butterfly vertebrae, fused vertebrae, spina bifida occulta, rib anomalies), and tubulointerstitial nephropathy (Table 383.6 , Fig. 383.2 –383.3). Other findings such as short stature, pancreatic insufficiency, vasculopathy (Moyamoya syndrome, stroke), and defective spermatogenesis can reflect or produce nutritional deficiency. Patients with Alagille syndrome are likely to have pruritus, xanthomas with markedly elevated serum cholesterol levels, and neurologic complications of vitamin E deficiency if untreated. Mutations in human Jagged l gene *(JAG1)*, which encodes a ligand for the notch receptor, are linked to ~90% of patients with Alagille syndrome. Alagille syndrome type 2 is due to mutations in *NOTCH2.* Although cirrhosis and manifestations of end-stage liver disease are uncommon early in life, some patients may later develop these complications. Long-term care includes monitoring cardiac and renal function as well as screening for the development of hepatocellular carcinoma.

Table 383.6

Classic Criteria, Based on 5 Body Systems for a Diagnosis of Alagille Syndrome

SYSTEM/PROBLEM	DESCRIPTION
Liver/cholestasis	Usually presenting as jaundice with conjugated hyperbilirubinemia in the neonatal period, often with pale stools
Dysmorphic facies	Broad forehead, deep-set eyes, sometimes with upslanting palpebral fissures, prominent ears, straight nose with bulbous tip, and pointed chin giving the face a somewhat triangular appearance
Congenital heart disease	Most frequently peripheral pulmonary artery stenosis, but also pulmonary atresia, atrial septal defect, ventricular septal defect, and tetralogy of Fallot
Axial skeleton/vertebral anomalies	“Butterfly” vertebrae may be seen on an antero-posterior radiograph, and occasionally hemivertebrae, fusion of adjacent vertebrae, and spina bifida occulta
Eye/posterior embryotoxon	Anterior chamber defects, most commonly posterior embryotoxon, which is prominence of Schwalbe's ring at the junction of the iris and cornea

Biliary Atresia

The term *biliary atresia* is imprecise because the anatomy of abnormal bile ducts in affected patients varies markedly. A more appropriate terminology would reflect the pathophysiology, namely noncystic obliterative cholangiopathy. The term *obliterative cholangiopathy* may be divided into 2 major types: cystic and noncystic. The cystic disorders include the different types of **choledochal cysts** while the noncystic forms are different variants of biliary atresia in addition to neonatal sclerosing cholangitis.

Cystic biliary atresia is an uncommon variant of biliary atresia (about 10–20% of cases) and has a relatively favorable prognosis particularly with early surgery. This disorder is often misdiagnosed as a choledochal cyst. However, it can be differentiated by the absence of epithelial lining in biliary atresia as well as the lack of communication with the intrahepatic bile ducts as seen on intraoperative cholangiography.

There are 3 major variants of **noncystic biliary atresia** (Fig. 383.4). The **first type** (correctable biliary atresia), which presents in only 7% of the cases, is characterized by patency of the proximal extrahepatic bile ducts with atresia of the distal bile duct. In the **second type** , which is seen in 15% of the cases, there is atresia of the common hepatic duct at different levels. Patency of the gallbladder, cystic duct, and the common bile duct can be seen in some cases. The patent gall bladder and bile ducts can be used as biliary conduit. In the **third type** (the most *common* variant) there is nonpatency of the entire extrahepatic biliary system and intrahepatic bile ducts at the hilum.

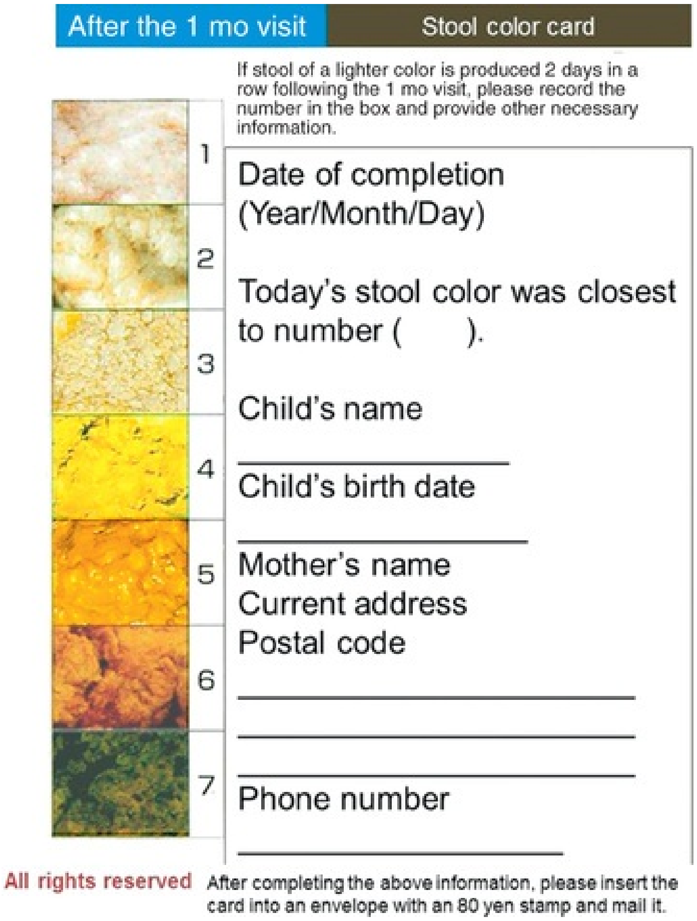
FIG. 383.4 Biliary atresia classified according to the area of involvement *(gray colored)* . Type I: Atresia of the distal bile duct with patent proximal extrahepatic bile duct. Type IIa: Atresia of the common hepatic duct. Type IIb: Atresia of the common hepatic duct, cystic duct, and common bile duct. Type III: Nonpatency of the entire extrahepatic biliary system and intrahepatic bile ducts at the hilum. (Modified from A-Kader HH, Feerick J, Rodriguez-Davalos M: After two centuries biliary atresia remains the darkest chapter in pediatric hepatology, *Ann Pediatr Child Health* 3[2]:1044,

2015, Fig. 2.)

Biliary atresia can also be classified into 3 categories based on the presence or absence of associated anomalies. The most common type, known as *perinatal* biliary atresia, affecting about 70% of the patients, is not associated with other anomalies or malformations. The patients may not be jaundiced at birth. An evolving process leads to progressive jaundice and acholic stools. Another type, seen in about 15% of the cases, can be associated with heterotaxia malformations including situs inversus, malrotation, polysplenia, interrupted inferior vena cava, and congenital heart disease. This type is also known as **biliary atresia splenic malformation (BASM) syndrome** and usually carries a poor prognosis. Other congenital malformations such as choledochal cysts, kidney anomalies, and cardiac defects can be seen in the third type, which affects the remaining 15% of the cases.

Biliary atresia has been detected in l in 10,000-15,000 live births. Biliary atresia is more common in East Asian countries; patients may be born term or preterm. Screening for biliary atresia in infants after birth is not universal, but stool color cards that help detect acholic stools have been used with some success (Fig. 383.5). In addition, any infant with new onset or persistent jaundice beyond 2 wk of life should be screened with a total and conjugated bilirubin level to detect cholestasis.



After the 1 mo visit

Stool color card

If stool of a lighter color is produced 2 days in a row following the 1 mo visit, please record the number in the box and provide other necessary information.

Date of completion (Year/Month/Day)

Today's stool color was closest to number (   ).

After completing the above information, please insert the card into an envelope with an 80 yen stamp and mail it.

FIG. 383.5 An example of a stool color card used in Tochigi Prefecture from August 1994 to March 2011 consisted of 7 photographic images of stool color taken in both healthy infants and infants with biliary atresia. Images 1-3 denote abnormal stool color, whereas images 4-7 reflect normal stool color. (From Gu YH, Yokoyama K, Mizuta K, et al: Stool color card screening for early detection of biliary atresia and long-term native liver survival: a 19-year cohort study in Japan, *J Pediatr* 166[4]:897–902, 2015, Fig. 2.)

Differentiation of Idiopathic Neonatal Hepatitis From Biliary Atresia

It may be difficult to clearly differentiate infants with biliary atresia who require surgical correction from those with intrahepatic disease (neonatal hepatitis) and patent bile ducts. No single biochemical test or imaging procedure is entirely satisfactory. Diagnostic schemas incorporate clinical, historical, biochemical, and radiologic features.

Idiopathic neonatal hepatitis has a familial incidence of approximately 20%, whereas biliary atresia is unlikely to recur within the same family. A few infants with fetal onset of biliary atresia have an increased incidence of other abnormalities, such as the polysplenia syndrome with abdominal heterotaxia, malrotation, levocardia, and intraabdominal vascular anomalies. Persistently acholic stools suggest biliary obstruction (biliary atresia), but patients with severe idiopathic neonatal hepatitis can have a transient severe impairment of bile excretion. Consistently pigmented stools rule against biliary atresia. Palpation of the liver might find an abnormal size or consistency in patients with biliary atresia; this is less common with idiopathic neonatal hepatitis.

Abdominal ultrasound is a helpful diagnostic tool in evaluating neonatal cholestasis because it identifies choledocholithiasis, perforation of the bile duct, or other structural abnormalities of the biliary tree such as a choledochal cyst. In patients with biliary atresia, ultrasound can detect associated anomalies such as abdominal polysplenia and vascular malformations. The gallbladder either is not visualized or is a microgallbladder in patients with biliary atresia. Children with intrahepatic cholestasis caused by idiopathic neonatal hepatitis, cystic fibrosis, or total parenteral nutrition can have similar ultrasonographic findings. Ultrasonographic triangular cord sign, which represents a cone-shaped fibrotic mass cranial to the bifurcation of the portal vein, may be seen in patients with biliary atresia (Figs. 383.6 and 383.7). The echogenic density, which represents the fibrous remnants at the porta hepatis of biliary atresia cases at surgery, may be a helpful diagnostic tool in evaluating patients with neonatal cholestasis. High-frequency ultrasonography (HUS) imaging produces much improved spatial resolution by sacrificing the depth of penetration and may prove to be superior to conventional ultrasonography in the diagnostic process of biliary atresia.

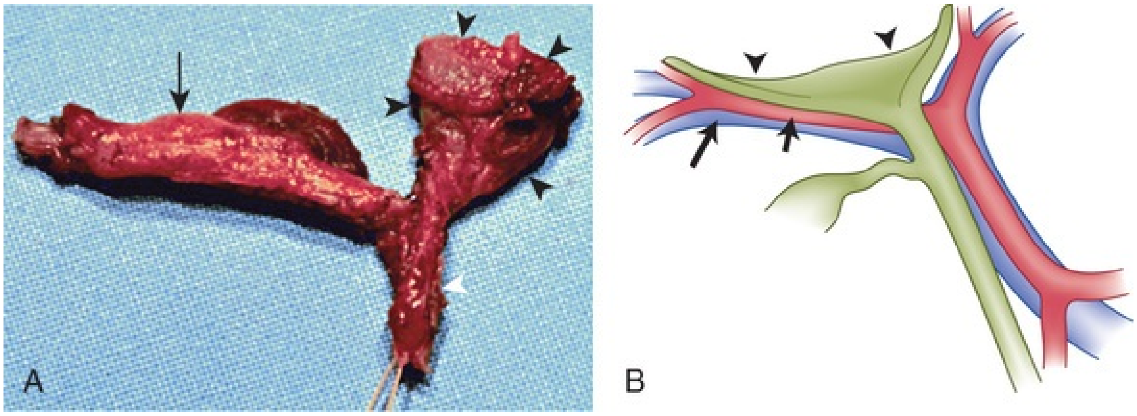

FIG. 383.6 Surgical findings of biliary atresia. A, Photograph of surgical specimen of obliterated extrahepatic bile ducts shows the fibrous ductal remnant *(black arrowheads)* in the porta hepatis, atretic gallbladder *(arrow)* , and fibrous common bile duct *(white arrowhead)* . The fibrous ductal remnant is a triangular cone-shaped mass. B, Schematic represents the anatomic relationship between the fibrous ductal remnant and blood vessels around the porta hepatis. The triangular, cone-shaped, fibrous ductal remnant *(black arrowheads, green*) is positioned anterior and slightly superior to the portal vein *(long arrow, blue)* and the hepatic artery *(short arrow, red)* . (A, From Park WH, Choi SO, Lee HJ, et al: A new diagnostic approach to biliary atresia with emphasis on the ultrasonographic triangular cord sign: comparison of ultrasonography, hepatobiliary scintigraphy, and liver needle biopsy in the evaluation of infantile cholestasis, *J Pediatr Surg* 32[11]:1555–1559, 1997.)

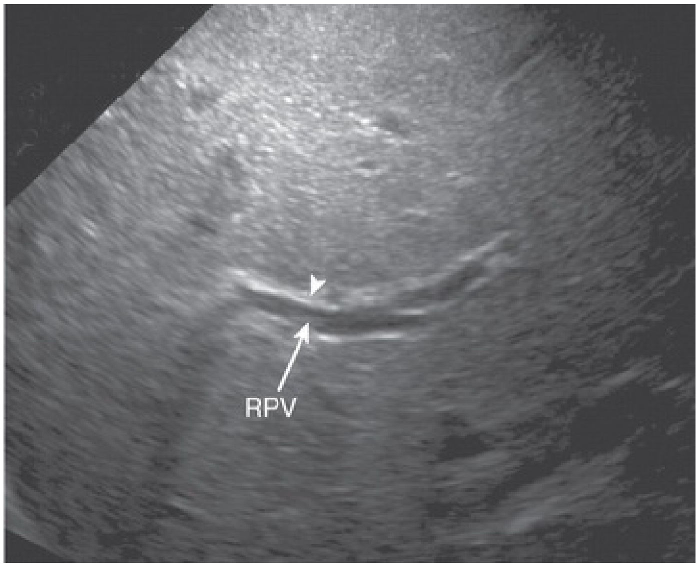

FIG. 383.7 Biliary atresia in an 8 wk old male with elevated conjugated bilirubin. Transverse sonogram shows the triangular cord sign seen as a linear cord of echogenicity *(arrowhead)* along the right portal vein *(RPV)* . (From Lowe LH: Imaging hepatobiliary disease in children, *Semin Roentgenol* 43[1]:39–49, 2008, Fig. 1B.)

Hepatobiliary scintigraphy with technetium-labeled iminodiacetic acid derivatives is a sensitive but not specific test for biliary atresia. It fails to identify other structural abnormalities of the biliary tree or vascular anomalies. The lack of the specificity of the test and the inherent delay (5 days of phenobarbital preloading) makes this procedure impractical and of limited value in the evaluation of children with suspected biliary atresia.

The role of endoscopic retrograde cholangiopancreatography (ERCP) in the diagnostic process of biliary atresia remains indeterminate. Similarly, the value of magnetic resonance cholangiopancreatography (MRCP) in the diagnosis of biliary atresia has not been established.

Percutaneous liver biopsy is the most valuable procedure in the evaluation of neonatal hepatobiliary diseases and provides the most reliable discriminatory evidence. Biliary atresia is characterized by bile ductular proliferation, the presence of bile plugs, and portal or perilobular edema and fibrosis, with the basic hepatic lobular architecture intact. In neonatal hepatitis, there is severe, diffuse hepatocellular disease, with distortion of lobular architecture, marked infiltration with inflammatory cells, and focal hepatocellular necrosis; the bile ductules show little alteration. Giant cell transformation is found in infants with either condition and has no diagnostic specificity.

The histologic changes seen in patients with idiopathic neonatal hepatitis can occur in other diseases, including α_1 -antitrypsin deficiency, galactosemia, and various forms of intrahepatic cholestasis. Although paucity of intrahepatic bile ducts may be detected on liver biopsy even in the **first** few weeks of life, later biopsies in such patients reveal a more characteristic pattern.

Management of Patients With Suspected Biliary Atresia

All patients with suspected biliary atresia should undergo exploratory laparotomy and direct cholangiography to determine the presence and site of obstruction. Direct drainage can be accomplished in the patients with a correctable lesion. When no correctable lesion is found, an examination of frozen sections obtained from the transected porta hepatis can detect the presence of biliary epithelium and determine the size and patency of the residual bile ducts. In some cases, the cholangiogram indicates that the biliary tree is patent but of diminished caliber, suggesting that the cholestasis is not due to biliary tract obliteration but to bile duct paucity or markedly diminished flow in the presence of intrahepatic disease. In these cases, transection of or further dissection into the porta hepatis should be avoided.

For patients in whom no correctable lesion is found, the **hepatoportoenterostomy (Kasai) procedure** should be performed. The rationale for this operation is that minute bile duct remnants, representing residual channels, may be present in the fibrous tissue of the porta hepatis; such channels may be in direct continuity with the intrahepatic ductule system. In such cases, transection of the porta hepatis with anastomosis of bowel to the proximal surface of the transection might allow bile drainage. If flow is not rapidly established in the first month of life, progressive obliteration and cirrhosis ensue. If microscopic channels of patency >150 μm in diameter are found, postoperative establishment of bile flow is likely. *The success rate for establishing good bile flow after the Kasai operation is much higher (90%) if performed before 8 wk of life.* Therefore, early referral and prompt evaluation of infants with suspected biliary atresia is important. Educating parents, increased awareness among healthcare providers, and broader implementation of the stool card program are imperative to avoid delayed diagnosis and achieve favorable outcomes.

Some patients with biliary atresia, even of the *noncorrectable* type, derive long-term benefits from interventions such as the Kasai procedure. In most, a degree of hepatic dysfunction persists. Patients with biliary atresia usually have persistent inflammation of the intrahepatic biliary tree, which suggests that biliary atresia reflects a dynamic process involving the entire hepatobiliary system. This might account for the ultimate development of complications such as portal hypertension. The short-term benefit of hepatoportoenterostomy is decompression and drainage sufficient to forestall the onset of cirrhosis and sustain growth until a successful liver transplantation can be done. The use of steroids following the Kasai procedure has not been shown to improve the patient or the native liver survival rates. Similarly, there is no convincing data to support the use of antibiotics or choleretic agents after surgery.

Management of Chronic Cholestasis

With any form of neonatal cholestasis, whether the primary disease is idiopathic neonatal hepatitis, intrahepatic cholestasis, or biliary atresia, affected patients are at increased risk for progression and complications of chronic cholestasis. These reflect various degrees of residual hepatic functional capacity and are due directly or indirectly to diminished bile flow. Any substance normally excreted into bile is retained in the liver, with subsequent accumulation in tissue and in serum. Involved substances include bile acids, bilirubin, cholesterol, and trace elements. Decreased delivery of bile acids to the proximal intestine leads to inadequate digestion and absorption of dietary long-chain triglycerides and fat-soluble vitamins. Impairment of hepatic metabolic function can alter hormonal balance and utilization of nutrients. Progressive liver damage can lead to biliary cirrhosis, portal hypertension, and liver failure.

Treatment of patients with cholestasis is empirical and is guided by careful monitoring (Table 383.7). No therapy is known to be effective in halting the progression of cholestasis or in preventing further hepatocellular damage and cirrhosis. Growth failure is a major concern and is related in part to malabsorption and malnutrition resulting from ineffective digestion and absorption of dietary fat. Use of a medium-chain triglyceride-containing formula can improve caloric balance. With chronic cholestasis and prolonged survival, children with hepatobiliary disease can experience deficiencies of the fat-soluble vitamins (A, D, E, and K). Metabolic bone disease is common. It is essential to monitor the fat-soluble vitamin status in patients.

Table 383.7

Suggested Medical Management of Persistent Cholestasis

CLINICAL IMPAIRMENT	MANAGEMENT
Malnutrition resulting from malabsorption of dietary long-chain triglycerides	Replace with dietary formula or supplements containing medium-chain triglycerides
Fat-soluble vitamin malabsorption	
Vitamin A deficiency (night blindness, thick skin)	Replace with 10,000-15,000 IU/day as Aquasol A
Vitamin E deficiency (neuromuscular degeneration)	Replace with 50-400 IU/day as oral α-tocopherol or TPaGS
Vitamin D deficiency (metabolic bone disease)	Replace with 5,000-8,000 IU/day of D_2 or 3-5 µg/kg/day of 25-hydroxycholecalciferol
Vitamin K deficiency (hypoprothrombinemia)	Replace with 2.5-5.0 mg every other day as water-soluble derivative of menadione
Micronutrient deficiency	Calcium, phosphate, or zinc supplementation
Deficiency of water-soluble vitamins	Supplement with twice the recommended daily allowance
Retention of biliary constituents such as cholesterol (itch or xanthomas)	Administer choleretic bile acids (ursodeoxycholic acid, 15-30 mg/kg/day)
Progressive liver disease; portal hypertension (variceal bleeding, ascites, hypersplenism)	Interim management (control bleeding; salt restriction; spironolactone)
End-stage liver disease (liver failure)	Transplantation

TPGS , D-α-tocopherol polyethylene glycol 1000 succinate.

A **degenerative neuromuscular syndrome** is found in patients with chronic cholestasis, caused by vitamin E deficiency; affected children experience progressive areflexia, cerebellar ataxia, ophthalmoplegia, and decreased vibratory sensation. Specific morphologic lesions were found in the central nervous system, peripheral nerves, and muscles. These lesions are preventable and are not commonly seen today; they were potentially reversible in children younger than 3-4 yr of age. Affected children have low serum vitamin E concentrations, increased hydrogen peroxide hemolysis, and low ratios of serum vitamin E to total serum lipids (<0.6 mg/g for children younger than 12 yr and <0.8 mg/g for older patients). Vitamin E deficiency may be prevented by oral administration of large doses (up to 1,000 IU/day); patients unable to absorb sufficient quantities may require administration of D-α-tocopheryl polyethylene glycol 1,000 succinate orally. Serum levels should be monitored as a guide to efficacy.

Pruritus is a particularly troublesome complication of chronic cholestasis, often with the appearance of xanthomas. Both features seem to be related to the accumulation of cholesterol and bile acids in serum and in tissues. Elimination of these retained compounds is difficult when bile ducts are obstructed, but if there is any degree of bile duct patency, administration of ursodeoxycholic acid can increase bile flow or interrupt the enterohepatic circulation of bile acids and thus decrease the xanthomas and ameliorate the pruritus (see Table 383.7). Ursodeoxycholic acid therapy can also lower serum cholesterol levels. The recommended initial dose is 15 mg/kg/24 hr. Inhibition of the apical sodium dependent bile acid transporter prevents the reabsorption of bile acids in the terminal ileum, is currently under investigation, and may prove to be of therapeutic benefit to relieve pruritus and improve the quality of life.

Partial external biliary diversion (PEBD) is efficacious in managing pruritus refractory to medical therapy and provides a favorable outcome in a select group of patients with chronic cholestasis who have not yet developed cirrhosis. The surgical technique involves resecting a segment of intestine to be used as a biliary conduit. One end of the conduit is attached to the gallbladder and the other end is brought out to the skin, forming a stoma. The main drawback of the procedure is the need to use an ostomy bag. Open button cholecystostomy and laparoscopic PEBD are modified surgical approaches, which have been reported to be efficacious in relieving pruritus. Ileal exclusion has been used successfully but it is less effective compared to PEBD. Unfortunately in some patients who continue to experience excoriating pruritus, liver transplantation is the only remaining consideration.

Progressive fibrosis and cirrhosis lead to the development of portal hypertension and consequently to ascites and variceal hemorrhage. The presence of ascites is a risk factor for the development of spontaneous bacterial peritonitis. *The first step in the management of patients with ascites is to rule out spontaneous bacterial peritonitis and restrict sodium intake to 0.5 g (~1-2 mEq/kg/24 hr)*. There is no need for fluid restriction in patients with adequate renal output. Should this be ineffective, diuretics may be helpful. The diuretic of choice is spironolactone (1-3.3 mg/kg/day orally or divided every 12 hr). If spironolactone alone does not control ascites, the addition of another diuretic such as thiazide or furosemide may be beneficial. Patients with ascites but without peripheral edema are at risk for reduced plasma volume and decreased urine output during diuretic therapy. Tense ascites alters renal blood flow and systemic hemodynamics. Paracentesis and intravenous albumin infusion can improve hemodynamics, renal perfusion, and symptoms. Follow-up includes dietary counseling and monitoring of serum and urinary electrolyte concentrations.

In patients with portal hypertension, variceal hemorrhage and the development of hypersplenism are common. It is important to ascertain the cause of bleeding because episodes of gastrointestinal hemorrhage in patients who have chronic liver disease may be from gastritis or peptic ulcer disease. Because the management of these various complications differs, differentiation, perhaps via endoscopy, is necessary before treatment is initiated. If the patient is volume depleted, blood transfusion should be carefully administered, avoiding over transfusion, which can precipitate further bleeding. Balloon tamponade is not recommended in children because it can be associated with significant complications. Sclerotherapy or endoscopic variceal ligation may be useful palliative measures in the management of bleeding varices and may be superior to surgical alternatives.

For patients with advanced liver disease, hepatic transplantation has a success rate >90%. If the operation is technically feasible, it will prolong life and might correct the metabolic error in diseases such as α_1 -antitrypsin deficiency, tyrosinemia, and Wilson disease. Success depends on adequate intraoperative, preoperative, and postoperative care, and on cautious use of immunosuppressive agents. Scarcity of donors of small livers limits the application of liver transplantation for infants and children. The use of reduced-size transplants and living donors increases the ability to treat small children successfully.

Prognosis

For patients with idiopathic neonatal hepatitis, the variable prognosis might reflect the heterogeneity of the disease. In sporadic cases, 60–70% recover with no evidence of hepatic structural or functional impairment. Approximately 5–10% have persistent fibrosis or inflammation, and a smaller percentage have more severe liver disease, such as cirrhosis. Infants usually die early in the course of the illness, owing to hemorrhage or sepsis. Of infants with idiopathic neonatal hepatitis of the familial variety, only 20–30% recover; 10–15% acquire chronic liver disease with cirrhosis. Liver transplantation may be required.

383.2

Cholestasis in the Older Child

H. Hesham Abdel-Kader Hassan, William F. Balistreri

Cholestasis with onset after the neonatal period is most often caused by acute viral hepatitis or exposure to hepatotoxic drugs. However, many of the conditions causing neonatal cholestasis can also cause chronic cholestasis in older patients. Consequently, older children and adolescents with conjugated hyperbilirubinemia should be evaluated for acute and chronic viral hepatitis, α_1 -antitrypsin deficiency, Wilson disease, liver disease associated with inflammatory bowel disease, sclerosing cholangitis, autoimmune hepatitis, drug-induced liver injury and the syndromes of intrahepatic cholestasis. Other causes include obstruction caused by cholelithiasis, abdominal tumors, enlarged lymph nodes, or hepatic inflammation resulting from drug ingestion. Management of cholestasis in the older child is similar to that proposed for neonatal cholestasis (see Table 383.7).

CHAPTER 384

Metabolic Diseases of the Liver

Anna L. Peters, William F. Balistreri

Metabolic liver diseases in children, although individually rare, altogether represent a significant cause of morbidity and mortality. This is because the liver has a central role in synthetic, degradative, and regulatory pathways involving carbohydrate, protein, lipid, trace element, and vitamin metabolism. Therefore, inborn errors of metabolism will result in metabolic abnormalities, specific enzyme deficiencies or defects, and disorders of protein transport that can have primary or secondary effects on the liver (Table 384.1). Liver disease can arise when absence of an enzyme produces a block in a metabolic pathway, when unmetabolized substrate accumulates proximal to a block, when deficiency of an essential substance produced distal to an aberrant chemical reaction develops, or when synthesis of an abnormal metabolite occurs. The spectrum of pathologic changes includes **hepatocyte injury,** with subsequent failure of other metabolic functions, often resulting in cirrhosis and/or liver cancer; abnormal **storage** of lipid, glycogen, or other products manifested as hepatomegaly, often with complications specific to deranged metabolism (hypoglycemia with glycogen storage disease); and absence of structural change despite profound **metabolic effects,** as seen in patients with urea cycle defects. Clinical manifestations of metabolic diseases of the liver mimic infections, intoxications, and hematologic and immunologic diseases (Table 384.2).

Table 384.1

Inborn Errors of Metabolism That Affect the Liver

DISORDERS OF CARBOHYDRATE METABOLISM
• Disorders of galactose metabolism   • Galactosemia (galactose-1-phosphate uridyltransferase deficiency) • Disorders of fructose metabolism

  - Hereditary fructose intolerance (aldolase deficiency)
  - Fructose-1,6 diphosphatase deficiency
- Glycogen storage diseases
  - Type I
  - Von Gierke Ia (glucose-6-phosphatase deficiency)
  - Type Ib (glucose-6-phosphatase transport defect)
  - Type III Cori/Forbes (glycogen debrancher deficiency)
  - Type IV Andersen (glycogen branching enzyme deficiency)
  - Type VI Hers (liver phosphorylase deficiency)
- Congenital disorders of glycosylation (multiple subtypes)

DISORDERS OF AMINO ACID AND PROTEIN METABOLISM

- Disorders of tyrosine metabolism
  - Hereditary tyrosinemia type I (fumarylacetoacetate deficiency)
  - Tyrosinemia, type II (tyrosine aminotransferase deficiency)
- Inherited urea cycle enzyme defects
  - CPS deficiency (carbamoyl phosphate synthetase I deficiency)
  - OTC deficiency (ornithine transcarbamoylase deficiency)
  - Citrullinemia type I (argininosuccinate synthetase deficiency)
  - Argininosuccinic aciduria (argininosuccinate deficiency)
  - Argininemia (arginase deficiency)
  - N-AGS deficiency (*N* -acetylglutamate synthetase deficiency)
- Maple serum urine disease (multiple possible defects[*])

DISORDERS OF LIPID METABOLISM

- Wolman disease (lysosomal acid lipase deficiency)
- Cholesteryl ester storage disease (lysosomal acid lipase deficiency)
- Homozygous familial hypercholesterolemia (low-density lipoprotein receptor deficiency)
- Gaucher disease type I (β-glucocerebrosidase deficiency)
- Niemann-Pick type C (NPC 1 and 2 mutations)

DISORDERS OF BILE ACID METABOLISM

- Defects in bile acid synthesis (several specific enzyme deficiencies)
- Zellweger syndrome—cerebrohepatorenal (multiple mutations in peroxisome biogenesis genes)

DISORDERS OF METAL METABOLISM

- Wilson disease (ATP7B mutations)
- Hepatic copper overload
- Indian childhood cirrhosis
- Neonatal iron storage disease

DISORDERS OF BILIRUBIN METABOLISM

- Crigler-Najjar (bilirubin-uridine diphosphoglucuronate glucuronosyltransferase mutations)
  - Type I
  - Type II
- Gilbert disease (bilirubin-uridine diphosphoglucuronate glucuronosyltransferase polymorphism)
- Dubin-Johnson syndrome (multiple drug-resistant protein 2 mutation)
- Rotor syndrome

MISCELLANEOUS

- α_1 -Antitrypsin deficiency
- Citrullinemia type II (citrin deficiency)
- Cystic fibrosis (cystic fibrosis transmembrane conductance regulator mutations)
- Erythropoietic protoporphyria (ferrochelatase deficiency)
- Polycystic kidney disease
- Mitochondrial hepatopathies (see Table 383.3 and Chapter 388)

[*] Maple syrup urine disease can be caused by mutations in branched-chain α-keto dehydrogenase, keto acid decarboxylase, lipoamide dehydrogenase, or dihydrolipoamide dehydrogenase.

Table 384.2

Clinical Manifestations That Suggest the Possibility of Metabolic Disease

Recurrent vomiting, failure to thrive, short stature
Dysmorphic features
Jaundice, hepatomegaly (±splenomegaly), fulminant hepatic failure, edema/anasarca
Hypoglycemia, organic acidemia, lactic acidemia, hyperammonemia, bleeding (coagulopathy)
Developmental delay/psychomotor retardation, hypotonia, progressive neuromuscular deterioration, seizures, myopathy, neuropathy
Cardiac dysfunction/failure
Unusual odors
Rickets
Cataracts

Many metabolic diseases are detected in expanded newborn metabolic screening programs (see Chapter 102). Clues are provided by family history of a similar illness or by the observation that the onset of symptoms is closely associated with a change in dietary habits; in patients with hereditary fructose intolerance, symptoms follow ingestion of fructose (sucrose). Clinical and laboratory evidence often guides the evaluation. Liver biopsy offers morphologic study and permits enzyme assays, as well as quantitative and qualitative assays of various other constituents (e.g., hepatic copper content in Wilson disease). Genetic/molecular diagnostic approaches are also available. Such studies require cooperation of experienced laboratories and careful attention to collection and handling of specimens. Treatment depends on the specific type of defect and although relatively uncommon, altogether metabolic diseases of the liver account for up to 10% of the indications for liver transplantation in children, a number that may be underestimated given the acute nature of some of these conditions, precluding complete diagnostic investigation prior to transplantation.

384.1

Inherited Deficient Conjugation of Bilirubin (Familial Nonhemolytic Unconjugated Hyperbilirubinemia)

Anna L. Peters, William F. Balistreri

Bilirubin is the metabolic end product of heme. Before excretion into bile, it is first glucuronidated and made water-soluble by the enzyme bilirubin-uridine diphosphoglucuronate glucuronosyltransferase (UDPGT). UDPGT activity is deficient or altered in 3 genetically and functionally distinct disorders (Crigler-Najjar [CN] syndromes type I and II and Gilbert syndrome), producing congenital nonobstructive, nonhemolytic, **unconjugated** hyperbilirubinemia. UGT1A1 is the primary UDPGT isoform needed for bilirubin glucuronidation. Complete absence of UGT1A1 activity causes CN type I, while CN type II is caused by decreased UGT1A1 activity to ~10% of normal.

Gilbert syndrome, the most common hereditary hyperbilirubinemia syndrome, occurs in 5–10% of the white population. Common polymorphisms resulting in a TA insertion in the promoter region of *UGT1A1* lead to decreased binding of the TATA binding protein and decrease normal gene activity by ~30%. Snapback primer genotyping can distinguish all *UGT1A1* promoter genotypes and can provide a definitive diagnosis. Unlike the CN syndromes, Gilbert syndrome usually occurs after puberty, is not associated with chronic liver disease, and no treatment is required. Disease manifestations include fluctuating mild elevations in total serum bilirubin concentration from 1 to 6 mg/dL with no evidence of liver injury or hemolysis. Because UGT1A1 catalyzes water-soluble glucuronidation and detoxification of multiple substrates other than bilirubin (i.e., drugs, hormones, environmental toxins, and aromatic hydrocarbons), mutations in the *UGT1A1* gene are implicated in cancer risk and predispose to drug toxicity and episodic jaundice specifically in cancer chemotherapy.

Crigler-Najjar Syndrome Type I (Glucuronyl Transferase Deficiency)

CN type I is a rare, autosomal recessive disease caused by homozygous or compound heterozygous mutations in the *UGT1A1* gene which result in a premature stop codon or frameshift mutation and complete absence of UGT1A1 activity. At least 59 mutations have been identified to date. Parents of affected children have partial defects in conjugation, as determined by hepatic specific enzyme assay or by measurement of glucuronide formation but have normal serum unconjugated bilirubin levels.

Clinical Manifestations

Severe unconjugated hyperbilirubinemia develops in homozygous affected infants in the first 3 days of life. Without treatment, serum unconjugated bilirubin concentrations reach 25-35 mg/dL in the 1st mo, which can cause **kernicterus** . Stools are pale yellow. Persistent unconjugated hyperbilirubinemia at levels >20 mg/dL without hemolysis after the 1st wk of life should suggest the syndrome.

Diagnosis

The diagnosis of CN type I is based on the early age of onset and the extreme level of bilirubin elevation in the absence of hemolysis. In affected infants, bile contains no bilirubin glucuronide and bilirubin concentration in bile is <10 mg/dL compared with normal concentrations of 50-100 mg/dL. The diagnosis is established by measuring hepatic glucuronyl transferase activity in a liver specimen obtained by percutaneous liver biopsy; open liver biopsy should be avoided because surgery and anesthesia can precipitate kernicterus. DNA diagnosis is also available and may be preferable. Identification of the heterozygous state in parents also strongly suggests the diagnosis. The differential diagnosis of unconjugated hyperbilirubinemia is discussed in Chapter 123.3 .

Treatment

The serum unconjugated bilirubin concentration should be maintained at <20 mg/dL for the first few weeks of life, and even lower in low birthweight infants. This usually requires repeated exchange transfusions and **phototherapy** in the immediate neonatal period. Oral calcium phosphate supplementation renders phototherapy more effective as it forms complexes with bilirubin in the gut. Phenobarbital therapy, through CYP450 enzyme induction, should be considered to determine responsiveness and differentiation between CN types I and II. In patients with CN type I there is no response to phenobarbital treatment.

The risk of kernicterus persists into adult life, although the serum bilirubin levels required to produce brain injury beyond the neonatal period are considerably higher (usually >35 mg/dL). Therefore, phototherapy is generally continued through the early years of life. In older infants and children, phototherapy is used mainly during sleep so as not to interfere with normal activities. Despite the administration of increasing intensities of light for longer periods, the serum bilirubin response to phototherapy decreases with age. Additional adjuvant therapy using agents that bind photobilirubin products such as cholestyramine or agar can also be used to interfere with the enterohepatic recirculation of bilirubin.

Prompt treatment of intercurrent infections, febrile episodes, and other types of illness might help prevent the later development of kernicterus, which can occur at bilirubin levels of 45-55 mg/dL. All reported patients with CN type I have eventually experienced severe kernicterus by young adulthood.

Orthotopic liver transplantation cures the disease and has been successful in a small number of patients. Isolated hepatocyte transplantation has been reported as bridge therapy to liver transplantation, with most but not all patients eventually requiring orthotopic transplantation. Other therapeutic modalities have included plasmapheresis and limitation of bilirubin production. The latter option, inhibiting bilirubin generation, is possible via inhibition of heme oxygenase using metalloporphyrin therapy.

Crigler-Najjar Syndrome Type II (Partial Glucuronyl Transferase Deficiency)

CN type II is an autosomal recessive disease caused by homozygous missense mutations in UGT1A1 resulting in reduced (partial) enzymatic activity. More than 45 mutations have been identified to date. Type II disease can be distinguished from type I by the marked decline in serum bilirubin level that occurs in type II disease after treatment with phenobarbital secondary to an inducible phenobarbital response element on the UGT1A1 promoter.

Clinical Manifestations

When this disorder appears in the neonatal period, unconjugated hyperbilirubinemia usually occurs in the first 3 days of life; serum bilirubin concentrations can be in a range compatible with physiologic jaundice or can be at pathologic levels. The concentrations characteristically remain elevated into and after the 3rd wk of life, persisting in a range of 1.5-22 mg/dL; concentrations in the lower part of this range can create uncertainty about whether chronic hyperbilirubinemia is present. Development of kernicterus is unusual. Stool color is normal, and the infants are without clinical signs or symptoms of disease. There is no evidence of hemolysis. Liver enzymes, albumin, and PT/INR are typically normal.

Diagnosis

Concentration of bilirubin in bile is nearly normal in patients with CN type II. Jaundiced infants and young children with CN type II syndrome respond readily to 5 mg/kg/day of oral phenobarbital, with a decrease in serum bilirubin concentration to 2-3 mg/dL in 7-10 days.

Treatment

Long-term reduction in serum bilirubin levels can be achieved with continued administration of phenobarbital at 5 mg/kg/day. Therapy must be lifelong. The cosmetic and psychosocial benefit should be weighed against the risks of an effective dose of the drug because there is a small long-term risk of kernicterus even in the absence of hemolytic disease. Orlistat, an irreversible inhibitor of intestinal lipase, increases fecal fat excretion and may decrease plasma unconjugated bilirubin concentrations (~10%) in patients with CN types I and II.

Inherited Conjugated Hyperbilirubinemia

Conjugated hyperbilirubinemia can be caused by rare autosomal recessive conditions characterized by asymptomatic mild jaundice. In these conditions, the transfer of bilirubin and other organic anions from the hepatocyte into bile is defective. Chronic mild conjugated hyperbilirubinemia is usually detected during adolescence or early adulthood but can occur as early as 2 yr of age. The results of other routine liver tests are normal. Jaundice can be exacerbated by infection, pregnancy, oral contraceptives, alcohol consumption, and surgery. There is usually no morbidity and life expectancy is normal.

Dubin-Johnson Syndrome

Dubin-Johnson syndrome is an autosomal recessive inherited defect in hepatocyte secretion of bilirubin glucuronide. The defect in hepatic excretory function is not limited to conjugated bilirubin excretion but also involves several organic anions normally excreted from the liver cell into bile. Disease results from absent function of multiple drug-resistant protein 2 (MRP2, encoded by the gene *ABCC2*), an adenosine triphosphate–dependent canalicular transporter. More than 10 different mutations, including compound heterozygous mutation in the *CMOAT* gene, have been identified and either affect localization of MRP2 with resultant increased degradation or impair MRP2 transporter activity in the canalicular membrane. Bile acid excretion and serum bile acid levels are normal. Total urinary coproporphyrin excretion is normal in quantity but coproporphyrin I excretion increases to approximately 80% with a concomitant decrease in coproporphyrin III excretion. Normally, coproporphyrin III is >75% of the total. Cholangiography fails to visualize the biliary tract and x-ray of the gallbladder is also abnormal. Liver histology demonstrates normal architecture, but hepatocytes contain black pigment similar to melanin. Liver function is normal and prognosis is excellent. The most commonly reported symptoms are abdominal pain and fatigue, jaundice, dark urine, and slight enlargement of the liver. Jaundice fluctuates in intensity and is aggravated by intercurrent disease. Rarely, Dubin-Johnson can present in the neonatal period with severe conjugated hyperbilirubinemia with serum bilirubin >20 mg/dL and hepatosplenomegaly. No treatment is indicated for disease which presents outside of the neonatal period.

Rotor Syndrome

Rotor Syndrome is an autosomal recessive disease resulting from biallelic inactivating mutations in *SLCO1B1* and *SLCO1B3* result in functional deficiencies of both OATP1B1 and OATP1B protein. Importantly, these mutations may confer significant drug toxicity risk. These patients present similarly to Dubin-Johnson syndrome, with asymptomatic mild and fluctuating conjugated hyperbilirubinemia, with total serum bilirubin levels between 2 and 5 mg/dL. Unlike Dubin-Johnson syndrome, total urinary coproporphyrin excretion is elevated with a relative increase in the amount of the coproporphyrin I isomer. If liver biopsy is performed, there is no abnormal pigmentation in contrast to

Dubin-Johnson. The gallbladder is normal by roentgenography. Rotor syndrome is benign and no treatment is indicated.

384.2

Wilson Disease

Anna L. Peters, William F. Balistreri

Wilson disease (hepatolenticular degeneration) is an autosomal recessive disorder that can be associated with liver disease, degenerative changes in the brain, and Kayser-Fleischer (K-F) rings in the cornea (Fig. 384.1). The incidence is approximately 1/30,000 births worldwide. Specific treatment is available; however this disease is progressive and potentially fatal if untreated. Prompt diagnostic evaluation for Wilson disease in all patients over age 5 yr presenting with any form of liver disease facilitates expeditious initiation of treatment of the disease, appropriate genetic counseling, screening of first-degree relatives, and also allows appropriate treatment of non-Wilsonian liver disease once copper toxicosis is ruled out.

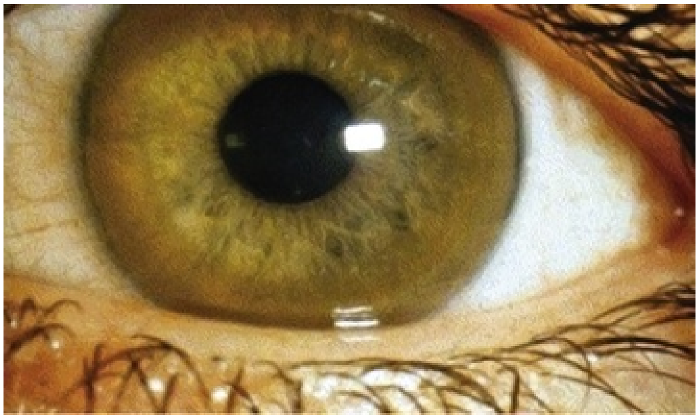

FIG. 384.1 Kayser-Fleischer ring. There is a brown discoloration at the outer margin of the cornea because of the deposition of copper in Descemet's membrane. Here it is clearly seen against the light green iris. Slit-lamp examination is required for secure detection. (From Ala A, Walker AP, Ashkan K, et al: Wilson's disease, *Lancet* 369:397–408, 2007.)

Pathogenesis

The abnormal gene for Wilson disease is found on chromosome 13 (13q14.3), and encodes *ATP7B* , a copper transporting P-type adenosine triphosphatase (ATPase) which is mainly expressed in hepatocytes and is critical for biliary copper excretion and for copper incorporation into ceruloplasmin. Absence or malfunction of ATP7B results in decreased biliary copper excretion and diffuse accumulation of copper in the cytosol of hepatocytes. With time, liver cells become overloaded and copper is redistributed to other tissues, including the brain and kidneys, causing toxicity, primarily as a potent inhibitor of enzymatic processes. Ionic copper inhibits pyruvate oxidase in brain and ATPase in membranes, leading to decreased adenosine triphosphate-phosphocreatine and potassium content of tissue.

More than 500 mutations have been identified, of which >380 have a confirmed role in disease pathogenesis; genetic testing should be able to identify a pathologic variant. Most patients are compound heterozygotes. Mutations that abolish gene function are associated with an onset of disease symptoms as early as 3 yr of age, when Wilson disease might not typically be considered in the differential diagnosis. Milder mutations can be associated with neurologic symptoms or liver disease as late as 80 yr of age. The most commonly occurring disease-causing *ATP7B* mutations result in a protein which binds copper but is unable to effectively traffic to the apical surface of hepatocytes to perform its copper-exporting function. Pharmacologic inhibition of p38 and Jun N-terminal kinase mitogen-activated protein kinase (JNK MAPK) signaling pathways in vitro can rescue this defect and are potential new therapeutic targets.

Clinical Manifestations

Forms of Wilsonian hepatic disease include asymptomatic hepatomegaly (with or without splenomegaly), subacute or chronic hepatitis, and acute hepatic failure (with or without hemolytic anemia). Cryptogenic cirrhosis, portal hypertension, ascites, edema, variceal bleeding, or other effects of hepatic dysfunction (delayed puberty, amenorrhea, coagulation defects) can be manifestations of Wilson disease.

Disease presentations are variable, with a tendency to familial patterns. Liver disease is the most common disease manifestation in children and can precede neurologic symptoms by as long as 10 yr. Females are 3 times more likely than males to present with acute hepatic failure. When Wilson disease presents after age 20, *neurologic symptoms* are the most common manifestation.

Neurologic disorders can develop insidiously or precipitously, with intention tremor, dysarthria, rigid dystonia, Parkinsonism, choreiform movements, lack of motor coordination, deterioration in school performance, psychosis, or behavioral changes. K-F rings are absent in young patients with hepatic Wilson disease up to 50% of the time but are present in 95% of patients with neurologic symptoms. **Psychiatric manifestations** include depression, personality changes, anxiety, obsessive-compulsive behavior, or psychosis.

Coombs-negative **hemolytic anemia** may be an initial manifestation, possibly related to the release of large amounts of copper from damaged hepatocytes; this form of Wilson disease is usually fatal without transplantation. During hemolytic episodes, urinary copper excretion and serum free copper levels are markedly elevated. Manifestations of renal Fanconi syndrome and progressive renal failure with alterations in tubular transport of amino acids, glucose, and uric acid may be present. Unusual manifestations include arthritis, pancreatitis, nephrolithiasis, infertility or recurrent miscarriages, cardiomyopathy, and hypoparathyroidism.

Pathology

All grades of hepatic injury occur in patients with Wilson disease with steatosis, hepatocellular ballooning and degeneration, glycogen granules, minimal inflammation, and enlarged Kupffer cells being most common. The earliest histologic feature of Wilson disease is mild steatosis which may mimic nonalcoholic fatty liver disease or nonalcoholic steatohepatitis. Additionally, the lesion may be indistinguishable from that of autoimmune hepatitis. With progressive parenchymal damage, fibrosis and cirrhosis develop. Ultrastructural changes primarily involve the mitochondria and include increased density of the matrix material, inclusions of lipid and granular material, and increased intracristal space with dilation of the tips of the cristae.

Diagnosis

Wilson disease should be considered in children and teenagers with unexplained acute or chronic liver disease, neurologic symptoms of unknown cause, acute hemolysis, psychiatric illnesses, behavioral changes, Fanconi syndrome, or unexplained bone (osteoporosis, fractures) or muscle disease (myopathy, arthralgia). The clinical suspicion is confirmed by study of indices of copper metabolism.

Most patients with Wilson disease have decreased serum ceruloplasmin levels (<20 mg/dL). The failure of copper to be incorporated into ceruloplasmin leads to a plasma protein with a shorter half-life and, therefore, a reduced steady-state concentration of ceruloplasmin in the circulation. Serum ceruloplasmin levels should be interpreted with caution. Acute inflammatory states and elevated estrogen levels (pregnancy, hormone therapy, or use of oral contraception) can falsely increase ceruloplasmin levels. Additionally, serum ceruloplasmin may be low in autoimmune hepatitis, celiac disease, familial aceruloplasminemia, or in carriers of ATP7B mutations (mild variants of Menkes disease: occipital horn syndrome) who do not show copper overload disease. The serum free copper level may be elevated in early Wilson disease (>1.6 µmol/L), and urinary copper excretion (normally <40 µg/day) is increased to >100 µg/day and often up to 1,000 µg or more per day. Typical urinary copper excretion in patients with untreated Wilson disease is >1.6 µmol/24 hr. in adults and >0.64 µmol/24 hr in children. In equivocal cases, the response of urinary copper output to chelation may be of diagnostic help. Prior to a 24 hr urine collection patients are given 2 500 mg oral doses of D -penicillamine 12 hr apart; affected patients excrete >1,600 µg/24 hr.

Demonstration of K-F rings, which might not be present in younger children, requires a slit-lamp examination by an ophthalmologist. After adequate treatment, K-F rings resolve. Liver biopsy can determine the extent and severity of liver disease and for measuring the hepatic copper content (normally <10 µg/g dry weight) but is only required if clinical signs and noninvasive tests do not allow a final diagnosis or if another liver disorder is suspected. Hepatic copper accumulation is the hallmark of Wilson disease and measurement of hepatic parenchymal copper concentration is the method of choice for diagnosis. Hepatic copper content >250 µg/g dry weight (>4 µmol/g dry weight) is the best biochemical evidence for Wilson disease, but lowering the threshold to 1.2 µmol/g dry weight improves sensitivity without significantly affecting specificity. Intermediate levels of hepatic copper may be present in asymptomatic carriers. In later stages of Wilson disease, hepatic copper content can be unreliable because cirrhosis leads to variable hepatic copper distribution and sampling error.

First-degree relatives of patients with Wilson disease should be screened for presymptomatic disease. This screening should include determination of the serum ceruloplasmin level and 24-hr urinary copper excretion. If these results are abnormal or equivocal, liver biopsy should be carried out to determine morphology and hepatic copper content. Genetic screening by either linkage analysis or direct DNA mutation analysis is possible, especially if the mutation for the proband case is known or the patient is from an area where a specific mutation is prevalent, such as in central and eastern Europe where the *H1069Q* mutation is present in 50–80% of patients.

Treatment

Once the diagnosis of Wilson disease is made, lifelong treatment should be initiated and is focused on limiting copper uptake and promoting copper excretion through dietary and pharmacologic measures. The normal diet contains 2-5 mg of copper per day. For patients with Wilson disease, the dietary intake of copper should be restricted to <1 mg/day. High copper content foods such as liver, shellfish, nuts, and chocolate should be avoided. If the copper content of the drinking water exceeds 0.1 mg/L, it may be necessary to demineralize the water.

The initial treatment in symptomatic patients is the administration of copper-chelating agents, which leads to rapid excretion of excess deposited copper. Chelation therapy is managed with oral administration of D -penicillamine (β,βdimethylcysteine) in a dose of 1 g/day in 2 doses before meals for adults and 20 mg/kg/day for pediatric patients or triethylene tetramine dihydrochloride (Trien, TETA, trientine) at a dose of 0.5-2.0 g/day for adults and 20 mg/kg/day for children. In response to chelation, urinary copper excretion increases, with marked improvement in hepatic and neurologic function and the disappearance of K-F rings.

Approximately 10–50% of patients initially treated with penicillamine for neurologic symptoms have a worsening of their condition. Toxic effects of penicillamine occur in 10–20% and consist of hypersensitivity reactions (i.e., Goodpasture syndrome, systemic lupus erythematosus, and polymyositis), interaction with collagen and elastin, deficiency of other elements such as zinc, and aplastic anemia and nephrosis. Because penicillamine is an antimetabolite of vitamin B_6 , additional amounts of this vitamin are necessary. For these reasons, trientene is the preferred alternative and is considered first-line therapy for some patients. Trientine has few known side effects. Ammonium tetrathiomolybdate is another alternative chelating agent under investigation for patients with neurologic disease; initial results suggest that significantly fewer patients experience neurologic deterioration with this drug compared to penicillamine. The initial dose is 120 mg/day (20 mg between meals 3 times daily and 20 mg with meals 3 times daily). Side effects include anemia, leukopenia, thrombocytopenia, and mild elevations of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Because of its extensive decoppering effect, ammonium tetrathiomolybdate also has antiangiogenic effects.

Zinc has also been used as adjuvant therapy, maintenance therapy, or primary therapy in presymptomatic patients, owing to its unique ability to impair the gastrointestinal absorption of copper. Zinc acetate can be given (adults) at a dose of 25-50 mg of elemental zinc 3 times a day, and 25 mg 3 times a day in children over age 5 yr. Side effects are predominantly limited to gastric irritation but also include reduced leukocyte chemotaxis and elevations in serum lipase and/or amylase. Current guidelines recommend that all symptomatic patients with Wilson disease receive a chelating agent (penicillamine or trientine). Patients should be counseled not to suddenly stop these medications, since sudden discontinuation of therapy can precipitate fulminant Wilson disease. Zinc may have a role as a first-line therapy in patients with neurologic disease, but exclusive monotherapy with zinc in symptomatic liver disease is controversial and not recommended. Antioxidants (vitamin E and curcumin) and pharmacologic chaperones (4-phenylbutyrate and curcumin) may have a role as adjunctive treatment but more research is needed.

Prognosis

Untreated patients with Wilson disease can die of hepatic, neurologic, renal, or hematologic complications. Medical therapy is rarely effective in those presenting with acute liver failure. The prognosis for patients receiving prompt and continuous penicillamine is variable and depends on the time of initiation of and the individual response to chelation. Liver transplantation should be considered for patients with acute liver failure or decompensated cirrhosis due to Wilson disease. Liver transplantation for progressive neurologic disease remains controversial. Liver transplantation is curative, with a 5-yr survival rate of 85–90%. In asymptomatic siblings of affected patients, early institution of chelation or zinc therapy can prevent disease manifestations.

384.3

Indian Childhood Cirrhosis

Anna L. Peters, William F. Balistreri

Indian childhood cirrhosis (ICC) is a chronic liver disease of infants and young children unique to the Indian subcontinent, but variants of this syndrome have been described in other populations and have been named accordingly (Tyrolean or North American childhood cirrhosis). ICC-like disease has also been reported in the Middle East, West Africa, and Central America. Affected children present with jaundice, pruritus, lethargy, and hepatosplenomegaly with rapid progression to cirrhosis. Untreated severe ICC has a mortality of 40–50% within 4 wk. Histologically, ICC is characterized by hepatocyte necrosis, Mallory bodies, intralobular fibrosis, inflammation, and excess hepatic copper deposition. Treatment is supportive, especially in the late stages of disease. Copper chelation with D-penicillamine has been beneficial in open-label pre-icteric cases of ICC, however, it is unclear whether these cases were simply less severely affected and would have spontaneously improved without treatment.

The etiology of ICC has remained elusive. It was once believed that excess copper ingestion in the setting of a genetic susceptibility to copper toxicosis was the most likely cause. Epidemiologic data demonstrates that the copper toxicity theory is unlikely. The increased hepatic copper content, usually >700 µg/g dry weight, seen in ICC is only seen in the late stages of disease and is accompanied by even higher levels of zinc, a non-hepatotoxic metal. Furthermore, the copper-contaminated utensils used to feed babies and implicated in excess copper ingestion are found in only 10–15% of all cases. The current hypothesis implicates the postnatal use of local hepatotoxic therapeutic remedies, although the exact causative agent is unknown. North American ICC is due to mutations in the *UTP4* gene.

Over the last few decades, as the awareness of the disease has increased, the incidence of ICC has decreased to the point of being virtually eliminated in some areas of India. However, established and atypical cases are probably being missed because of lack of histologic confirmation and lack of awareness of the protean manifestations and natural history of this disease.

384.4

Gestational Alloimmune Liver Disease (Neonatal Iron Storage

Disease)

Anna L. Peters, William F. Balistreri

Neonatal iron storage disease (NISD), also known as **neonatal hemochromatosis,** is a rare form of fulminant liver disease that manifests in the first few days of life. This disease is unrelated to the familial forms of hereditary hemochromatosis that occur in adulthood. NISD has a high rate of recurrence in families, with approximately 80% probability that subsequent infants will be affected. NISD is postulated to be a gestational alloimmune disease and has also been classified as **gestational alloimmune liver disease** . During gestation, the maternal immune system becomes sensitized to an unknown fetal hepatocyte cell surface antigen. Maternal immunoglobulin G to this fetal antigen then crosses the placenta and induces hepatic injury via immune system activation. The defining feature of gestational alloimmune liver disease is complement-mediated hepatocyte injury, the evidence for which comes from detection of the C5b-9 complex by immunohistochemistry on liver tissue of affected infants. Additional evidence of a gestational insult is given by the fact that affected infants may be born prematurely or with intrauterine growth restriction. Several infants with NISD also have renal dysgenesis.

Excess non-transferrin-bound iron in gestational alloimmune liver disease may result from fetal liver injury that causes reduced synthesis of key iron regulatory and transport proteins. The pattern of extrahepatic siderosis appears to be determined by the normal capacity of various tissues to import non–transferrin-bound iron and not export cellular iron. It is thought that fetal liver injury is the primary event leading to the development of the neonatal hemochromatosis phenotype, providing further evidence that this is not a primary iron overload disease.

NISD is a rapidly fatal, progressive illness characterized by hepatomegaly, hypoglycemia, hypoprothrombinemia, hypoalbuminemia, hyperferritinemia, and hyperbilirubinemia. The coagulopathy is refractory to therapy with vitamin K. Liver biopsy demonstrates severe liver injury with acute and chronic inflammation, fibrosis, and cirrhosis; in some cases there are no surviving hepatocytes. The diagnosis is established in the neonate with severe liver injury and evidence of extrahepatic siderosis either by MRI indicating increased iron deposition in organs such as the pancreas or heart, or by increased iron staining in oral submucosal gland biopsy. The differential diagnosis includes other causes of neonatal hepatic failure such as citrin deficiency, herpes simplex virus (HSV) hepatitis, and familial hemophagocytic lymphohistiocytosis.

The prognosis for affected infants is generally poor. Intravenous immunoglobulin (IVIG) combined with double volume exchange transfusion has been shown to remove the injury-causing maternal IgG and improve outcomes in infants with NISD. Liver transplantation should also be an early consideration. Recurrences of NISD in subsequent pregnancies may be modified with IVIG administered to the mother once weekly from the 14th wk of gestation until delivery. The largest experience reports 48 women with previous infants with NISD who successfully delivered 52 babies after IVIG treatment. The majority of infants had biochemical evidence of liver disease with elevated serum α-fetoprotein and ferritin. All infants survived with medical therapy or no therapy.

384.5

Miscellaneous Metabolic Diseases of the Liver

Anna L. Peters, William F. Balistreri

α_1 -Antitrypsin Deficiency

α_1 -Antitrypsin deficiency is an autosomal recessive disorder caused by mutation in the *SERPINA1* gene. α_1 -antitrypsin, a protease inhibitor (Pi) synthesized by the liver, protects lung alveolar tissues from destruction by neutrophil elastase (see Chapter 421). α_1 -Antitrypsin is present in more than 20 different codominant alleles, only a few of which are associated with defective Pis. The most common allele of the Pi system is M, and the normal phenotype is PiMM. The Z allele predisposes to clinical deficiency; patients with liver disease are usually PiZZ homozygotes and have serum α_1 -antitrypsin levels <2 mg/mL (~10–20% of normal). The incidence of the PiZZ genotype in the white population is estimated at 1 in 2,000-4,000 live births. A small percentage of patients homozygous for deficiency of the major serum Pi α_1 -antitrypsin develop neonatal cholestasis or later-onset childhood cirrhosis. Compound heterozygotes PiZ-, PiSZ, PiZI are not a cause of liver disease alone but can act as modifier genes, increasing the risk of progression in other liver disease such as nonalcoholic fatty liver disease and hepatitis C. The null phenotype only causes lung disease, and results from either stop codons in the coding exon of the *SERPINA1* gene or complete deletion of *SERPINA1* coding exons leading to the absence of α_1 -antitrypsin protein.

Newly formed α_1 -antitrypsin polypeptide normally enters the endoplasmic reticulum, where it undergoes enzymatic modification and folding before transport to the plasma membrane, where it is excreted as a 55 kDa glycoprotein. In affected patients with PiZZ, the rate at which the α_1 -antitrypsin polypeptide folds is decreased, and this delay allows the formation of polymers that are retained in the endoplasmic reticulum. How the polymers cause liver damage is not completely elucidated, but research indicates that accumulation of abnormally folded protein leads to activation of stress and proinflammatory pathways in the endoplasmic reticulum and hepatocyte programmed cell death. In liver biopsies from patients, polymerized α_1 -antitrypsin peptides can be seen by electron microscopy and histochemically as periodic acid–Schiff-positive diastase-resistant globules primarily in periportal hepatocytes, but also in

Kupffer cells and biliary epithelial cells. The pattern of neonatal liver injury can be highly variable, and liver biopsies might demonstrate hepatocellular necrosis, inflammatory cell infiltration, bile duct proliferation, periportal fibrosis, or cirrhosis.

The course of liver disease is highly variable in patients with α_1 -antitrypsin deficiency. Prospective studies in Sweden have shown that only 10% of patients develop clinically significant liver disease by their fourth decade, indicating that other genetic traits or environmental factors likely influence the development of liver disease. Infants with liver disease are indistinguishable from other infants with “idiopathic” neonatal hepatitis, of whom they constitute approximately 5–10%. Jaundice, acholic stools, and hepatomegaly are present in the 1st wk of life, but the jaundice usually clears by 2-4 mo of age. Complete resolution, persistent liver disease, or the development of cirrhosis can follow. Older children can present with asymptomatic hepatomegaly or manifestations of chronic liver disease or cirrhosis with evidence of portal hypertension. Patients with cirrhosis due to alpha-1 antitrypsin deficiency are at high risk to develop hepatocellular carcinoma. Emphysema is not typically observed in children but an increased risk for developing asthma is reported. Cigarette smoking promotes development of lung disease, so parents should be counseled on smoking cessation and exposure reduction as part of their anticipatory guidance, and older children and adolescents should be advised not to smoke and given cessation counseling if they smoke.

Treatment is supportive, although research is ongoing to develop therapies for α_1 -antitrypsin deficiency-associated liver disease which stimulate intracellular degradation of the abnormally folded Z protein polymers. Liver transplantation is indicated for hepatocellular carcinoma or end-stage liver disease with portal hypertension, with survival rates of ~90%.

Citrin Deficiency

Neonatal intrahepatic cholestasis caused by citrin deficiency (NICCD) presents in the first few months of life with manifestations that initially may be indistinguishable from other causes of neonatal cholestasis, especially biliary atresia. Patients may have jaundice, hepatomegaly, liver dysfunction with coagulopathy, fatty liver infiltration, and hyperammonemia with or without hypoglycemia. Presymptomatic patients may be identified from the newborn metabolic screen with hypergalactosemia, hypermethionemia, and hyperphenylalanemia, but not all patients are identified by newborn screening.

Mutations in the *SLC25A13* gene cause NICCD with an autosomal recessive pattern of inheritance. *SLC25A13* encodes citrin, a mitochondrial carrier protein (calcium binding aspartate-glutamate carrier) involved in the urea cycle, gluconeogenesis and glycolysis. Mutations are more common in those of East Asian descent. Affected infants have hypergalactosemia, elevated bile acids, vitamin K-dependent coagulopathy, and elevated levels of citrulline and methionine. Treatment is supportive in the form of providing fat-soluble vitamin supplementation and dietary feeding with a low-galactose/lactose formula enriched with medium chain triglycerides. More severely affected patients can develop liver failure requiring liver transplantation in the 1st yr of life.

CHAPTER 385

Viral Hepatitis

M. Kyle Jensen, William F. Balistreri

Viral hepatitis continues to be a major health problem in both developing and developed countries; there has been significant progress in efforts to recognize and to treat infected subjects. This disorder is caused by the 5 pathogenic hepatotropic viruses recognized to date: hepatitides A (HAV), B (HBV), C (HCV), D (HDV), and E (HEV) viruses (Table 385.1). Many other viruses (and diseases) can cause hepatitis, usually as a component of a multisystem disease. These include herpes simplex virus, cytomegalovirus, Epstein-Barr virus, varicella-zoster virus, HIV, rubella, adenoviruses, enteroviruses, parvovirus B19, and arboviruses (Table 385.2).

Table 385.1

Features of the Hepatotropic Viruses

VIROLOGY	HAV RNA	HBV DNA	HCV RNA	HDV RNA	HEV RNA
Incubation (days)	15-19	60-180	14-160	21-42	21-63
Transmission					
• Parenteral	Rare	Yes	Yes	Yes	No
• Fecal–oral	Yes	No	No	No	Yes
• Sexual	No	Yes	Rare	Yes	No
• Perinatal	No	Yes	Uncommon (5–15%)	Yes	No
Chronic infection	No	Yes	Yes	Yes	No
Fulminant disease	Rare	Yes	Rare	Yes	Yes

NONALCOHOLIC FATTY LIVER DISEASE

Idiopathic

Reye syndrome
Other

From Wyllie R, Hyams JS, editors: *Pediatric gastrointestinal and liver disease* , ed 3, Philadelphia, 2006, WB Saunders.

The hepatotropic viruses are a heterogeneous group of infectious agents that cause similar acute clinical illness. In most pediatric patients, the acute phase causes no or mild clinical disease. Morbidity is related to rare cases of **acute liver failure (ALF)** in susceptible patients, or to the development of a chronic disease state and attendant complications that several of these viruses (hepatitides B, C, and D) commonly cause.

Issues Common to All Forms of Viral Hepatitis

Differential Diagnosis

Often what brings the patient with hepatitis to medical attention is clinical icterus, with yellow skin and/or mucous membranes. The liver is usually enlarged and tender to palpation and percussion. Splenomegaly and lymphadenopathy may be present. Extrahepatic symptoms (rashes, arthritis) are more commonly seen in HBV and HCV infections. Clinical signs of bleeding, altered sensorium, or hyperreflexia should be carefully sought, because they mark the onset of encephalopathy and ALF.

The differential diagnosis varies with age of presentation. In the newborn period, infection is a common cause of conjugated hyperbilirubinemia; the infectious cause is either a bacterial agent (e.g., *Escherichia coli* , Listeria, syphilis) or a nonhepatotropic virus (e.g., enteroviruses, cytomegalovirus, and herpes simplex virus, which may also cause a nonicteric severe hepatitis). Metabolic diseases (α_1 -antitrypsin deficiency, cystic fibrosis, tyrosinemia), anatomic causes (biliary atresia, choledochal cysts), and inherited forms of intrahepatic cholestasis should always be excluded.

In later childhood, extrahepatic obstruction (gallstones, primary sclerosing cholangitis, pancreatic pathology), inflammatory conditions (autoimmune hepatitis, juvenile inflammatory arthritis, Kawasaki disease), immune dysregulation (hemophagocytic lymphohistiocytosis), infiltrative disorders (malignancies), toxins and medications, metabolic disorders (Wilson disease, cystic fibrosis), and infection (Epstein-Barr virus, varicella, malaria, leptospirosis, syphilis) should be ruled out.

Pathogenesis

The acute response of the liver to hepatotropic viruses involves a direct cytopathic and/or an immune-mediated injury. The entire liver is involved. Necrosis is usually most marked in the centrilobular areas. An acute mixed inflammatory infiltrate predominates in the portal areas but also affects the lobules. The lobular architecture remains intact, although balloon degeneration and necrosis of single or groups of parenchymal cells commonly occur. Fatty change is rare except with HCV infection. Bile duct proliferation, but not bile duct damage, is common. Diffuse Kupffer cell hyperplasia is noticeable in the sinusoids. Neonates often respond to hepatic injury by forming *giant cells* . In fulminant hepatitis, parenchymal collapse occurs on the described background. With recovery, the liver morphology returns to normal within 3 mo of the acute infection. If chronic hepatitis develops, the inflammatory infiltrate settles in the periportal areas and often leads to progressive scarring. Both of these hallmarks of chronic hepatitis are seen in cases of HBV and HCV.

Common Biochemical Profiles in the Acute Infectious Phase

Acute liver injury caused by these viruses manifests in 3 main functional liver biochemical profiles. These serve as an important guide to diagnosis, supportive care, and monitoring in the acute phase of the infection for all viruses. As a reflection of *cytopathic injury* to the hepatocytes, there is a rise in serum levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). The magnitude of enzyme elevation does not correlate with the extent of hepatocellular necrosis and has little prognostic value. There is usually slow improvement over several weeks, but AST and ALT levels *lag* the serum bilirubin level, which tends to normalize first. Rapidly falling aminotransferase levels can predict a poor outcome, particularly if their decline occurs in conjunction with a rising bilirubin level and a prolonged prothrombin time (PT); this combination of findings usually indicates that massive hepatic injury has occurred.

Cholestasis , defined by elevated serum conjugated bilirubin levels, results from abnormal bile flow at the canalicular and cellular level because of hepatocyte damage and inflammatory mediators. Elevation of serum alkaline phosphatase, 5′-nucleotidase, and γ-glutamyl transpeptidase levels, mark cholestasis. Absence of cholestatic markers does not rule out progression to chronicity in HCV or HBV infections.

Altered synthetic function is the most important marker of liver injury. Synthetic dysfunction is reflected by a combination of abnormal protein synthesis (prolonged PT, high international normalized ratio [INR], low serum albumin levels), metabolic disturbances (hypoglycemia, lactic acidosis, hyperammonemia), poor clearance of medications dependent on liver function, and altered sensorium with increased deep tendon reflexes (hepatic encephalopathy). Monitoring of synthetic function should be the main focus in clinical follow-up to define the severity of the disease. In the acute phase, the degree of liver synthetic dysfunction guides treatment and helps to establish intervention criteria. *Abnormal liver synthetic function is a marker of liver failure and is an indication for prompt referral to a transplant center.* Serial assessment is necessary because liver dysfunction does not progress linearly.

Hepatitis A

Hepatitis A is the most prevalent form; this virus is also responsible for most forms of acute and benign hepatitis. Although fulminant hepatic failure due to HAV can occur, it is rare (<1% of cases in the United States) and occurs more often in adults than in children and in hyperendemic communities.

Etiology

HAV is an RNA virus, a member of the picornavirus family. It is heat stable and has limited host range—namely, the human and other primates.

Epidemiology

HAV infection occurs throughout the world but is most prevalent in developing countries. In the United States, 30–40% of the adult population has evidence of previous HAV infection. Hepatitis A is thought to account for approximately 50% of all clinically apparent acute viral hepatitis in the United States. As a result of aggressive implementation of childhood vaccination programs, the prevalence of symptomatic HAV cases worldwide has declined significantly.

However, outbreaks in developing countries and in daycare centers (where the spread of HAV from young, nonicteric, infected children can occur easily) as well as multiple foodborne and waterborne outbreaks have justified the implementation of intensified universal vaccination programs.

HAV is highly contagious. Transmission is almost always by person-to-person contact through the fecal–oral route. Perinatal transmission occurs rarely. No other form of transmission is recognized. HAV infection during pregnancy or at the time of delivery does not appear to result in increased complications of pregnancy or clinical disease in the newborn. In the United States, increased risk of infection is found in contacts with infected persons, childcare centers, and household contacts. Infection is also associated with contact with contaminated food or water and after travel to endemic areas. Common source foodborne and waterborne outbreaks continue to occur, including several caused by contaminated shellfish, frozen berries, and raw vegetables; no known source is found in about half of the cases.

The mean incubation period for HAV is approximately 3 wk. Fecal excretion of the virus starts late in the incubation period, reaches its peak just before the onset of symptoms, and resolves by 2 wk after the onset of jaundice in older subjects. The duration of fecal viral excretion is prolonged in infants. The patient is, therefore, contagious before clinical symptoms are apparent and remains so until viral shedding ceases.

Clinical Manifestations

HAV is responsible for acute hepatitis only. Often, this is an *anicteric* illness, with clinical symptoms indistinguishable from other forms of viral gastroenteritis, particularly in young children.

The illness is more likely to be symptomatic in older adolescents or adults, in patients with underlying liver disorders, and in those who are immunocompromised. It is characteristically an acute febrile illness with an abrupt onset of anorexia, nausea, malaise, vomiting, and jaundice. The typical duration of illness is 7-14 days (Fig. 385.1).

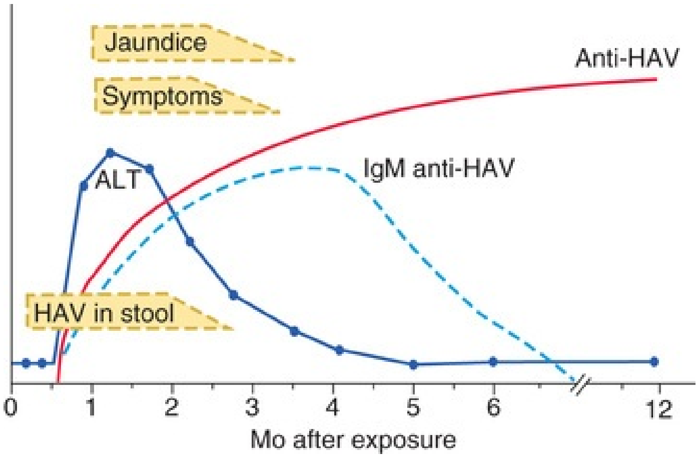

FIG. 385.1 The serologic course of acute hepatitis A. ALT, alanine aminotransferase; HAV, hepatitis A virus; IgM, immunoglobulin class M. (From Goldman L, Ausiello D: *Cecil textbook of medicine,* ed 22, Philadelphia, 2004, WB Saunders, p 913.)

Other organ systems can be affected during acute HAV infection. Regional lymph nodes and the spleen may be enlarged. The bone marrow may be moderately hypoplastic, and aplastic anemia has been reported. Tissue in the small intestine might show changes in villous structure, and ulceration of the gastrointestinal tract can occur, especially in fatal cases. Acute pancreatitis and myocarditis have been reported, though rarely, and nephritis, arthritis, leukocytoclastic vasculitis, and cryoglobulinemia can result from circulating immune complexes.

Diagnosis

Acute HAV infection is diagnosed by detecting antibodies to HAV, specifically, anti-HAV (immunoglobulin [Ig] M) by radioimmunoassay or, rarely, by identifying viral particles in stool. A viral polymerase chain reaction (PCR) assay is available for research use (Table 385.3). Anti-HAV is detectable when the symptoms are clinically apparent, and it remains positive for 4-6 mo after the acute infection. A neutralizing anti-HAV (IgG) is usually detected within 8 wk of symptom onset and is measured as part of a total anti-HAV in the serum. Anti-HAV (IgG) confers long-term protection. Rises in serum levels of ALT, AST, bilirubin, alkaline phosphatase, 5′-nucleotidase, and γ-glutamyl transpeptidase are almost universally found and do not help to differentiate the cause of hepatitis.

Table 385.3

Diagnostic Blood Tests: Serology and Viral Polymerase Chain Reaction

HAV	HBV	HCV	HDV	HEV

[*] Research tool.

[†] Still poses a risk for reactivation.

HAV, hepatitis A virus; HBs, hepatitis B surface; HBsAg, hepatitis B surface antigen; Ig, immunoglobulin; PCR, polymerase chain reaction.

Complications

Although most patients achieve full recovery, distinct complications can occur. *ALF* from HAV infection is an infrequent complication of HAV. Those at risk for this complication are adolescents and adults, but also immunocompromised patients or those with underlying liver disorders. The height of HAV viremia may be linked to the severity of hepatitis. In the United States, HAV represents <0.5% of pediatric-age ALF; HAV is responsible for up to 3% mortality in the adult population with ALF. In endemic areas of the world, HAV constitutes up to 40% of all cases of pediatric ALF. HAV can also progress to a *prolonged cholestatic syndrome* that waxes and wanes over several months. Pruritus and fat malabsorption are problematic and require symptomatic support with antipruritic medications and fat-soluble vitamin supplementation. This syndrome occurs in the absence of any liver synthetic dysfunction and resolves without sequelae.

Treatment

There is no specific treatment for hepatitis A. Supportive treatment consists of intravenous hydration as needed, and antipruritic agents and fat-soluble vitamins for the prolonged cholestatic form of disease. Serial monitoring for signs of ALF is prudent and, if ALF is diagnosed, a prompt referral to a transplantation center can be lifesaving.

Prevention

Patients infected with HAV are contagious for 2 wk before and approximately 7 days after the onset of jaundice and should be excluded from school, childcare, or work during this period. Careful hand-washing is necessary, particularly after changing diapers and before preparing or serving food. In hospital settings, contact and standard precautions are recommended for 1 wk after onset of symptoms.

Immunoglobulin

Indications for intramuscular administration of Ig include preexposure and postexposure prophylaxis (Table 385.4). Ig is recommended for *preexposure* prophylaxis for susceptible travelers to countries where HAV is endemic, and it provides effective protection for up to 2 mo. *HAV vaccine* given any time before travel is preferred for *preexposure* prophylaxis in healthy persons, but *Ig* ensures an appropriate prophylaxis in children *younger than 12 mo* old, patients allergic to a vaccine component, or those who elect not to receive the vaccine. If travel is planned in <2 wk, older patients, immunocompromised hosts, and those with chronic liver disease or other medical conditions should receive *both* Ig and the HAV vaccine.

Table 385.4

Indications and Updated Dosage Recommendations for GamaSTAN S/D Human Immune Globulin for Preexposure and Postexposure Prophylaxis Against Hepatitis A Infection

INDICATION	UPDATED DOSAGE RECOMMENDATION
Preexposure prophylaxis	

Up to 1 mo of travel	0.1 mL/kg
Up to 2 mo of travel	0.2 mL/kg
2 mo of travel or longer	0.2 mL/kg (repeat every 2 mo)
Postexposure prophylaxis	0.1 mL/kg

From Nelson NP: Updated dosing instruction for immune globulin (human) gamaSTAN S/D for hepatitis A virus prophylaxis, *MMWR* 66(36):959–960, 2017, Table, p. 959.

Ig prophylaxis in *postexposure* situations should be used as soon as possible (it is not effective if administered more than 2 wk after exposure). It is exclusively used for children younger than 12 mo old, immunocompromised hosts, those with chronic liver disease or in whom vaccine is contraindicated. Ig is preferred in patients older than 40 yr of age, with HAV vaccine preferred in healthy persons 12 mo to 40 yr old. An alternative approach is to immunize previously unvaccinated patients who are 12 *mo* old *or older* with the age-appropriate vaccine dosage as soon as possible. Ig is not routinely recommended for sporadic nonhousehold exposure (e.g., protection of hospital personnel or schoolmates). The vaccine has several advantages over Ig, including long-term protection, availability, and ease of administration, with cost similar to, or less than, that of Ig.

Vaccine

The availability of 2 inactivated, highly immunogenic, and safe HAV vaccines has had a major impact on the prevention of HAV infection. Both vaccines are approved for children older than 12 mo. They are administered intramuscularly in a 2-dose schedule, with the second dose given 6-12 mo after the first dose. Seroconversion rates in children exceed 90% after an initial dose and approach 100% after the second dose; protective antibody titer persists for longer than 10 yr in most patients. The immune response in immunocompromised persons, older patients, and those with chronic illnesses may be suboptimal; in those patients, combining the vaccine with Ig for pre- and postexposure prophylaxis is indicated. HAV vaccine may be administered simultaneously with other vaccines. A combination HAV and HBV vaccine is approved in adults older than age 18 yr. For healthy persons at least 12 mo old, vaccine is preferable to Ig for preexposure and postexposure prophylaxis (see Table 385.3).

In the United States and some other countries, universal vaccination is now recommended for all children older than 12 mo. Nevertheless, studies show <50% of U.S. adolescents have received even a single dose of the vaccine, and <30% have received the complete vaccine series. The vaccine is effective in curbing outbreaks of HAV because of rapid seroconversion and the long incubation period of the disease.

Prognosis

The prognosis for the patient with HAV is excellent, with no long-term sequelae. The only feared complication is ALF. Nevertheless, HAV infection remains a major cause of morbidity; it has a high socioeconomic impact during epidemics and in endemic areas.

Hepatitis B

Etiology

HBV, a member of the Hepadnaviridae family, has a circular, partially double-stranded DNA genome composed of approximately 3,200 nucleotides. Four constitutive genes have been identified: the S (surface), C (core), X, and P (polymer) genes. The surface of the virus includes particles, designated as the hepatitis B surface antigen (HBsAg), which consist of 22 nm diameter spherical particles and 22 nm wide tubular particles with a variable length of up to 200 nm. The inner portion of the virion contains the hepatitis B core antigen (HBcAg), the nucleocapsid that encodes the viral DNA, and a nonstructural antigen called the hepatitis B e antigen (HBeAg), a nonparticulate soluble antigen derived from HBcAg by proteolytic self-cleavage. HBeAg serves as a marker of active viral replication and usually correlates with the HBV DNA levels. Replication of HBV occurs predominantly in the liver but also occurs in the lymphocytes, spleen, kidney, and pancreas.

Epidemiology

HBV has been detected worldwide, with an estimated 400 million persons chronically infected. The areas of highest prevalence of HBV infection are sub-Saharan Africa, China, parts of the Middle East, the Amazon basin, and the Pacific Islands. In the United States, the native population in Alaska had the highest prevalence rate before the implementation of their universal vaccination programs. An estimated 1.25 million persons in the United States are chronic HBV carriers, with approximately 300,000 new cases of HBV occurring each year, the highest incidence being among adults 20-39 yr of age. One in 4 chronic

HBV carriers will develop serious sequelae in their lifetime. The number of new cases in children reported each year is thought to be low but is difficult to estimate because many infections in children are asymptomatic. In the United States, since 1982 when the first vaccine for HBV was introduced, the overall incidence of HBV infection has been reduced by more than half. Since the implementation of universal vaccination programs in Taiwan and the United States, substantial progress has been made toward eliminating HBV infection in children in these countries. In fact, in Alaska, where HBV neared epidemic proportions, universal newborn vaccination with mass screening and immunization of susceptible Alaska Natives virtually eliminated symptomatic HBV and secondary hepatocellular carcinoma (HCC).

HBV is present in high concentrations in blood, serum, and serous exudates and in moderate concentrations in saliva, vaginal fluid, and semen. Efficient transmission occurs through blood exposure and sexual contact. Risk factors for HBV infection in children and adolescents include acquisition by intravenous drugs or blood products, contaminated needles used for acupuncture or tattoos, sexual contact, institutional care, and intimate contact with carriers. No risk factors are identified in approximately 40% of cases. HBV is not thought to be transmitted via indirect exposure, such as sharing toys. After infection, the incubation period ranges from 45-160 days, with a mean of approximately 120 days. In children, the most important risk factor for acquisition of HBV remains perinatal exposure to an HBsAg-positive mother. The risk of transmission is greatest if the mother is HBeAg-positive; up to 90% of these infants become chronically infected if untreated. Additional risk factors include high maternal HBV viral load (HBeAg/HBV DNA titers) and delivery of a prior infant who developed HBV despite appropriate prophylaxis. In most perinatal cases, serologic markers of infection and antigenemia appear 1-3 mo after birth, suggesting that transmission occurred at the time of delivery. Virus contained in amniotic fluid or in maternal feces or blood may be the source. Immunoprophylaxis with hepatitis B immunoglobulin (HBIG) and the HBV immunization, given within 12 hr of delivery, is highly effective in preventing infection and protects >95% of neonates born to HBsAg-positive mothers. Of the 22,000 infants born each year to HBsAg-positive mothers in the United States, >98% receive immunoprophylaxis and are thus protected. Infants who fail to receive the complete vaccination series (e.g., homeless children, international adoptees, and children born outside the United States) have the highest incidence of developing chronic HBV. These and all infants born to HBsAg-positive mothers should have follow-up HBsAg and anti-HBs tested to determine appropriate follow-up. The mothers (HBeAg positive) of these infants who develop chronic HBV infection should receive antiviral therapy during the third trimester for subsequent pregnancies.

HBsAg is inconsistently recovered in human milk of infected mothers. Breastfeeding of nonimmunized infants by infected mothers does not seem to confer a greater risk of hepatitis than does formula feeding.

The risk of developing chronic HBV infection, defined as being positive for HBsAg for longer than 6 mo, is inversely related to age of acquisition. In the United States, although <10% of infections occur in children, these infections account for 20–30% of all chronic cases. This risk of chronic infection is 90% in children younger than 1 yr; the risk is 30% for those 1-5 yr of age and 2% for adults. Chronic HBV infection is associated with the development of chronic liver disease and HCC. The carcinoma risk is independent of the presence of cirrhosis and was the most prevalent cancer-related death in young adults in Asia where HBV was endemic.

HBV has 10 genotypes (A-J). A is pandemic, B and C are prevalent in Asia, D is seen in Southern Europe, E in Africa, F in the United States, G in the United States and France, H in Central America, I in southeast Asia, and J in Japan. Genetic variants have become resistant to some antiviral agents.

Pathogenesis

The acute response of the liver to HBV is similar to that of other viruses. Persistence of histologic changes in patients with hepatitis B indicates development of chronic liver disease. HBV, unlike the other hepatotropic viruses, is a predominantly noncytopathogenic virus that causes injury mostly by immune-mediated processes. The severity of hepatocyte injury reflects the degree of the immune response, with the most complete immune response being associated with the greatest likelihood of viral clearance but also the most severe injury to hepatocytes. The first step in the process of acute hepatitis is infection of hepatocytes by HBV, resulting in expression of viral antigens on the cell surface. The most important of these viral antigens may be the nucleocapsid antigens—HBcAg and HBeAg. These antigens, in combination with class I major histocompatibility proteins, make the cell a target for cytotoxic T-cell lysis.

The mechanism for development of chronic hepatitis B is less well understood. To permit hepatocytes to continue to be infected, the core protein or major histocompatibility class I protein might not be recognized, the cytotoxic lymphocytes might not be activated, or some other, yet unknown mechanism might interfere with destruction of hepatocytes. This tolerance phenomenon predominates in the perinatally acquired cases, resulting in a high incidence of persistent HBV infection in children with no or little inflammation in the liver, normal liver enzymes, and markedly elevated HBV viral load. Although end-stage liver disease rarely develops in those patients, the inherent HCC risk is high, possibly related, in part, to uncontrolled viral replication cycles.

ALF has been seen in infants of chronic carrier mothers who have anti-HBe or are infected with a precore-mutant strain. This fact led to the postulate that HBeAg exposure in utero in infants of chronic carriers likely induces tolerance to the virus once infection occurs postnatally. In the absence of this tolerance, the liver is massively attacked by T cells and the patient presents with ALF.

Immune-mediated mechanisms are also involved in the extrahepatic conditions that can be associated with HBV infections. Circulating immune complexes containing HBsAg can result in polyarteritis nodosa, membranous or membranoproliferative glomerulonephritis, polymyalgia rheumatica, leukocytoclastic vasculitis, and Guillain-Barré syndrome.

Clinical Manifestations

Many acute cases of HBV infection in children are asymptomatic, as evidenced by the high carriage rate of serum markers in persons who have no history of acute hepatitis (Table 385.5). The usual acute symptomatic episode is similar to that of HAV and HCV infections but may be more severe and is more likely to include involvement of skin and joints (Fig. 385.2).

Table 385.5

Typical Interpretation of Test Results for Hepatitis B Virus Infection

HBsAg	TOTAL ANTI-HBc	IgM ANTI-HBc	ANTI-HBs	HBV DNA	INTERPRETATION
−	−	−	−	−	Never infected
+	−	−	−	+ or −	Early acute infection; transient (up to 18 days) after vaccination
+	+	+	−	+	Acute infection

−	+	+	+ or −	+ or −	Acute resolving infection
−	+	−	+	−	Recovered from past infection and immune
+	+	−	−	+	Chronic infection
−	+	−	−	+ or −	False-positive (i.e., susceptible); past infection; “low-level” chronic infection; or passive transfer of anti-HBc to infant born to HBsAg-positive mother
−	−	−	+	−	Immune if anti-HBs concentration is ≥10 mIU/mL after vaccine series completion; passive transfer after hepatitis B immune globulin administration

−, negative; +, positive; anti-HBc, antibody to hepatitis B core antigen; anti-HBs, antibody to hepatitis B surface antigen; HBsAg, hepatitis B surface antigen; HBV DNA, hepatitis B virus deoxyribonucleic acid; IgM, immunoglobulin class M.

From Schillie S, Vellozzi C, Reingold A, et al: Prevention of hepatitis B virus infection in the United States: recommendations of the advisory committee on immunization practices, *MMWR* 67(1):1–29, 2018, Table 1, p. 7.

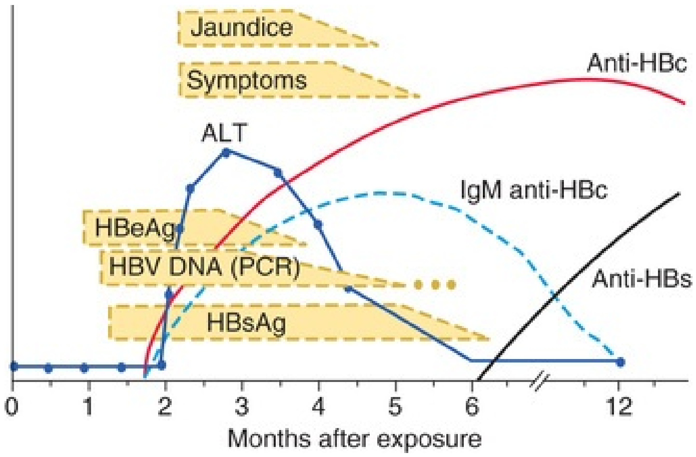

FIG. 385.2 **The serologic course of acute hepatitis B. ALT, alanine aminotransferase; HBc, hepatitis B core; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV DNA, hepatitis B virus deoxyribonucleic acid; IgM, immunoglobulin class M; PCR, polymerase chain reaction. (From Goldman L, Ausiello D: *Cecil textbook of medicine,* ed 22, Philadelphia, 2004, WB Saunders, p 914.)**

The first biochemical evidence of HBV infection is elevation of serum ALT levels, which begin to rise just before development of fatigue, anorexia, and malaise, at approximately 6-7 wk after exposure. The illness is preceded, in a few children, by a serum sickness–like prodrome marked by arthralgia or skin lesions, including urticarial, purpuric, macular, or maculopapular rashes. Papular acrodermatitis, the Gianotti-Crosti syndrome, can also occur. Other extrahepatic conditions associated with HBV infections in children include polyarteritis nodosa, glomerulonephritis, and aplastic anemia. Jaundice is present in approximately 25% of acutely infected patients and usually begins approximately 8 wk after exposure and lasts approximately 4 wk.

In the usual course of resolving HBV infection, symptoms persist for 6-8 wk. The percentage of children in whom clinical evidence of hepatitis develops is higher for HBV than for HAV, and the rate of ALF is also greater. Most patients do recover, but the *chronic carrier state* complicates up to 10% of cases acquired in adulthood. The rate of development of chronic infection depends largely on the mode and age of acquisition and occurs in up to 90% of perinatally-infected cases. Cirrhosis and HCC are only seen with chronic infection. Chronic HBV infection has 3 identified phases: immune tolerant, immune active, and inactive. Most children fall in the *immune-tolerant* phase, against which no effective therapy has been developed. Most treatments target the *immune active* phase of the disease, characterized by active inflammation, elevated ALT/AST levels, and progressive fibrosis. Spontaneous HBeAg seroconversion, defined as the development of anti-HBe and loss of HBeAg, occurs in the immune-tolerant phase, albeit at low rates of 4–5% per year. It is more common in childhood-acquired HBV rather than in perinatally transmitted infections. Seroconversion can occur over many years, during which time significant damage to the liver may take place. There are no large studies that accurately assess the lifetime risks and morbidities of children with chronic HBV infection, making decisions regarding the rationale, efficacy, and timing of still less-than-ideal treatments difficult. Reactivation of chronic infection has been reported in immunosuppressed children treated with chemotherapy, biologic immunomodulators such as infliximab, or T-cell depleting agents, leading to an increased risk of ALF or to rapidly progressing fibrotic liver disease (Table 385.6).

Table 385.6

Causes of Hepatitis Flares in Patients With Chronic Hepatitis B

CAUSE OF FLARE	COMMENT
Spontaneous	Factors that precipitate viral replication are unclear
Immunosuppressive therapy	Flares are often observed during withdrawal of the agent; preemptive antiviral therapy is required
Antiviral therapy for HBV	
Interferon	Flares are often observed during the second to third month of therapy in 30% of patients; may herald virologic response
Nucleoside analog	

During treatment	Flares are no more common than with placebo
Drug-resistant HBV	Severe consequences can occur in patients with advanced liver disease
On withdrawal	Flares are caused by the rapid re-emergence of wild-type HBV; severe consequences can occur in patients with advanced liver disease
HIV treatment	Flares can occur as a result of the direct toxicity of HAART or with immune reconstitution; HBV increases the risk of antiretroviral drug hepatotoxicity
Genotypic variation	
Precore and core promoter mutants	Fluctuations in serum alanine aminotransferase levels are common with precore mutants
Superinfection with other hepatitis viruses	May be associated with suppression of HBV replication

HAART, Highly active antiretroviral therapy; HBV, hepatitis B virus.

From Wells JT, Perillo R: Hepatitis B. In Feldman M, Friedman LS, Brandt LJ, editors: *Sleisenger and Fordtran's gastrointestinal and liver disease* , 10/e, Philadelphia, 2016, Elsevier, Table 79.1.

Diagnosis

The serologic profile of HBV infection is more complex than for HAV infection and differs depending on whether the disease is acute or chronic (Fig. 385.3 , see Table 385.5). Several antigens and antibodies are used to confirm the diagnosis of acute HBV infection (see Table 385.3). Routine screening for HBV infection requires assay of multiple serologic markers (HBsAg, anti-HBc, anti-HBs). HBsAg is an early serologic marker of infection and is found in almost all infected persons; its rise closely coincides with the onset of symptoms. Persistence of HBsAg beyond 6 mo defines the chronic infection state. During recovery from acute infection, because HBsAg levels fall before symptoms wane, IgM antibody to HBcAg (anti-HBc IgM) might be the only marker of acute infection. Anti-HBc IgM rises early after the infection and remains positive for many months before being replaced by anti-HBc IgG, which then persists for years. Anti-HBs marks serologic recovery and protection. Only anti-HBs is present in persons immunized with hepatitis B vaccine, whereas both anti-HBs and anti-HBc are detected in persons with resolved infection. HBeAg is present in active acute or chronic infection and is a marker of infectivity. The development of anti-HBe, termed seroconversion, marks improvement and is a goal of therapy in chronically infected patients. HBV DNA can be detected in the serum of acutely infected patients and chronic carriers. High DNA titers are seen in patients with HBeAg, and they typically fall once anti-HBe develops.

FIG. 385.3 Natural history of hepatitis B virus infection. HCC, hepatocellular carcinoma; OLT, orthotopic liver transplant.

Complications

ALF with coagulopathy, encephalopathy, and cerebral edema occurs more commonly with HBV than the other hepatotropic viruses. The risk of ALF is further increased when there is coinfection or superinfection with HDV or in an immunosuppressed host. Mortality from ALF is >30%, and liver transplantation is the only effective intervention. Supportive care aimed at sustaining patients and early referral to a liver transplantation center can be lifesaving. As mentioned, HBV infection can also result in chronic hepatitis, which can lead to cirrhosis, end-stage liver disease complications, and HCC. Membranous glomerulonephritis with deposition of complement and HBeAg in glomerular capillaries is a rare complication of HBV infection.

Treatment

Treatment of *acute* HBV infection is largely supportive. Close monitoring for liver failure and extrahepatic morbidities is key. Treatment of *chronic* HBV infection is in evolution; no 1 drug currently achieves consistent, complete eradication of the virus. The natural history of chronic HBV infection in children is complex, and there is a lack of reliable long-term outcome data on which to base treatment recommendations. Treatment of chronic HBV infection in children should be individualized and done under the care of a pediatric hepatologist experienced in treating the disease.

The goal of treatment is to reduce viral replication defined by having undetectable HBV DNA in the serum and development of anti-HBe, termed seroconversion. The development of anti-HBe transforms the disease into an inactive form, thereby decreasing infectivity, active liver injury and inflammation, fibrosis progression, and the risk of HCC. Treatment is only indicated for patients in the immune-active form of the disease, as evidenced by elevated ALT and/or AST, who have fibrosis on liver biopsy, putting the child at higher risk for cirrhosis during childhood.

Treatment Strategies

Interferon-*α2b* (IFN-α2b) has immunomodulatory and antiviral effects (Table 385.7). It has been used in children, with long-term viral response rates similar to the 25% rate reported in adults. Interferon (IFN) use is limited by its subcutaneous administration, treatment duration of 24 wk, and side effects (flu-like symptoms, marrow suppression, depression, retinal changes, autoimmune disorders). IFN is further contraindicated in decompensated cirrhosis. One advantage of IFN, compared to other treatments, is that viral resistance does not develop with its use.

Table 385.7

Positive and Negative Factors to Consider in the Decision to Treat Hepatitis B With Peginterferon or a Nucleoside or Nucleotide Analog

AGENT	POSITIVE FACTORS	NEGATIVE FACTORS
Peginterferon	Finite duration of treatment	Inconvenience of subcutaneous injection
	Durable off-treatment response	Frequent side effects
	More rapid disappearance of HBsAg Immunostimulatory as well as intrinsically antiviral	Clearance of HBsAg in a small minority of patients depending on genotype
		Potential risk of ALT flares in patients with advanced liver fibrosis
	Better tolerability compared with its use in hepatitis C	Relative contraindication in patients older than age 60 or those with comorbid illnesses
Nucleoside or nucleotide analog	Negligible side effects	Slight risk of nephropathy with nucleotide analogs (adefovir, tenofovir)
	Convenience; ready acceptance by patients	Drug expense can be considerable during long-term use
	Potent inhibition of virus replication Reduced drug resistance with the third-generation nucleoside analogs	Long or indefinite treatment needed for both HBeAg-positive and HBeAg-negative patients
		Access issues in developing nations

HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen.

From Wells JT, Perillo R: Hepatitis B. In Feldman M, Friedman LS, Brandt LJ, editors: *Sleisenger and Fordtran's gastrointestinal and liver disease* , 10/e, Philadelphia, 2016, Elsevier, Table 79.4.

Lamivudine is an oral synthetic nucleoside analog that inhibits the viral enzyme reverse transcriptase. In children older than 2 yr of age, its use for 52 wk resulted in HBeAg clearance in 34% of patients with an ALT >2 times normal; 88% remained in remission at 1 yr. It has a good safety profile. Lamivudine has to be used for ≥ 6 mo after viral clearance, and the emergence of a mutant viral strain (YMDD) poses a barrier to its long-term use. Combination therapy in children using IFN and lamivudine did not seem to improve the rates of response in most series.

Adefovir (a purine analog that inhibits viral replication) is approved for use in children older than 12 yr of age, in whom a prospective 1-yr study showed 23% seroconversion. No viral resistance was noted in that study but has been reported in adults.

Entecavir (a nucleoside analog that inhibits replication) is currently approved for use in children older than 2 yr of age. Prospective data has shown a 21% seroconversion rate in adults with minimal resistance developing. Patients in whom resistance to lamivudine developed have an increased risk of resistance developing to entecavir.

Tenofovir (a nucleotide analog that inhibits viral replication) is also approved for use in children older than 12 yr of age. Prospective data have shown a 21% seroconversion rate with a very low rate of resistance developing. Patients with lamivudine-resistant mutations do not appear to have an increased rate of resistance. Concern exists over long-term use and bone mineral density.

Peginterferon-α_2 has the same mechanism of action as IFN but is given once weekly. This formulation has not been approved in the United States but is recommended for the treatment of chronic HBV in other countries. Patients most likely to respond to currently available drugs have low serum HBV DNA titers, are HBeAg-positive, have active hepatic inflammation (ALT greater than twice the upper limit of normal for at least 6 mo), and recently acquired disease.

Immune tolerant patients—those with normal ALT and AST, who are HBeAg-positive with elevated viral load—are currently not considered for treatment, although the emergence of new treatment paradigms is promising for this large, yet hard-to-treat, subgroup of patients.

Prevention

The most effective prevention strategies have resulted from the screening of pregnant mothers and the use of HBIG and hepatitis B vaccine in infants (Tables 385.8 to 385.11). In HBsAg-positive and HBeAg-positive mothers, a 10% risk of chronic HBV infection exists compared to 1% in HBeAg-negative mothers. This knowledge offers screening strategies that may affect both mother and infant by using antiviral medications during the third trimester. Guidelines suggest that mothers with an HBV DNA viral load >200,000 IU/mL receive an antiviral such as telbivudine, lamivudine, or tenofovir during the third trimester, especially if they had a previous child who developed chronic HBV after receiving HBIG and the hepatitis B vaccine. This practice has proven safe with normal growth and development in infants of treated mothers.

Table 385.8

Strategy to Eliminate Hepatitis B Virus Transmission in the United States[*]

• Screening of all pregnant women for HBsAg
HBV DNA testing for HBsAg-positive pregnant women, with suggestion of maternal antiviral therapy to reduce perinatal transmission when HBV DNA is >200,000 IU/mL
Prophylaxis (HepB vaccine and hepatitis B immunoglobulin) for infants born to HBsAg-positive [†] women
• Universal vaccination of all infants beginning at birth [‡], [§] as a safeguard for infants born to HBV-infected mothers not identified prenatally
• Routine vaccination of previously unvaccinated children aged <19 yr
• Vaccination of adults at risk for HBV infection, including those requesting protection from HBV without acknowledgment of a specific risk factor

Table 385.11

Hepatitis B Vaccine Schedules for Children, Adolescents, and Adults

AGE GROUP	**SCHEDULE[*] (INTERVAL REPRESENTS TIME IN MONTHS FROM FIRST DOSE)**
Children (l-10 yr)	0, 1, and 6 mo 0, 1, 2, and 12 mo
Adolescents (11-19 yr)	0, 1, and 6 mo 0, 12, and 24 mo

	0 and 4-6 mo [†] 0, 1, 2, and 12 mo 0, 7 days, 21-30 days, 12 mo [‡]
Adults (≥20 yr)	0, 1, and 6 mo 0, 1, 2, and 12 mo 0, 1, 2, and 6 mo [§] 0, 7 days, 21-30 days, 12 mo [‡]

[*] Refer to package inserts for further information. For all ages, when the HepB vaccine schedule is interrupted, the vaccine series does not need to be restarted. If the series is interrupted after the 1st dose, the 2nd dose should be administered as soon as possible, and the 2nd and 3rd doses should be separated by an interval of at least 8 wk. If only the 3rd dose has been delayed, it should be administered as soon as possible. The final dose of vaccine must be administered at least 8 wk after the 2nd dose and should follow the 1st dose by at least 16 wk; the minimum interval between the 1st and 2nd doses is 4 wk. Inadequate doses of hepatitis B vaccine or doses received after a shorter-than-recommended dosing interval should be readministered, using the correct dosage or schedule. Vaccine doses administered ≤ 4 days before the minimum interval or age are considered valid. Because of the unique accelerated schedule for Twinrix, the 4-day guideline does not apply to the 1st 3 doses of this vaccine when administered on a 0-day, 7-day, 21-30-day, and 12-mo schedule (new recommendation).

[†] A 2-dose schedule of Recombivax adult formulation (10 µg) is licensed for adolescents aged 11-15 yr. When scheduled to receive the second dose, adolescents aged >15 yr should be switched to a 3-dose series, with doses 2 and 3 consisting of the pediatric formulation administered on an appropriate schedule.

[‡] Twinrix is approved for use in persons aged ≥ 18 yr and is available on an accelerated schedule with doses administered at 0, 7, 21-30 days, and 12 mo.

[§] A 4-dose schedule of Engerix administered in 2 1 mL doses (40 µg) on a 0-, 1-, 2-, and 6-mo schedule is recommended for adult hemodialysis patients.

From Schillie S, Vellozzi C, Reingold A, et al: Prevention of hepatitis B virus infection in the United States: recommendations of the advisory committee on immunization practices, *MMWR* 67(1):1–29, 2018, Table 4, p. 13.

Household, sexual, and needle-sharing contacts of patients with chronic HBV infection should be identified and vaccinated if they are susceptible to HBV infection. Patients should be advised about the perinatal and intimate contact risk of transmission of HBV. HBV is not spread by breastfeeding, kissing, hugging, or sharing water or utensils. Children with HBV should not be excluded from school, play, childcare, or work, unless they are prone to biting. A support group might help children to cope better with their disease. Families should not feel obligated to disclose the diagnosis as this information may lead to prejudice or mistreatment of the patient or the patient's family. All patients positive for HBsAg should be reported to the state or local health department, and chronicity is diagnosed if they remain positive past 6 mo HBIG.

HBIG is indicated only for specific *postexposure* circumstances and provides only temporary protection (3-6 mo). It plays a pivotal role in preventing *perinatal* transmission when administered within 12 hr of birth.

Universal Vaccination

Two single-antigen vaccines (Recombivax HB and Engerix-B) are approved for children and are the only preparations approved for infants younger than age 6 mo. Three combination vaccines can be used for subsequent immunization dosing and enable integration of the HBV vaccine into the regular immunization schedule. The safety profile of HBV vaccine is excellent. The most reported side effects are pain at the injection site (up to 29% of cases) and fever (up to 6% of cases). Seropositivity is >95% with all vaccines, achieved after the second dose in most patients. The third dose serves as a booster and may have an effect on maintaining long-term immunity. In immunosuppressed patients and infants whose birthweight is <2,000 g, a fourth dose is recommended (the birth dose does not count as part of the 3-dose series) and these infants should be checked for anti-HBs and HBsAg after completing these shots. In this group of infants, if the anti-HBs level is <10 mIU/mL, they should repeat the 3-dose series. Despite declines in the anti-HBs titer in time, most healthy vaccinated persons remain protected against HBV infection.

Current HBV vaccination recommendations are as noted in Tables 385.9 to 385.11 .

Postvaccination testing for HBsAg and anti-HBs should be done at 9-18 mo. If the result is positive for anti-HBs, the child is immune to HBV. If the result is positive for HBsAg only, the parent should be counseled, and the child evaluated by a pediatric hepatologist. If the result is negative for both HBsAg and anti-HBs, a second complete hepatitis B vaccine series should be administered, followed by testing for anti-HBs to determine if subsequent doses are needed.

Administration of 4 doses of vaccine is permissible when combination vaccines are used after the birth dose; this does not impact vaccine response.

Postexposure Prophylaxis

Recommendations for postexposure prophylaxis for prevention of hepatitis B infection depend on the conditions under which the person is exposed to HBV (see Table 385.11). Vaccination should never be postponed if written records of the exposed person's immunization history are not available, but every effort should still be made to obtain those records.

Special Populations

Patients with cirrhosis may not respond as well to the HBV vaccine and repeating anti-HBs titers should be performed. Adult studies suggest higher dosage or shorter interval between dosages may increase the immunization effectiveness. Patients with inflammatory bowel disease frequently have not been immunized, or did not develop complete immunity to HBV, as demonstrated by inadequate anti-HBs levels. These patients may be at risk for fulminant HBV (reactivation) when immunosuppression is started as part of their treatment regimen, specifically with biologic agents such as infliximab.

Prognosis

In general, the outcome after acute HBV infection is favorable, despite a risk of ALF. The risk of developing chronic infection brings the risks of liver cirrhosis and HCC to the forefront. Perinatal transmission leading to chronicity is responsible for the high incidence of HCC in young adults in endemic areas. Importantly, HBV infection and its complications are effectively controlled and prevented with vaccination and multiple clinical trials are ongoing in an effort to improve and guide treatment regimens.

Hepatitis C

Etiology

HCV is a single-stranded RNA virus, classified as a separate genus within the Flaviviridae family, with marked genetic heterogeneity. It has 6 major genotypes and numerous subtypes and quasi-species, which permit the virus to escape host immune surveillance. Genotype variation might partially explain the differences in clinical course and response to treatment. Genotype 1b is the most common genotype in the United States and is the least responsive to the approved pediatric medications.

Epidemiology

In the United States, HCV infection, the most common cause of chronic liver disease in adults, is responsible for 8,000-10,000 deaths per year. Approximately 4 million people in the United States and 170 million people worldwide are estimated to be infected with HCV. Approximately 85% of infected adults remain chronically infected. In children, seroprevalence of HCV is 0.2% in those younger than age 11 yr and 0.4% in children age 11 yr or older. However, even more children may be infected as only a small percentage of HCV-infected children are identified, and an even smaller number subsequently receive treatment. Appropriate identification, and screening, for infected individuals should be implemented.

Risk factors for HCV transmission in the United States included blood transfusion before 1992 as the most common route of infection, but, with current blood donor screening practices, the risk of HCV transmission is approximately 0.001% per unit transfused. Illegal drug use with exposure to blood or blood products from HCV-infected persons accounts for more than half of adult cases in the United States. Sexual transmission, especially through multiple sexual partners, is the second most common cause of infection. Other risk factors include occupational exposure, but approximately 10% of new infections have no known transmission source. In children, perinatal transmission is the *most* prevalent mode of transmission (see Table 385.1). Perinatal transmission occurs in up to 5% of infants born to viremic mothers. HIV coinfection and high viremia titers (HCV RNA-positive) in the mother can increase the transmission rate to 20%. The incubation period is 7-9 wk (range: 2-24 wk).

Pathogenesis

The pattern of acute hepatic injury is indistinguishable from that of other hepatotropic viruses. In chronic cases, lymphoid aggregates or follicles in portal tracts are found, either alone or as part of a general inflammatory infiltrate of the portal areas. Steatosis is also often seen in these liver specimens. HCV appears to cause injury primarily by cytopathic mechanisms, but immune-mediated injury can also occur. The cytopathic component appears to be mild because the acute illness is typically the least severe of all hepatotropic virus infections.

Clinical Manifestations

Acute HCV infection tends to be mild and insidious in onset (Fig. 385.4 ; see also Table 385.1). ALF rarely occurs. HCV is the most likely of all these viruses to cause chronic infection (Fig. 385.5). Of affected adults, <15% clear the virus; the rest develop chronic hepatitis. In pediatric studies, 6–19% of children achieved spontaneous sustained clearance of the virus during a 6-yr follow-up.

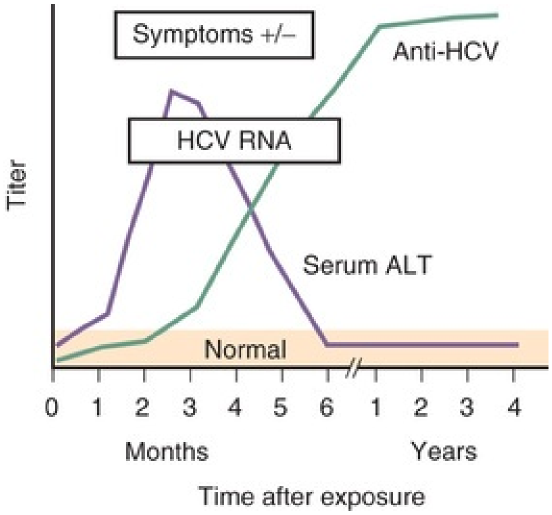

FIG. 385.4 Typical course of acute hepatitis B virus *(HCV)* infection followed by recovery. Symptoms may or may not be present during acute infection. Chronic HCV infection is also clinically silent until a complication develops. Serum aminotransferase levels fluctuate and are sometimes normal, but histologic inflammation is universal. Progression of liver fibrosis is slow over several years, unless comorbid factors are present, which can accelerate fibrosis progression. Approximately 25% of infected patients ultimately progress to cirrhosis, liver failure, and, occasionally, primary HCC within 20-30 yr of the acute infection. Although progression is rare within the pediatric age range, cirrhosis and HCC from HCV have been reported in children. The long-term morbidities constitute the rationale for diagnosis and treatment in children with HCV.

Chronic HCV infection can be associated with small vessel vasculitis and is a common cause of essential mixed cryoglobulinemia. Other extrahepatic manifestations, predominantly seen in adults, include cutaneous vasculitis, porphyria cutanea tarda, lichen planus, peripheral neuropathy, cerebritis, polyarthritis, membranoproliferative glomerulonephritis, and nephrotic syndrome. Antibodies to smooth muscle, antinuclear antibodies, and low thyroid hormone levels may also be present.

Diagnosis

Clinically available assays for detection of HCV infection are based on detection of antibodies to HCV antigens or detection of viral RNA (see Table 385.3); neither can predict the severity of liver disease.

The most widely used serologic test is the third-generation enzyme immunoassay to detect anti-HCV. The predictive value of this assay is greatest in high-risk populations, but the false-positive rate can be as high as 50–60% in low-risk populations. False-negative results also occur because antibodies remain negative for as long as 1-3 mo after clinical onset of illness. Anti-HCV is not a protective antibody and does not confer immunity; it is usually present simultaneously with the virus.

The most commonly used virologic assay for HCV is a PCR assay, which permits detection of small amounts of HCV RNA in serum and tissue samples within days of infection. The *qualitative* PCR detection is especially useful in patients with recent or perinatal infection, hypogammaglobulinemia, or immunosuppression and is highly sensitive. The *quantitative* PCR aids in identifying patients who are likely to respond to therapy and in monitoring response to therapy.

Screening for HCV should include all patients with the following risk factors: history of illegal drug use (even if only once), receiving clotting factors made before 1987 (when inactivation procedures were introduced) or blood products before 1992, hemodialysis, idiopathic liver disease, and children born to HCV-infected women (qualitative PCR in infancy and anti-HCV after 12-18 mo of age). In children, it is also important to consider whether the mother has any of the risk factors noted above that would increase her possibility of developing HCV. Routine screening of all pregnant women is currently not recommended. The Centers for Disease Control now recommends that all individuals born between 1945 and 1965 be screened.

Determining HCV genotype is also important, particularly when therapy is considered, because the response to the current therapeutic agents varies greatly. Genotype 1 traditionally responded poorly to therapy while genotypes 2 and 3 had a more favorable response. Newer agents, however, have led to changes in the treatment duration and anticipated outcome (as discussed later).

Aminotransferase levels typically fluctuate during HCV infection and do not correlate with the degree of liver fibrosis. A liver biopsy was previously the only means to assess the presence and extent of hepatic fibrosis, outside of overt signs of chronic liver disease. Newer noninvasive modalities using ultrasound or magnetic resonance elastography, however, are now used to estimate the degree of fibrosis and decrease the need for biopsy. This technology coupled with newer drug regimens have eliminated the need for liver biopsy in many cases of HCV. A liver biopsy is now primarily indicated to rule out other causes of overt liver disease.

Complications

The risk of ALF caused by HCV is low, but the risk of chronic hepatitis is the highest of all the hepatitis viruses. In adults, risk factors for progression to hepatic fibrosis include older age, obesity, male sex, and even moderate alcohol ingestion (two 1 oz. drinks per day). Progression to cirrhosis or HCC is a major cause of morbidity and the most common indication for liver transplantation in adults in the United States.

Treatment

In adults, *peginterferon* (subcutaneous, weekly) combined with ribavirin (oral, daily) was standard therapy until 2012 for genotype 1. Currently recommended first-line adult therapy for HCV includes taking 1 or 2 oral medications with direct-acting antiviral properties, for 12-24 wk dependent on HCV genotype and other clinical factors. Studies show these treatments are more effective and better tolerated, and these same medications are currently being evaluated in children and adolescents.

Traditionally, patients most likely to respond had mild hepatitis, shorter duration of infection, low viral titers, and either genotype 2 or 3 virus. Patients with genotype 1 virus responded poorly. Response to peginterferon alfa/ribavirin may be predicted by single-nucleotide polymorphisms near the interleukin 28B gene, but with these newer treatment regimens excellent response rates are being reported with shorter duration, IFN-free regimens.

The goal of treatment is to achieve a sustained viral response (SVR), as defined by the absence of viremia at a variable period after stopping the medications; SVR is associated with improved histology and decreased risk of morbidities.

The natural history of HCV infection in children is still being defined. It is believed that children have a higher rate of spontaneous clearance than adults (up to 45% by age 19 yr). A multicenter study followed 359 children infected with HCV over 10 yr. Only 7.5% had cleared the virus, and 1.8% progressed to decompensated cirrhosis. Treatment in adults with *acute* HCV in a pilot study showed an 88% SVR in genotype 1 subjects (treated with IFN and ribavirin for 24 wk). Such data, if confirmed, could raise the question whether children, with shorter duration of infection and fewer comorbid conditions than their adult counterparts, could be ideal candidates for treatment. Given the adverse effects of currently available therapy, this strategy is not recommended outside of clinical trials.

Peginterferon (Schering), IFN-α2b, and ribavirin are approved by the Food and Drug Administration (FDA) for use in children older than 3 yr of age with chronic hepatitis C. Studies of IFN monotherapy in children demonstrated a higher SVR than in adults, with better compliance and fewer side effects. An SVR up to 49% for genotype 1 was achieved in multiple studies. Factors associated with a higher likelihood of response are age younger than 12 yr, genotypes 2 and 3, and, in patients with genotype 1b, an RNA titer of <2 million copies/mL of blood, and viral response (PCR at wk 4 and 12 of treatment). Side effects of medications lead to discontinuation of treatment in a high proportion of patients; these include influenza-like symptoms, anemia, and neutropenia.

Long-term effects of these medicines also need to be evaluated as significant differences were noted in children's weight, height, body mass index, and body composition. Most of these delays improved following cessation of treatment, but height z-scores continued to lag behind.

Treatment may be considered for children infected with genotypes 2 and 3, because they have an 80–90% response rate to therapy with peginterferon and ribavirin. If the child has genotype 1b virus, the treatment choice remains more controversial as newer regimens are quickly becoming available.

Pediatric guidelines recommend treatment to eradicate HCV infection, prevent progression of liver disease and development of HCC, and to remove the stigma associated with HCV. Treatment should be considered for patients with evidence of advanced fibrosis or injury on liver biopsy. One approved treatment consists of 24-48 wk of peginterferon and ribavirin (therapy should be stopped if still detectable on viral PCR at 24 wk of therapy). In addition, sofosbuvir alone or in combination with ledipasvir has FDA approval for children ages 12-17 yr. The combination is indicated for HCV genotypes 1, 4, 5, and 6, while sofosbuvir with ribavirin is indicated for HCV genotypes 2 or 3; both regimens are used in children with mild or no cirrhosis.

Newer Treatments

Varying IFN-free regimens are now available for adults for all HCV genotypes allowing even greater likelihood of achieving viral eradication, with completely oral medication regimens, and without the use of IFN and its attendant side effects. With the rapid development of new medications and regimens, frequent review of up-to-date resources, such as www.hcvguidelines.org , will be vital to provide optimal care (Table 385.12).

Table 385.12

Ongoing Studies With Direct Acting Antiviral Combinations in Children With Chronic Hepatitis C Virus Infection

From Indolfi G, Serranti D, Resti M: Direct-acting antivirals for children and adolescents with chronic hepatitis C. *Lancet Child Adolesc* 2:298-304, 2018 (Table 1, p. 299).

Prevention

No vaccine is yet available to prevent HCV, although ongoing research suggests this will be possible in the future. Currently available Ig preparations are not beneficial, likely because preparations produced in the United States do not contain antibodies to HCV because blood and plasma donors are screened for anti-HCV and excluded from the donor pool. Broad neutralizing antibodies to HCV were found to be protective and might pave the road for vaccine development.

Once HCV infection is identified, patients should be screened yearly with a liver ultrasound and serum α-fetoprotein for HCC, as well as for any clinical evidence of liver disease. Vaccinating the affected patient against HAV and HBV will prevent superinfection with these viruses and the increased risk of developing severe liver failure.

Prognosis

Viral titers should be checked yearly to document spontaneous remission. Most patients develop chronic hepatitis. Progressive liver damage is higher in those with additional comorbid factors such as alcohol consumption, viral genotypic variations, obesity, and underlying genetic predispositions. Referral to a pediatric hepatologist is strongly advised to take advantage of up-to-date monitoring regimens and to optimize their enrollment in treatment protocols when available.

Hepatitis D

Etiology

HDV, the smallest known animal virus, is considered defective because it cannot produce infection without concurrent HBV infection. The 36 nm diameter virus is incapable of making its own coat protein; its outer coat is composed of excess HBsAg from HBV. The inner core of the virus is single-stranded circular RNA that expresses the HDV antigen.

Epidemiology

HDV can cause an infection at the same time as the initial HBV infection (coinfection), or HDV can infect a person who is already infected with HBV (superinfection). Transmission usually occurs by intrafamilial or intimate contact in areas of high prevalence, which are primarily developing countries (see Table 385.1). In areas of low prevalence, such as the United States, the parenteral route is far more common. HDV infections are uncommon in children in the United States but must be considered when ALF occurs. The incubation period for HDV superinfection is approximately 2-8 wk; with coinfection, the incubation period is similar to that of HBV infection.

Pathogenesis

Liver pathology in HDV-associated hepatitis has no distinguishing features except that damage is usually severe. In contrast to HBV, HDV causes injury directly by cytopathic mechanisms. The most severe cases of HBV infection appear to result from coinfection of HBV and HDV.

Clinical Manifestations

The symptoms of hepatitis D are similar to, but usually more severe than, those of the other hepatotropic viruses. The clinical outcome for HDV infection depends on the mechanism of infection. In coinfection, *acute* hepatitis, which is much more severe than for HBV alone, is common, but the risk of developing chronic hepatitis is low. In superinfection, acute illness is rare and chronic hepatitis is common. The risk of ALF is highest with superinfection. Hepatitis D should be considered in any child who experiences ALF.

Diagnosis

HDV has not been isolated and no circulating antigen has been identified. The diagnosis is made by detecting IgM antibody to HDV; the antibodies to HDV develop approximately 2-4 wk after coinfection and approximately 10 wk after a superinfection. A test for anti-HDV antibody is commercially available. PCR assays for viral RNA are available as research tools (see Table 385.2).

Treatment

The treatment is based on supportive measures once an infection is identified. There are no specific HDV-targeted treatments to date. The treatment is mostly based on controlling and treating HBV infection, without which HDV cannot induce hepatitis. Small research studies suggest that IFN is the preferred treatment regimen, but ongoing studies still seek the ideal management strategy and the regimen should be personalized for each patient.

Prevention

There is no vaccine for hepatitis D. Because HDV replication cannot occur without hepatitis B coinfection, immunization against HBV also prevents HDV infection. Hepatitis B vaccines and HBIG are used for the same indications as for hepatitis B alone.

Hepatitis E

Etiology

HEV has been cloned using molecular techniques. This RNA virus has a nonenveloped sphere shape with spikes and is similar in structure to the caliciviruses.

Epidemiology

Hepatitis E is the epidemic form of what was formerly called non-A, non-B hepatitis. Transmission is fecal–oral (often waterborne) and is associated with shedding of 27-34 nm particles in the stool (see Table 385.1). The highest prevalence of HEV infection has been reported in the Indian subcontinent, the Middle East, Southeast Asia, and Mexico, especially in areas with poor sanitation. The prevalence, however, appears to be increasing in the United

States and other developed countries and has been postulated to be the most common cause of acute hepatitis and jaundice in the world. The mean incubation period is approximately 40 days (range: 15-60 days).

Pathogenesis

HEV appears to act as a cytopathic virus. The pathologic findings are similar to those of the other hepatitis viruses.

Clinical Manifestations

The clinical illness associated with HEV infection is similar to that of HAV but is often more severe. As with HAV, chronic illness does not occur—the sole exception noted to date is chronic hepatitis E occurring in immunosuppressed patients (e.g., post-transplant). In addition to often causing a more severe episode than HAV, HEV tends to affect older patients, with a peak age between 15 and 34 yr. HEV is a major pathogen in pregnant women, in whom it causes ALF with a high fatality incidence. HEV could also lead to decompensation of preexisting chronic liver disease.

Diagnosis

Recombinant DNA technology has resulted in development of antibodies to HEV particles, and IgM and IgG assays are available to distinguish between acute and resolved infections (see Table 385.3). IgM antibody to viral antigen becomes positive after approximately 1 wk of illness. Viral RNA can be detected in stool and serum by PCR.

Prevention

A recombinant hepatitis E vaccine is highly effective in adults. No evidence suggests that immune-globulin is effective in preventing HEV infections. Ig pooled from patients in endemic areas might prove to be effective.

Approach to Acute or Chronic Hepatitis

Identifying deterioration of the patient with acute hepatitis and the development of ALF is a major contribution of the primary pediatrician (Fig. 385.6). If ALF is identified, the clinician should immediately refer the patient to a transplantation center; this can be lifesaving.

Once chronic infection is identified, close follow-up and referral to a pediatric hepatologist is recommended to enroll the patient in appropriate treatment trials. Treatment of chronic HBV and HCV in children should preferably be delivered within, or using data from, pediatric controlled trials as indications, timing, regimen, and outcomes remain to be defined and cannot be extrapolated from adult data. All patients with chronic viral hepatitis should avoid, as much as possible, further insult to the liver; HAV vaccine is recommended. Patients must avoid alcohol consumption and obesity, and they should exercise care when taking new medications, including nonprescription drugs and herbal medications.

International adoption and ease of travel continue to change the epidemiology of hepatitis viruses. In the United States, chronic HBV and HCV have a high prevalence among international adoptee patients; vigilance is required to establish early diagnosis in order to offer appropriate treatment as well as prophylactic measures to limit viral spread.

Chronic hepatitis can be a stigmatizing disease for children and their families. The pediatrician should offer, with proactive advocacy, appropriate support for them as well as needed education for their social circle. Scientific data and information about support groups are available for families on the websites for the American Liver Foundation (www.liverfoundation.org) and the North American Society for Pediatric Gastroenterology, Hepatology and Nutrition (www.naspghan.org), as well as through pediatric gastroenterology centers.

CHAPTER 386

Liver Abscess

Joshua K. Schaffzin, Robert W. Frenck Jr

Liver abscesses typically have 1 of 2 infectious etiologies: pyogenic, meaning involving bacteria, or parasitic, such as with amebiasis, ascariasis, or toxocariasis. Liver abscesses are typically difficult to detect due to nonspecific presentation, and diagnosis requires a high index of suspicion. Radiographic diagnosis is often contributory, but further confirmation is often indicated to differentiate infectious abscess from hydatid cyst and noninfectious causes, such as malignancy (primary hepatic or metastasis). The differential diagnosis also includes traumatic injury (including procedural, such as a misplaced vascular catheter).

Pyogenic liver abscesses are uncommon in children but have been reported in all ages. Bacteria can invade the liver through 1 of 4 sources: hematogenously through the hepatic artery (e.g., in the presence of bacteremia), through the biliary tract, through the portal vein (portal sepsis), and directly by contiguous infection. In neonates, a portal vein source can include the umbilical vein (e.g., in the presence of omphalitis or injury caused by an umbilical venous catheter). Pyogenic liver abscesses of unknown source are classified as cryptogenic. Children with chronic granulomatous disease (CGD), hyper–immunoglobulin E (hyper-IgE) syndrome, or malignancies are at increased risk of liver abscess. Pyogenic liver abscesses are also uncommon in adults, although the annual incidence is higher in Southeast Asia (estimated 17.6/100,000 population) than in the United States or Europe (estimated 2-5/100,000 population). They tend to occur more frequently in males, older ages, and in patients with diabetes or a history of liver transplantation or malignancy.

Clinical signs and symptoms of pyogenic liver abscess are nonspecific and can include fever, chills, malaise, fatigue, nausea, abdominal pain (with or without right upper quadrant tenderness), and hepatomegaly; jaundice is uncommon. The most common abnormal laboratory findings are elevated inflammatory markers and hypoalbuminemia. Hepatic function testing is often abnormally elevated, and leukocytosis is common. Radiologic confirmation is often obtained by ultrasound or CT (Fig. 386.1). Chest x-rays may show elevation of the right hemidiaphragm with a right pleural effusion. Solitary lesions of the right hepatic lobe are most common, although solitary abscesses can appear in any hepatic lobe or as multiple disseminated lesions (such as with disseminated candidiasis, bartonellosis, or rarely brucellosis).

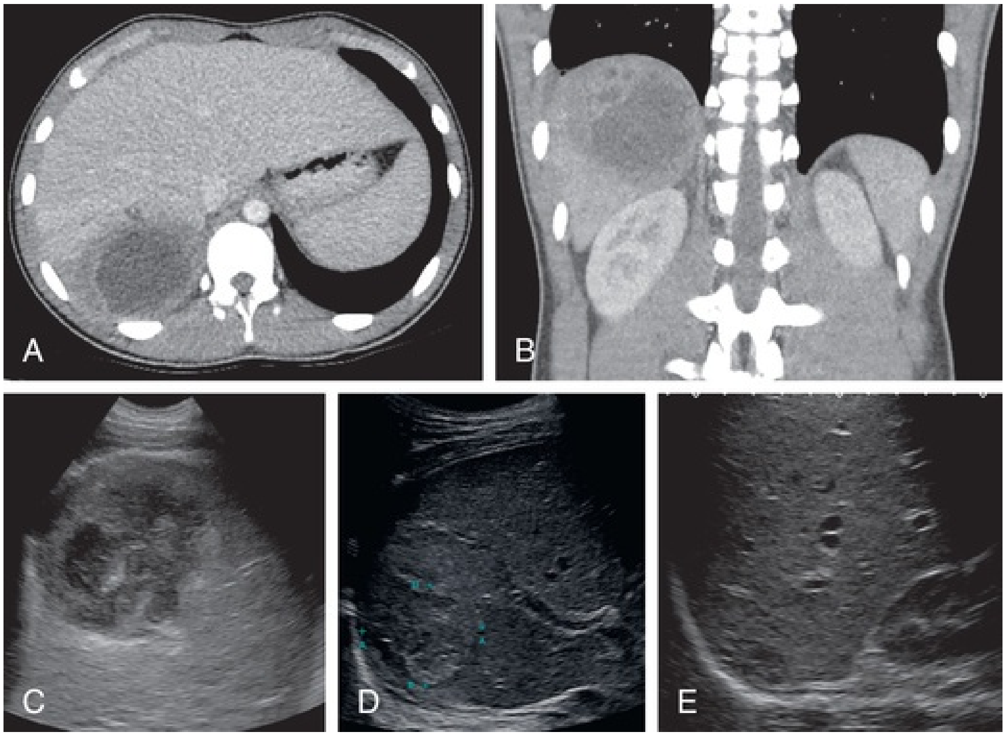

FIG. 386.1 CT (**A** and **B**) and ultrasound **(C)** images of a cryptogenic liver abscess in a 16 yr old male without known risk factors. The lesion was drained percutaneously, and cultures grew multiple anaerobic organisms (*Fusobacterium nucleatum* and *Parvimonas micra*). He was successfully treated with 2 wk of parenteral followed by 4 wk of oral therapy and was followed with serial ultrasounds 5 days **(D)** and 34 days **(E)** after drainage. (Courtesy Dr. Alexander Towbin, Cincinnati Children's Hospital, Cincinnati, Ohio.)

Cultures of pyogenic liver abscesses often yield mixed populations. In children, *Staphylococcus aureus*, *Streptococcus* spp., enteric Gram-negative organisms (*Escherichia coli*, *Klebsiella pneumoniae*, and *Serratia* in CGD patients), and anaerobic organisms are most common. Among adults, *K.*

pneumoniae predominates, followed by *E. coli* , with less common aerobic Gram-positive and anaerobic organisms. Blood cultures are often positive and may be helpful to determine a therapy plan.

Due to the wide range of causative organisms (i.e., aerobic Gram negative, *S. aureus* , and anaerobic organisms) empiric antimicrobial treatment needs to be broad. Potential empiric antimicrobial choices include; piperacillin-tazobactam, ampicillin-sulbactam, or metronidazole with a 3rd-generation cephalosporin. Depending on local prevalence and degree of suspicion, vancomycin may be added to cover methicillin-resistant *S. aureus* . Therapy can be modified based on culture sensitivities. Treatment duration is not standardized, and should be based on fever resolution, clinical and inflammatory marker improvement, and serial ultrasound monitoring. Many sources recommend completing 4-6 wk of therapy, with the first 2 wk administered parentally. Depending on the size and extent of the lesion(s), percutaneous or surgical drainage may be added to obtain samples for cultures and to shorten illness duration. Percutaneous options include single-pass needle or catheter aspiration, or insertion of a continuously draining catheter. In adults, unless there is evidence of rupture or spread, percutaneous drainage should be attempted first for large lesions (≥5-7 cm in diameter). Numerous case series of pyogenic liver abscess in premature infants described complete resolution with antibiotic therapy alone, and some advocate for this as an initial approach in smaller lesions. Resolution can be monitored by trending inflammatory markers and/or serial imaging.

Amebic liver abscess (ALA) is the most common extraintestinal manifestation of *Entamoeba histolytica* infection. Although more common in endemic areas, cases can be diagnosed in the United States among travelers to, and immigrants from, endemic areas. Presentation can be delayed by mo to yr. ALA is more common among adults aged 18-55, and males predominate. Amoebic trophozoites invade colonic mucosa and reach the liver through the portal circulation. Patients may not have an associated colitis. Fever, right upper quadrant pain, anorexia, and weight loss are often present. Laboratory evaluation typically reveals a leukocytosis without eosinophilia and increased alkaline phosphatase. Ultrasonography or CT demonstrates the abscess (Fig. 386.2).

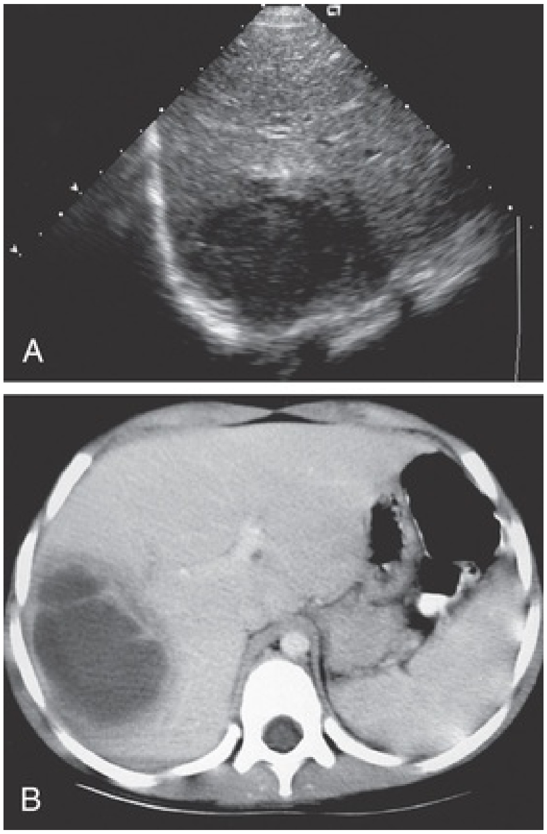

FIG. 386.2 Amebic abscess. **A,** Sonogram demonstrates a hypoechogenic mass in the right lobe of the liver with a more hypoechoic surrounding rim. **B,** CT scan demonstrates a low-attenuation mass in the right lobe of the liver with a prominent halo. (From Kuhn JP, Slovis TL, Haller JO: *Caffrey's pediatric diagnostic imaging* , vol 2, ed 10, Philadelphia, 2004, Mosby, p. 1473.)

Diagnosis of ALA is often confirmed by serum ELISA. Serology is considered reliable in nonendemic areas but can be prone to false negatives early in the infection and cannot distinguish active infection from previous exposure. Testing for *E. histolytica* presence in stool is specific but not very sensitive, and patients with ALA may not have detectable organism in their stool. Most sensitive and specific among stool assays is PCR, followed by stool antigen detection, and least reliable is microscopy, because *E. histolytica* cannot easily be distinguished microscopically from its clinically benign relatives *Entamoeba dispar* and *Entamoeba moshkovskii* .

Prior to effective treatment, ALA-associated mortality was high; it has since decreased significantly. Treatment involves 7-10 days of a nitroimidazole (most commonly metronidazole) to kill trophozoites, followed by 7 days of a luminal agent (such as paromomycin) to kill colonic cysts. Patients with large abscesses

(≥5-7 cm in diameter) may benefit from percutaneous aspiration in addition to medical therapy.

CHAPTER 387

Liver Disease Associated With Systemic Disorders

Bernadette E. Vitola, William F. Balistreri

Liver disease is found in a wide variety of systemic illnesses, both as a result of the primary pathologic process and as a secondary complication of the disease or associated therapy.

Inflammatory Bowel Disease

Ulcerative colitis and Crohn disease (Chapter 362) are associated with hepatobiliary disease that includes autoimmune and inflammatory processes related to inflammatory bowel disease (IBD) (sclerosing cholangitis, autoimmune hepatitis [AIH]), drug toxicity (thiopurines, methotrexate, 5-ASA, biologics), malnutrition and disordered physiology (fatty liver, cholelithiasis), bacterial translocation and systemic infections (hepatic abscess, portal vein thrombosis), hypercoagulability (infarction, Budd-Chiari), and long-term complications of these liver diseases, such as ascending cholangitis, cirrhosis, portal hypertension, and biliary carcinoma. Hepatobiliary manifestations may continue to progress even when intestinal symptoms are well-controlled and are unrelated to either the severity or duration of intestinal disease.

Sclerosing cholangitis is the most common hepatobiliary disease associated with IBD, occurring in 2–8% of adult patients with ulcerative colitis and less often in Crohn disease. Conversely, 70–90% of patients with sclerosing cholangitis have ulcerative colitis. In pediatric patients with IBD, the diagnosis typically occurs in the 2nd decade of life, with a median age of 14 yr. Sclerosing cholangitis is characterized by progressive inflammation and fibrosis of segments of the intrahepatic and extrahepatic bile ducts and can progress to complete obliteration. Genetic susceptibility has been demonstrated. Many patients are asymptomatic, and the disease is initially diagnosed by routine liver function testing that reveals elevated serum alkaline phosphatase (AP), 5′-nucleotidase, or γ-glutamyl transpeptidase (GGT) activities. Antinuclear or anti–smooth muscle antibodies might also be present in the serum. Ten to 15% of adult patients present with symptoms including anorexia, weight loss, pruritus, fatigue, right upper quadrant pain, and jaundice; intermittent acute cholangitis accompanied by fever, jaundice, and right upper quadrant pain can also occur. Portal hypertension can develop with progressive disease. These symptoms are less common in children, in whom hepatobiliary disease is often recognized by routine screening of liver function tests. In children with sclerosing cholangitis, approximately 11% present initially with hepatic manifestations, and the associated asymptomatic IBD is discovered only on subsequent endoscopy.

Magnetic resonance cholangiography is an established first line diagnostic test for sclerosing cholangitis. Characteristic findings include beading and irregularity of the intrahepatic and extrahepatic bile ducts. Liver biopsy typically reveals periductal fibrosis and inflammation, fibroobliterative cholangitis, and portal fibrosis, but it is not required for the diagnosis in patients with radiologic evidence of sclerosing cholangitis. However, biopsy is required to evaluate for overlap with autoimmune hepatitis or autoimmune sclerosing cholangitis.

Sclerosing cholangitis is strongly associated with hepatobiliary malignancies (cholangiocarcinoma, hepatocellular carcinoma, gallbladder carcinoma) with a reported incidence varying between 9% and 14%. In 1 large series, patients with IBD and sclerosing cholangitis had a 10-fold increased risk of colorectal carcinoma and a 14-fold increased risk of pancreatic cancer compared with the general population. Tumor serology (CA 19-9) and cross-sectional liver imaging may be a useful screening strategy to identify patients with sclerosing cholangitis at increased risk for cholangiocarcinoma.

There is no definitive medical treatment for sclerosing cholangitis; liver transplantation is the only long-term option for progressive cirrhosis, and autoimmune disease can recur in the allograft in 20–25% of patients. Short-term therapy aims at improving biliary drainage and attempting to slow the obliterative process. Ursodeoxycholic acid, at a dose of 15 mg/kg/24 hr, may improve bile flow and laboratory parameters but has not been shown to improve clinical outcome. Dominant extrahepatic biliary strictures may be dilated or endoscopically stented. Immunosuppressive therapy with corticosteroids and/or azathioprine may improve biochemical parameters but has been disappointing in halting long-term histologic progression. Symptomatic therapy should be initiated for pruritus (rifampin, ursodeoxycholic acid, diphenhydramine), malnutrition (enteral supplementation), and ascending cholangitis (antibiotics) as indicated. Total colectomy has not been beneficial in preventing or managing hepatobiliary complications in patients with ulcerative colitis. However, in patients with end-stage liver disease requiring liver transplantation, those with active IBD are 10-fold more likely to lose their grafts.

IBD-associated AIH can closely resemble IBD-associated sclerosing cholangitis, a condition often referred to as **overlap syndrome** or autoimmune sclerosing cholangitis (ASC). These patients typically exhibit hyperglobulinemia (marked increase in serum immunoglobulin [Ig] G levels). In some children the disease is initially diagnosed as AIH and later is found to be sclerosing cholangitis after cholangiography. In other cases, AIH manifests well after diagnosis of IBD-associated sclerosing cholangitis. Liver biopsy in patients with ASC shows interface hepatitis, in addition to the bile duct injury associated with sclerosing cholangitis. Immunosuppressive medication (corticosteroids and/or azathioprine) is the mainstay of therapy for ASC; long-term response does not appear to be as favorable as in AIH alone. Long-term survival in children with ASC appears to be similar to those with sclerosing cholangitis, with an overall median (50%) survival free of liver transplantation of 12.7 yr.

Fatty liver disease might also be more prevalent in adult patients with IBD, ranging from 25% to 40% in 1 large series and often correlates with severity of IBD. Gallstones are more prevalent in those with Crohn disease (11%) than in those with ulcerative colitis (7.5%) and in normal subjects (5%). However, the true prevalence of these IBD-associated liver diseases in pediatric patients is unknown.

Bacterial Sepsis

Sepsis can mimic liver disease and should be excluded in any critically ill patient who develops cholestasis in the absence of markedly elevated serum aminotransferase or AP levels, even when other signs of infection are not evident. Gram-negative organisms are most often isolated from blood cultures, in particular *Escherichia coli, Klebsiella pneumoniae*, and *Pseudomonas aeruginosa*. Lipopolysaccharides and other bacterial endotoxins are thought to interfere with bile secretion by directly altering the structure or function of bile canalicular membrane transport proteins. The serum bilirubin level, predominantly the conjugated fraction, is elevated. Serum AP and aminotransferase activities may also be elevated. Liver biopsy shows intrahepatic cholestasis with little or no hepatocyte necrosis. Kupffer cell hyperplasia and an increase in inflammatory cells are also common. Similar findings can occur with urosepsis.

Celiac Disease

Celiac disease (Chapter 364.2) may present with elevated aminotransferase levels and prolonged prothrombin time, as well as hepatic histologic changes, such as mild periportal and lobular inflammation. These abnormalities typically all improve on a gluten-free diet. Gastrointestinal symptoms may not be present. Other autoimmune liver diseases (AIH, primary sclerosing cholangitis) have also been associated with celiac disease, although they may not respond as well to a gluten-free diet.

Cardiac Disease

Hepatic injury can occur as a complication of severe acute or chronic congestive heart failure (Chapter 469), cyanotic congenital heart disease (Chapters 456 and 457), and acute ischemic shock. In all conditions, passive congestion and reduced cardiac output can contribute to liver damage. Elevated central venous pressure is transmitted to the hepatic veins, smaller venules, and, ultimately, the surrounding hepatocytes, resulting in hepatocellular atrophy in the centrilobular zone of the liver. Owing to decreased cardiac output, there is decreased hepatic arterial blood flow, and centrilobular hypoxia results. Hepatic necrosis leads to lactic acidosis, elevated aminotransferase levels, cholestasis, prolonged prothrombin time, cirrhosis, and possibly hypoglycemia due to impaired hepatocellular metabolism. Jaundice, tender hepatomegaly, and, in some cases, ascites and splenomegaly can occur. However, aminotransferases are often minimally elevated with slowly progressive fibrosis because there is minimal inflammation or cell death.

After acute hypovolemic shock, serum aminotransferase levels can rise to extremely high levels but rapidly return to normal when perfusion and cardiac function improve. Hepatic necrosis or acute liver failure can occur in infants with hypoplastic left heart syndrome and coarctation of the aorta. High systemic venous pressures after Fontan procedures can also lead to hepatic dysfunction, marked by prolonged prothrombin time, and cardiac cirrhosis. The aim of therapy in all causes of cardiac-associated liver disease is to improve cardiac output, reduce systemic venous pressures, and monitor for other signs of hypoperfusion. Even mild liver disease can have an impact on mortality after cardiac surgery, with poorer outcomes with progressively worse liver disease. In adults with cirrhosis undergoing cardiac surgery, overall mortality was 17% but varied significantly from 5% with mild disease to 70% with advanced liver disease.

Cholestasis Associated With Chronic Total Parenteral Nutrition

Total parenteral nutrition (TPN) can cause a variety of liver diseases, including hepatic steatosis, gallbladder and bile duct damage, and cholestasis. Cholestasis is the most severe complication and can lead to progressive fibrosis and cirrhosis. It is the major factor limiting effective long-term use of TPN in children and adults. Risk factors for TPN-associated cholestasis include prolonged duration of TPN (particularly soy-based lipids), prematurity, low birthweight, sepsis, necrotizing enterocolitis, and short bowel syndrome.

The pathogenesis of TPN-associated cholestasis is multifactorial. Sepsis; excess caloric intake; high amounts of protein, fat, or carbohydrate; specific amino acid toxicities; nutrient deficiencies; and toxicities related to components such as manganese, aluminum, and copper can all contribute to hepatic injury. The type (soy based), volume, and frequency of lipid administered may be a significant factor. Prolonged enteral fasting compromises mucosal integrity and increases bacterial mucosal translocation. Fasting also decreases release of cholecystokinin, which promotes bile flow. This leads to biliary stasis, cholestasis, and formation of biliary sludge and gallstones, which exacerbates hepatic dysfunction. Sepsis, in particular due to Gram-negative bacteria and associated endotoxins, can also exacerbate liver damage.

Early histologic findings include macrovesicular steatosis, canalicular cholestasis, and periportal inflammation. These changes can regress after cessation of short-term TPN. Prolonged duration of TPN is marked by bile duct proliferation or ductopenia, portal fibrosis, and expansion of portal triads, and it can progress to cirrhosis and end-stage liver disease.

Clinical onset is typically marked by gradual onset of cholestasis, developing after more than 2 wk of TPN. In low birthweight infants, the onset of jaundice can overlap the phase of physiologic (unconjugated) hyperbilirubinemia. Any icteric infant who has received TPN for more than 1 wk should have bilirubin fractionated. With prolonged duration, hepatic enlargement or splenomegaly can develop. Serum bile acid concentrations can increase. Rises in serum aminotransferase levels may be a late finding. An elevation in serum AP activity may be due to rickets, a common complication of TPN in low birthweight infants.

In addition to cholestasis, biliary complications of intravenous nutrition include cholelithiasis and the development of biliary sludge, associated with thick, inspissated gallbladder contents. These may be asymptomatic. Hepatic steatosis or elevated serum aminotransferase levels can also occur in the absence of cholestasis, particularly in older children. This is generally mild and resolves after TPN is discontinued. Serum bilirubin and bile acid levels remain within the normal range. Other causes of liver disease should also be considered, especially if evidence of hepatic dysfunction persists despite weaning from TPN and initiating enteral feeds. If serum AP or aminotransferase levels remain elevated, liver biopsy may be necessary for accurate diagnosis.

Treatment of TPN-associated cholestasis is focused on avoiding progressive liver injury by limiting the duration of the infusion whenever possible. Enteral feeding should be initiated as soon as tolerated and prolonged fasting should be avoided. Even small volumes of nutrients given by intermittent oral feedings or by continuous nasogastric drip promote bile flow, enterohepatic recirculation of bile acids, and intestinal motility, and they enhance mucosal barrier function, reducing the risk of bacterial translocation. Improved TPN solutions that meet the specific needs of neonates can prevent deficiencies and toxicities. The risk of further hepatic injury should always be considered when weighing the option of continuing TPN indefinitely, and all efforts should be made to try to advance enteral feeds whenever possible. There has been concern that the soy-based lipid infusion provided with TPN may be a significant contributing factor to TPN-associated cholestasis as a result of proinflammatory omega-6 fatty acids. Several strategies have been used to minimize exposure to these fatty acids by limiting total lipid and/or introducing alternate sources of lipid including fish oil and olive oil to provide more omega-3 fatty acids. The long-term effects of these strategies on essential fatty acid deficiency or growth are unclear although there is some evidence that TPN-associated cholestasis may improve.

Ursodeoxycholic acid therapy may be beneficial in improving jaundice and hepatosplenomegaly. Other therapies, such as administration of antibiotics to reduce intraluminal bacterial overgrowth or oral administration of taurine or cholecystokinin, remain experimental.

Cystic Fibrosis

Cystic fibrosis (CF) (Chapter 432) is caused by mutations in the *CFTR* gene, which impair chloride transport across the apical membranes of epithelial cells in numerous organs (including cholangiocytes). Many patients with CF have some evidence of hepatobiliary disease; however, less than one-third of these patients develop clinically significant liver disease. Hepatobiliary complications account for approximately 2.5% of overall mortality in patients with CF. The onset of liver disease occurs at a median age of 10 yr, and >90% occurs by 20 yr.

Focal biliary cirrhosis is the pathognomonic liver lesion in CF and is postulated to result, in part, from impaired secretory function of the bile duct epithelium. Blockage of biliary ductules secondary to viscid secretions results in periductal inflammation, bile duct proliferation, and increased fibrosis within focal portal tracts. Gradual progression to multilobular cirrhosis can occur and result in portal hypertension and end-stage liver disease in 1–8% of patients. Liver disease tends to occur mainly in males with pancreatic insufficiency and requires 2 CFTR mutations without residual function. One candidate gene modifier for clinical phenotypes of CF-related liver disease that shows a strong association is SERPINA1. However, additional study of mutational analysis is necessary before we are able to predict which patients with CF will develop liver disease. Clinical risk factors that may be associated with liver disease include older age, pancreatic insufficiency, male gender, and possibly a history of meconium ileus.

Treatment with oral ursodeoxycholic acid (10-15 mg/kg/day) may be beneficial in improving liver function, presumably by improving bile flow; further research is necessary to determine whether a true long-term benefit exists. Because it is difficult to predict which patients will develop liver disease, prophylactic therapy is not possible. Progression of liver disease is generally slow; the major concern is the development of portal hypertension and the associated complications.

Bone Marrow Transplantation

Liver disease is common in patients who have received hematopoietic stem cell transplantation (SCT), whether the cells are harvested from bone marrow or peripheral blood (Chapters 161-165). The pathogenesis is varied and includes infections (viral, bacterial, or fungal); toxicity from parenteral nutrition, chemotherapy, or radiation; venoocclusive disease (VOD); graft versus host disease (GVHD); or hemosiderosis secondary to iron overload from frequent blood transfusions. GVHD, drug toxicity, and sepsis are the most common causes of liver dysfunction after allogeneic SCT.

Diagnosis is often challenging due to the coexistence of multiple risk factors. Clinical course, symptoms and signs, and biochemical liver function and viral serologic tests must be considered in making the correct diagnosis. Percutaneous liver biopsy may be necessary; histology can show extensive bile duct injury in GVHD, viral inclusions in cytomegalovirus disease, or the characteristic endothelial lesion in VOD. It is important to diagnose the cause accurately, because treatment for GVHD differs markedly from that of other conditions (i.e., initiating immunosuppression for GVHD) and can worsen hepatitis secondary to infections.

GVHD of the liver can be acute or chronic but often occurs with the presence of GVHD in other target organs such as the skin and gut (Chapter 163). Hepatic GVHD is caused by immunologic reaction to bile duct epithelium, leading to a nonsuppurative cholangitis. Histologic features of GVHD include loss of intralobular bile ducts, endothelial injury of hepatic and portal venules, and hepatocellular necrosis.

Onset typically occurs at the time of donor engraftment (days 14-21 after SCT). In acute hepatic GVHD, serum aminotransferase levels can rise markedly in the absence of elevated bilirubin, AP, and GGT levels, mimicking viral hepatitis. Acute hepatic GVHD can manifest both early (days 14-21) and late (>day 70) after allogeneic SCT. In chronic hepatic GVHD, serum aminotransferase levels are not as markedly elevated and cholestasis is more prominent, with marked rises in serum conjugated bilirubin, GGT, and AP levels. Other signs and symptoms can include hepatic tenderness, dark urine, acholic stools, itching, and anorexia.

VOD of the liver usually develops in the first 3 wk after SCT. The incidence ranges from 5% to 39% in pediatric patients, with reported mortality rates varying from 0% to 47%. Risk factors include trauma, high-dose conditioning regimens, coagulopathies, sickle cell anemia, leukemia, polycythemia vera, thalassemia major, hepatic abscesses, irradiation, GVHD, iron overload, preexisting liver disease, and younger age. VOD is caused by fibrous obliteration of the terminal hepatic venules and small lobular veins, with resultant damage to the surrounding hepatocytes and sinusoids. It is not associated with thrombus formation, in contrast with Budd-Chiari syndrome, which involves occlusion of the larger hepatic veins or inferior vena cava by a web, mass, or thrombus.

Pathologic changes in patients with VOD are best demonstrated using special (trichrome) stains to highlight the central veins. The lesions may be patchy. Later in the course, hepatic venules may be completely obliterated.

Symptoms typically include jaundice, painful hepatomegaly, rapid weight gain, and ascites, although jaundice can be absent in nearly a third of pediatric patients with VOD. VOD resolves in the majority of patients but can also lead to multisystem organ failure, hepatic encephalopathy, and fulminant hepatic failure. Less-severe forms may be characterized by jaundice and ascites with a slow resolution; in very mild cases, histologic changes may be the sole manifestation. The diagnosis rests on the exclusion of other diseases, such as GVHD, congestive cardiomyopathy, constrictive pericarditis, and Budd-Chiari syndrome.

Treatment for VOD with defibrotide, an agent with antithrombotic and thrombolytic properties, at doses of 20-40 mg/kg/day, has been successful in multicenter trials in both adult and pediatric patients. Complete response rates vary between 36% and 76% and survival >100 days post SCT of 32–79%, with better outcomes in pediatric patients. Little toxicity has been noted; however, pediatric patients are at a higher risk of bleeding with treatment compared with adults. Oral ursodeoxycholic acid can decrease the incidence of severe liver disease in patients undergoing SCT and has been shown to reduce the incidence of VOD and transplant-related mortality in adults. Supportive management includes maintaining intravenous hydration and renal perfusion.

Hemoglobinopathies

Patients with sickle cell anemia (Chapter 489.1) or thalassemia (Chapter 489.10) can have hepatic dysfunction due to acute or chronic viral hepatitis, hemosiderosis from frequent transfusion therapy, hepatic crises related to severe intrahepatic cholestasis, sequestration, or ischemic necrosis. Cholelithiasis and hemosiderosis are both common and treatable. Higher volume of transfusions is associated with both higher hepatic iron content and fibrosis. Chelation therapy for iron overload is usually safe and effective but needs to be properly managed and monitored via imaging and serum ferritin levels.

Hepatic sickle cell crisis or “sickle hepatopathy” occurs in ~10% of patients with sickle cell disease. It manifests with intense RUQ pain and tenderness, fever, leukocytosis, and jaundice. Bilirubin levels may be markedly elevated; serum ALP levels may be only moderately elevated. It can be difficult to distinguish sickle hepatopathy from viral hepatitis, acute cholecystitis, or choledocholithiasis; therefore these conditions should be excluded. In general, hepatic sickle cell crisis is self-limited and symptoms resolve within 1-3 wk. **Sickle cell intrahepatic cholestasis** manifests as hepatomegaly, abdominal pain, hyperbilirubinemia, and coagulopathy and can progress to acute liver failure, leaving transplantation as the only therapeutic option. Transplantation carries a high risk for graft loss due to vascular complications.

On occasion, children with sickle cell disease experience a benign elevation of bilirubin levels >20 mg/dL but unaccompanied by severe pain or fever. There is no change in hematocrit or reticulocyte count nor any association with a hemolytic crisis.

Histiocytic Disorders

Langerhans cell histiocytosis (Chapter 534.1), the most common of the histiocytoses, typically affects the bone and skin. However, it can cause infiltration of high-risk organs such as the liver resulting in periportal inflammation and sclerosing cholangitis. Liver involvement often results in worse outcomes. Hemophagocytic lymphohistiocytosis (HLH) (Chapter 534.2) is a multiorgan, severe, and potentially fatal inflammatory process associated with activation of macrophages that mimics sepsis. The hepatic manifestation of HLH is usually acute liver failure with portal inflammatory infiltrates and hemophagocytosis noted on liver biopsy.

387.1

Nonalcoholic Fatty Liver Disease

Bernadette E. Vitola, William F. Balistreri

Nonalcoholic fatty liver disease (NAFLD) , a spectrum of liver diseases strongly associated with obesity, is the most common chronic liver disease in children. NAFLD can range from fatty liver alone to a triad of fatty infiltration, inflammation, and fibrosis termed **nonalcoholic steatohepatitis (NASH)** , which resembles alcoholic liver disease but occurs with little or no exposure to ethanol. Unlike adults, NASH in children has 2 distinct histologic types. **Type 1 NASH** resembles adult histologic findings with steatosis and balloon degeneration of hepatocytes and/or periportal fibrosis. **Type 2 NASH** includes steatosis and portal inflammation.

Many patients with NAFLD are asymptomatic. Liver histology, obtained from autopsy data, suggest that 10% of children and 38% of obese children aged 2-19 yr old have NAFLD. The risk is lower in African-American children. Elevated serum aminotransferase levels are not sensitive or specific markers for NAFLD. A normal serum ALT level is present in 21–23% of pediatric patients with NAFLD. Although ultrasonography detects NAFLD, no current imaging modalities distinguish between simple steatosis and NASH. A liver biopsy may be required for a delimiting diagnosis. There are no reliable biomarkers available to serve as an alternative to liver biopsy.

The estimated prevalence of fatty liver disease in adults is thought to be as high as 15–20% for NAFLD overall and 2–4% for NASH. Risk factors in pediatric cohorts include obesity, male gender, white or Hispanic ethnicity, hypertriglyceridemia, and insulin resistance. Hepatic steatosis alone may be benign, but up to a quarter of patients with NASH can develop progressive fibrosis with resultant cirrhosis. The long-term prognosis of NASH that has developed in childhood is unknown.

Children diagnosed with NAFLD should be screened for comorbid conditions, including diabetes, hypertension, dyslipidemia, and obstructive sleep apnea. Obese and overweight children with other risk factors >3 yr of age should be screened for NAFLD by checking aminotransferase levels and liver ultrasound, even though neither is highly sensitive or specific. MRI is in use for clinical trials, but further studies are needed prior to its standard use in patient care.

Lysosomal acid lipase deficiency (LAL-D) , an autosomal recessive disorder due to mutations in *LIPA* may produce a hepatic steatosis like syndrome. In contrast to NAFLD, patients with LAL-D usually demonstrate microvesicular or mixed micro- and macrovesicular steatosis not macrovesicular changes.

Therapeutic trials in children and adolescents with biopsy-proven NAFLD/NASH are rare. Although there is no definitive treatment for NAFLD, gradual weight loss is effective in normalizing serum ALT levels and improving NAFLD. Low glycemic index foods and substituting polyunsaturated fatty acids for saturated fats may help. Vitamin E and vitamin C provide no additional benefit to the efficacy of lifestyle intervention (diet and exercise) in improving steatosis or biochemical abnormalities in pediatric NAFLD. However, vitamin E has been shown to improve balloon degeneration in children with NASH. Metformin has produced mixed results in the treatment of NAFLD. Thiazolidinediones (pioglitazone, rosiglitazone) improve liver histology in adults with NASH but have not been studied in children. In view of the potential role of the gut microbiome in contributing to the pathogenesis of NAFLD, the role of probiotics as an adjunct to lifestyle changes is under investigation. A preliminary study using ω-3 docosahexaenoic acid in children showed improved insulin sensitivity, ALT, triglycerides, BMI, and histology in children with NAFLD. Cysteamine bitartrate (slow release), a potential precursor of glutathione, an antioxidant, may reduce liver enzyme levels, as well as serum leptin and adiponectin levels, and is also a potential candidate for the treatment of NAFLD. GLP-1 is a neuropeptide (incretin) that has an antihyperglycemic effect. A meta-analysis demonstrated decreased ALT and improved imaging findings, as well as histologic features in adults with NAFLD and diabetes treated with GLP-1 agonists. In adults, a fibroblast growth factor 19 (FGF-19)-like agent has shown preliminary positive results. FGF-19 regulates bile acid, carbohydrate and energy metabolism.

CHAPTER 388

Mitochondrial Hepatopathies

Samar H. Ibrahim, William F. Balistreri

A wide variety of mitochondrial disorders are associated with liver disease. Hepatocytes contain a high density of mitochondria because the liver, with its biosynthetic and detoxifying functions, is highly dependent on adenosine triphosphate. Defects in mitochondrial function can lead to impaired oxidative phosphorylation, increased generation of reactive oxygen species, impairment of other metabolic pathways, and activation of mechanisms of cellular death.

Mitochondrial disorders can be divided into primary, in which the mitochondrial defect is the primary cause of the disorder, and secondary, in which mitochondrial function is affected by exogenous injury or a genetic mutation that affects nonmitochondrial proteins (see Chapter 105.4). Primary mitochondrial disorders can be caused by mutations affecting mitochondrial DNA (mtDNA) or by nuclear genes that encode mitochondrial proteins or cofactors (see Chapter 383 —Table 383.3 and Table 388.1). Specific patterns may be noted (Table 388.2). Secondary mitochondrial disorders include diseases with an uncertain etiology, such as Reye syndrome; disorders caused by endogenous or exogenous toxins, drugs, or metals; and other conditions in which mitochondrial oxidative injury may be involved in the pathogenesis of liver injury.

Table 388.1

Genotypic Classification of Primary Mitochondrial Hepatopathies and Organ Involvement

GENE	RESPIRATORY CHAIN COMPLEX	HEPATIC HISTOLOGY	OTHER ORGANS INVOLVED	CLINICAL FEATURES
Deletion	Multiple	Steatosis,	Kidney, heart,	Sideroblastic anemia, variable

	(Pearson)	fibrosis	CNS, muscle	thrombocytopenia and neutropenia, persistent diarrhea
MPV17	I, III, IV	Steatosis	CNS, muscle, gastrointestinal tract	Adult-onset multisystemic involvement: myopathy, ophthalmoplegia, severe constipation, parkinsonism
DGUOK	I, III, IV	Steatosis, fibrosis	Kidneys, CNS, muscle	Nystagmus, hypotonia, renal Fanconi syndrome, acidosis
MPV17	I, III, IV	Steatosis, fibrosis	CNS, PNS	Hypotonia
SUCLG1	I, III, IV	Steatosis	Kidneys, CNS, muscle	Myopathy, sensorineural hearing loss, respiratory failure
POLG1	I, III, IV	Steatosis, fibrosis	CNS, muscle	Liver failure preceded by neurologic symptoms, intractable seizures, ataxia, psychomotor regression
C10orf2/Twinkle	I, III, IV	Steatosis	CNS, muscle	Infantile-onset spinocerebellar ataxia, loss of skills
BCS1L	III (GRACILE)		CNS ±, muscle ±, kidneys	Fanconi-type renal tubulopathy
SCO1	IV	Steatosis, fibrosis	Muscle	
TRMU	I, III, IV	Steatosis, fibrosis		Infantile liver failure with subsequent recovery
EFG1	I, III, IV	Steatosis	CNS	Severe, rapidly progressive encephalopathy
EFTu	I, III, IV	Unknown	CNS	Severe lactic acidosis, rapidly fatal encephalopathy

CNS, central nervous system; *GRACILE,* growth restriction, aminoaciduria, cholestasis, iron overload, lactic acidosis, and early death; *PNS,* peripheral nervous system.

Epidemiology

Mitochondrial respiratory chain disorders of all types affect 1 in 20,000 children younger than 16 yr of age; liver involvement has been reported in 10–20% of patients with respiratory chain defect. Primary mitochondrial disorders, including mtDNA depletion syndromes (MDSs), occur in 1 in 5,000 live births and are a known cause of acute liver failure in children <2 yr of age.

More than 200 pathogenic point mutations, deletions, insertions, and rearrangements that involve mtDNA and nuclear DNA and encodes mitochondrial proteins are identified. Mitochondrial genetics are unique because mitochondria are able to replicate, transcribe, and translate their mitochondrial-derived DNA independently. A typical hepatocyte contains approximately 1,000 copies of mtDNA. Oxidative phosphorylation (the process of adenosine triphosphate production) occurs in the respiratory chain located in the inner mitochondrial membrane and is divided into 5 multienzyme complexes: reduced nicotinamide adenine dinucleotide coenzyme Q reductase (complex I), succinate–coenzyme Q reductase (complex II), reduced coenzyme Q–cytochrome-*c* reductase (complex III), cytochrome-*c* oxidase (complex IV), and adenosine triphosphate synthase (complex V). The respiratory chain peptide components are encoded by both nuclear and mtDNA genes, hence mutations in either genome can result in disorders of oxidative phosphorylation. Thirteen essential polypeptides are synthesized from the small 16.5-kilobase circular double-stranded mtDNA. mtDNA also encodes the 24 transfer RNAs required for intramitochondrial protein synthesis, whereas nuclear genes encode more than 70 respiratory chain subunits and an array of enzymes and cofactors required to maintain mtDNA, including DNA polymerase-γ (POLG), thymidine kinase 2, and deoxyguanosine kinase.

The expression of mitochondrial disorders is complex, and epidemiologic studies are hampered by technical difficulties in collecting and processing the tissue specimens needed to make accurate diagnoses, the variability in clinical presentation, and the fact that most disorders display maternal inheritance with variable penetrance (see Chapter 97). mtDNA mutates 10 times more often than nuclear DNA due to a lack of introns, protective histones, and an effective repair system in mitochondria. Mitochondrial genetics also displays a threshold effect in that the type and severity of mutation required for clinical expression varies among people and organ systems; this is explained by the concept of heteroplasmy, in which cells and tissues harbor both normal and mutant mtDNA in various amounts because of random partitioning during cell division. Mutations, deletions, or duplications in either mitochondrial or nuclear genes can cause disease, and mutations in nuclear genes that control mtDNA replication, transcription, and translation may lead to **MDS** or to a translational disorder.

Clinical Manifestations

Defects in oxidative phosphorylation can affect any tissue to a variable degree, with the most energy-dependent organs being the most vulnerable. One should consider the diagnosis of a mitochondrial disorder in a patient of any age who presents with progressive, multisystem involvement that cannot be explained by a specific diagnosis. Gastrointestinal complaints include vomiting, diarrhea, constipation, failure to thrive, and abdominal pain; certain mitochondrial disorders have characteristic gastrointestinal presentations. Pearson marrow-pancreas syndrome manifests with sideroblastic anemia and exocrine pancreatic insufficiency, whereas mitochondrial neurogastrointestinal encephalomyopathy manifests with chronic intestinal pseudo-obstruction and cachexia. Hepatic presentations range from chronic cholestasis, hepatomegaly, cirrhosis, and steatosis to fulminant hepatic failure and death. Patients with certain mitochondrial diseases may have normal or minimally elevated lactate levels even in the setting of a metabolic crisis. The lactate-to-pyruvate molar ratio (L:P) has been proposed as a screening test for mitochondrial disorders because it reflects the equilibrium between the product and substrate of the reaction catalyzed by lactase dehydrogenase. An L:P ≥ 25 has been considered to be highly suggestive of respiratory chain dysfunction; however, an elevated lactate or an elevated L:P can also represent secondary mitochondrial dysfunction occurring as a result of severe liver disease.

Primary Mitochondrial Hepatopathies

Neonatal Liver Failure

A common presentation of respiratory chain defects is severe liver failure manifested as jaundice, hypoglycemia, coagulopathy, renal dysfunction, and hyperammonemia, with onset within the first few weeks to months of life. **Cytochrome-*c* oxidase** (complex IV) is the most common deficiency in these infants, although complexes I and III and MDSs are also implicated (see Tables 388.1 and 383.3). The key biochemical features include a markedly elevated plasma lactate concentration, an elevated molar ratio of plasma lactate to pyruvate (L:P) (>25), and a raised ratio of β-hydroxybutyrate to acetoacetate

(>4.0). Symptoms are nonspecific and include lethargy and vomiting. Most patients additionally have neurologic involvement that manifests as a weak suck, recurrent apnea, or myoclonic epilepsy. Liver biopsy shows predominantly microvesicular steatosis, cholestasis, bile duct proliferation, glycogen depletion, and iron overload. With standard therapy the prognosis is poor, and most patients die from liver failure or infection in the first few months of life.

Alpers Syndrome (Alpers-Huttenlocher Syndrome or Alpers Hepatopathic Poliodystrophy)

Diagnostic criteria include refractory mixed-type seizures with a focal component; psychomotor regression that is episodic and triggered by intercurrent infections; and hepatopathy with or without acute liver failure. Alpers syndrome manifests from infancy up to 8 yr of age with seizures, hypotonia, feeding difficulties, psychomotor regression, and ataxia. Patients develop hepatomegaly and jaundice and have a slower progression to liver failure than those with cytochrome-*c* oxidase deficiency. Elevated blood or cerebrospinal fluid lactate and pyruvate levels are supportive of the diagnosis, in addition to characteristic electroencephalographic findings (high-amplitude slow activity with polyspikes), asymmetric abnormal visual evoked responses, and low-density areas or atrophy in the occipital or temporal lobes on computed tomography scanning of the brain. In some patients complex I deficiency has been found in liver or muscle mitochondria. The disease is inherited in an autosomal recessive fashion; mutations in the catalytic subunit of the nuclear gene mtDNA *POLG* have been identified in multiple families with Alpers syndrome, leading to the advent of molecular diagnosis for Alpers syndrome. Patients with *POLG* mutations are susceptible to *valproate-induced* liver dysfunction.

Mitochondrial DNA Depletion Syndrome

MDS is characterized by a tissue-specific reduction in mtDNA copy number, leading to deficiencies in complexes I, III, and IV. MDS manifests with phenotypic heterogeneity; multisystem and localized disease forms include myopathic, hepatocerebral, and liver-restricted presentations. Infants with the hepatocerebral form present in the neonatal period. The first symptoms are metabolic; these rapidly progress to hepatic failure with hypoglycemia and vomiting. This stage is followed by neurologic involvement affecting the central and peripheral systems. Laboratory studies are characterized by lactic acidosis, hypoglycemia, and markedly elevated α-fetoprotein in plasma. In some patients, iron overload has been found with elevated transferrin saturation, high ferritin levels, and iron accumulation in hepatocytes and Kupffer cells. Death usually occurs by 1 yr of age. Spontaneous recovery has been reported in a patient with liver-restricted disease. Inheritance is autosomal recessive and mutations in the nuclear deoxyguanosine kinase gene *(DGUOK)* have been identified in many patients with hepatocerebral MDS. Thymidine kinase 2 has been implicated in the myopathic form; no known genetic defect has been identified in liver-restricted MDS. Multiple other nuclear genes including *POLG, MPV17,* Twinkle helicase gene, and *SUCLG1* have been implicated in hepatocerebral MDS. Liver biopsies of patients with MDS show microvesicular steatosis, cholestasis, focal cytoplasmic biliary necrosis, and cytosiderosis in hepatocytes and sinusoidal cells. Ultrastructural changes are characteristic, with oncocytic transformation of mitochondria, which is characterized by mitochondria with sparse cristae, granular matrix, and dense or vesicular inclusions. If the native DNA-encoded complex II is normal and the activities of the other complexes are decreased, one should investigate mtDNA copy numbers for a MDS. Diagnosis is established by the demonstration of a low ratio of mtDNA (<10%) to nuclear DNA in affected tissues and/or genetic testing. Importantly, the sequence of the mitochondrial genome is normal.

Navajo Neurohepatopathy

Navajo neurohepatopathy (NNH) is an autosomal recessive sensorimotor neuropathy with progressive liver disease found only in Navajo Indians of the southwestern United States. The incidence is 1 in 1,600 live births. Diagnostic criteria include sensory neuropathy; motor neuropathy; corneal anesthesia; liver disease; metabolic or infectious complications including failure to thrive, short stature, delayed puberty, or systemic infection; and evidence of central nervous system demyelination on radiographic imaging and peripheral nerves biopsies. An *MPV17* gene mutation is implicated in the pathogenesis of NNH. Interestingly, this is the same gene implicated in MDS (see earlier), demonstrating that NNH may be a specific type of MDS found only in Navajos. NNH is divided into three phenotypic variations based on age of presentation and clinical findings.

First, **classic NNH** appears in infancy with severe progressive neurologic deterioration manifesting clinically as weakness, hypotonia, loss of sensation with accompanying acral mutilation, corneal ulcerations, and poor growth. Liver disease, present in the majority of patients, is secondary and variable; it includes asymptomatic elevations of liver function tests, Reye syndrome–like episodes, and hepatocellular carcinoma or cirrhosis. γ-Glutamyl transpeptidase levels tend to be higher than in other forms of NNH. Liver biopsy might show chronic portal tract inflammation and cirrhosis, but there is shows less cholestasis, hepatocyte ballooning, and giant cell transformation than in other forms of NNH.

Infantile NNH manifests between the ages of 1 and 6 mo with jaundice and failure to thrive and progresses to liver failure and death by 2 yr of age. Patients have hepatomegaly with moderate elevations in aspartate aminotransferase, alanine aminotransferase, and γ-glutamyl transpeptidase. Liver biopsy demonstrates pseudoacinar formation, multinucleate giant cells, portal and lobular inflammation, canalicular cholestasis, and microvesicular steatosis. Progressive neurologic symptoms are not usually noticed at presentation but develop later.

Childhood NNH manifests from age 1-5 yr with the acute onset of fulminant hepatic failure leading to death within months. Most patients also have evidence of neuropathy at presentation. Liver biopsies are similar to those in infantile NNH except for significant hepatocyte ballooning and necrosis, bile duct proliferation, and cirrhosis, which are also seen.

There is no effective treatment for any of the forms of NNH, and neurologic symptoms often preclude liver transplantation. The identical *MPV17* mutation is seen in patients with both the infantile and classic forms of NNH, highlighting the clinical heterogeneity of NNH.

Pearson Syndrome

Pearson marrow-pancreas syndrome has a neonatal-onset with severe macrocytic anemia, variable neutropenia and thrombocytopenia, and ringed sideroblasts in the bone marrow. Diarrhea and fat malabsorption develop in early childhood secondary to extensive pancreatic fibrosis, acinar atrophy, and partial villous atrophy of the small intestine. The liver involvement includes hepatomegaly, steatosis, and cirrhosis. Liver failure and death have been reported before the age of 4 yr. Other features of the syndrome include renal tubular disease, photosensitivity, diabetes mellitus, hydrops fetalis, and the late development of visual impairment, tremor, ataxia, proximal muscle weakness, external ophthalmoplegia, and a pigmentary retinopathy. Methylglutaconic aciduria is a useful diagnostic marker. Large deletions of mtDNA are reported in most patients, resulting in deficiency of complexes I and III. mtDNA deletions can be detected in patients' cultured fibroblasts as well as in peripheral blood lymphocytes.

Villous Atrophy Syndrome

Children with this disease present with severe anorexia, vomiting, chronic diarrhea, and villous atrophy in the 1st yr of life. Hepatic involvement includes mild elevation of aminotransferase levels, hepatomegaly, and steatosis. Lactic acidosis is worsened with high-dextrose intravenous infusions or enteral nutrition. Diarrhea improves by 5 yr of age in association with the normalization of intestinal biopsies. Subsequently patients develop retinitis pigmentosa, cerebellar ataxia, sensorineural deafness, and proximal muscle weakness, with eventual death late in the 1st decade of life. The disease is attributed to a mtDNA rearrangement defect. A complex III deficiency was found in the muscle of affected patients.

GRACILE Syndrome

The acronym GRACILE summarizes the most important clinical features, namely fetal growth restriction (birth weight about −4 SD), aminoaciduria (caused by Fanconi-type tubulopathy), cholestasis (with steatosis and cirrhosis), iron overload, severe lactic acidosis, and early death. The syndrome is associated with mutations of the complex III assembly factor BCS1L. The liver histology shows microvesicular steatosis and cholestasis with abundant iron accumulation in hepatocytes and Kupffer cells. The liver iron content decreases slightly with age, concomitantly with increasing fibrosis and cirrhosis. Abnormal aminotransferase levels and coagulation are noted, but the cause of death seems to be related more to energy depletion than to liver failure. About half of these patients die within the first 2 wk of life.

Mutations in Nuclear Translation and Elongation

Factor Genes

Mutations in nuclear translation factor genes *(TRMU)* of the respiratory chain enzyme complexes have been identified as the etiology of acute liver failure manifesting at ages 1 day to 6 mo. The respiratory chain deficit was similar to that seen in MDS, where the activity of the native DNA-encoded complex II was normal whereas complexes I, III, and IV were decreased. The elongation factor EFG1 (gene *GFM1*) mutation was associated with fetal growth restriction, lactic acidosis, liver dysfunction that progresses into liver failure and death. The mutation in the elongation factor EFTu manifests as severe lactic acidosis and lethal encephalopathy with mild hepatic involvement.

Secondary Mitochondrial Hepatopathies

Secondary mitochondrial hepatopathies are caused by exposure to a hepatotoxic metal, drug, toxin, or endogenous metabolite. In the past, the most common secondary mitochondrial hepatopathy was **Reye syndrome,** the prevalence of which peaked in the 1970s and had a mortality rate of >40%. Although mortality has not changed, the prevalence has decreased from >500 cases in 1980 to approximately 35 cases per year since. The decline in the reported incidence of Reye syndrome may be partially related to more accurate modern diagnosis of infectious, metabolic, or toxic disease, thus reducing the percentage of idiopathic or true cases of Reye syndrome. Reye syndrome is precipitated in a genetically susceptible person by the interaction of a viral infection (influenza, varicella) and salicylate and/or antiemetic use. Clinically it is characterized by a preceding viral illness that appears to be resolving and the acute onset of vomiting and encephalopathy (see Table 388.3). Neurologic symptoms can rapidly progress to seizures, coma, and death. Liver dysfunction is invariably present when vomiting develops, with coagulopathy and elevated serum levels of aspartate aminotransferase, alanine aminotransferase, and ammonia. Importantly, patients remain anicteric and serum bilirubin levels are normal. Liver biopsies show microvesicular steatosis without evidence of liver inflammation or necrosis. Death is usually secondary to increased intracranial pressure and cerebral herniation. Patients who survive have full recovery of liver function but should be carefully screened for fatty-acid oxidation and fatty-acid transport defects (Table 388.4).

Table 388.3

Clinical Staging of Reye Syndrome and Reye-Like Diseases

Symptoms at the time of admission:

I. Usually quiet, **lethargic** and sleepy, vomiting, laboratory evidence of liver dysfunction
II. Deep lethargy, **confusion,** delirium, combativeness, hyperventilation, hyperreflexia
III. Obtunded, **light coma** ± seizures, **decorticate** rigidity, intact pupillary light reaction
IV. Seizures, deepening coma, **decerebrate rigidity,** loss of oculocephalic reflexes, fixed pupils
V. Coma, loss of deep tendon reflexes, respiratory arrest, fixed dilated pupils, **flaccidity/decerebration** (intermittent); isoelectric electroencephalogram

Table 388.4

Diseases That Present a Clinical or Pathologic Picture Resembling Reye Syndrome

- Metabolic disease
  - Organic aciduria
  - Disorders of oxidative phosphorylation
  - Urea cycle defects (carbamoyl phosphate synthetase, ornithine transcarbamylase)
  - Defects in fatty acid oxidation metabolism
  - Acyl–coenzyme A dehydrogenase deficiencies
  - Systemic carnitine deficiency
  - Hepatic carnitine palmitoyltransferase deficiency
  - 3-OH, 3-methylglutaryl-coenzyme A lyase deficiency
  - Fructosemia
  - Infantile liver failure syndrome 1. Caused by leucyl-tRNA synthetase (LARS) gene mutations
- Central nervous system infections or intoxications (meningitis), encephalitis, toxic encephalopathy
- Hemorrhagic shock with encephalopathy
- Drug or toxin ingestion (salicylate, valproate)

Acquired abnormalities of mitochondrial function can be caused by several drugs and toxins, including valproic acid, cyanide, amiodarone, chloramphenicol, iron, the emetic toxin of *Bacillus cereus*, and nucleoside analogs. Valproic acid is a branched fatty acid that can be metabolized into the mitochondrial toxin 4-envalproic acid. Children with underlying respiratory chain defects appear more sensitive to the toxic effects of this drug, and valproic acid is reported to precipitate liver failure in patients with **Alpers syndrome** and **cytochrome-*c* oxidase deficiency.** Nucleoside analogs directly inhibit mitochondrial respiratory chain complexes. The reverse transcriptase inhibitors zidovudine, didanosine, stavudine, and zalcitabine—used to treat HIV-infected patients—inhibit DNA POLG of mitochondria and can block elongation of mtDNA, leading to mtDNA depletion. Other conditions that can lead to mitochondrial oxidative stress include cholestasis, nonalcoholic steatohepatitis,

α_1 -antitrypsin deficiency, and Wilson disease.

Diagnostic Evaluation

Screening tests include common biochemical tests (comprehensive metabolic profile, INR, α-fetoprotein, CPK, phosphorus, complete blood cell count, ammonia, lactate, pyruvate, serum ketone bodies: both quantitative 3-hydroxybutyrate and quantitative acetoacetate, total free fatty acids, serum acylcarnitine profile; serum-free and total carnitines, urine organic acids, and serum amino acids) (Table 388.5). These results will guide subsequent confirmatory testing to establish a molecular diagnosis. Genotyping, including single gene or panel screening for common mitochondrial disease, is used in clinical practice. Whole exome or genome sequencing is also helpful and is replacing single gene or gene panel testing. However, the identification of multiple gene variants of uncertain significance will require detailed clinical and biochemical confirmation for interpretation. Tissue (liver biopsy, skin fibroblast, and muscle biopsy) may be needed to make a specific biochemical diagnosis.

Table 388.5

Tiered Investigations in Suspected Mitochondrial Liver Disease

TIER 1
Pre-/postprandial plasma lactate, glucose, FFA, and 3-OH
Plasma carnitine, acylcarnitines
Plasma amino acids, creatine kinase, thymidine
Urinary organic acids, amino acids, tubular resorption phosphate, albumin/creatinine ratio CSF lactate/protein (if feasible)
Electrocardiography and echocardiography
Electroencephalography and visual-evoked potentials
Common mutations in *POLG, DGUOK, MPV17,* and *TRMU*
TIER 2
Tissue analysis
Liver biopsy : (if feasible). Tissue for light microscopy, electron microscopy, and Oil Red O stain
Frozen tissue for respiratory chain enzyme activity analysis and mtDNA copy number
Muscle biopsy : Tissue for light microscopy, electron microscopy, Oil Red O stain, and histochemistry for respiratory chain complexes
Frozen tissue for respiratory chain enzyme activity analysis and mtDNA copy number

Skin biopsy: set up for fibroblast culture

TIER 3

Cranial MRI/MRS

TIER 4

Extended molecular screening. This will be guided by the clinical phenotype, results of the tissue analysis, and local facilities

Currently suggested genes should include *SUCLG1, BCS1L, SOC1, TFSM, TWINKLE, ACAD9, EARS2, GFM1, RRM2B, TK2* , and *SUCLA2*

From Wyllie R, Hyams JS, Kay M, editors: *Pediatric gastrointestinal and liver disease* , ed 5, Philadelphia, 2016, Elsevier (Box 71-3, p. 876).

Treatment of Mitochondrial Hepatopathies

There is no effective therapy for most patients with mitochondrial hepatopathies; neurologic involvement often precludes orthotopic liver transplantation. Patients with mitochondrial disorders remain at risk for transplant-related worsening of their underlying metabolic disease, especially patients with *POLG* -related disease. Several therapeutic drug combinations—including antioxidants, vitamins, cofactors, and electron acceptors—have been proposed, but no randomized controlled trials have been completed to evaluate them. Treatment strategies are supportive and include the infusion of sodium bicarbonate for acute metabolic acidosis, transfusions for anemia and thrombocytopenia, and exogenous pancreatic enzymes for pancreatic insufficiency. It is important to discontinue or avoid medications that may exacerbate hepatopathy, including sodium valproate, tetracycline, and macrolide antibiotics, azathioprine, chloramphenicol, quinolones, and linezolid. Ringer lactate should be avoided because patients with liver dysfunction may not be able to metabolize lactate. Propofol should be avoided during anesthesia because of potential interference with mitochondrial function. In patients with lactic acidosis, lactate levels should be monitored during procedures. It is important to maintain anabolism using a balanced intake of fat and carbohydrates while avoiding unbalanced intakes (e.g., glucose only at a high intravenous rate) or fasting for >12 hr.

CHAPTER 389

Autoimmune Hepatitis

Benjamin L. Shneider, Frederick J. Suchy

Autoimmune Hepatitis

Chronic Liver Disease

Autoimmune hepatitis is a chronic hepatic inflammatory process manifested by elevated serum aminotransaminase concentrations, liver-associated serum autoantibodies, and/or hypergammaglobulinemia. The serological autoantibody profile defines 2 main types of autoimmune hepatitis: AIH type 1, with positivity for anti-nuclear antibodies (ANA) and/or anti–smooth muscle antibody (SMA) and AIH type 2, with positivity for anti–liver kidney microsomal type 1 antibody (anti-LKM-1). The targets of the inflammatory process can include hepatocytes and to a lesser extent bile duct epithelium. Chronicity is determined either by duration of liver disease (typically >3-6 mo) or by evidence of chronic hepatic decompensation (hypoalbuminemia, thrombocytopenia) or physical stigmata of chronic liver disease (clubbing, spider telangiectasia, splenomegaly, ascites). The severity is variable; the affected child might have only biochemical evidence of liver dysfunction, might have stigmata of chronic liver disease, or can present in hepatic failure.

Chronic hepatitis can also be caused by persistent viral infection (see Chapter 358), drugs (see Chapter 363), metabolic diseases (see Chapter 361), fatty liver disease, or idiopathic disorders, which may have features of autoimmunity (Table 389.1). More than 90% of hepatitis B infections in the 1st yr of life become chronic, compared with 5–10% among older children and adults. Chronic hepatitis develops in >50% of acute hepatitis C virus infections. Transmission can occur during the perinatal period from an infected mother or in adolescents from parenteral drug abuse. Hepatitis A does not lead to chronic liver disease. Hepatitis E can become chronic in immunosuppressed patients.

Drugs commonly used in children that can cause chronic liver injury, which can mimic autoimmune hepatitis, include isoniazid, methyldopa, pemoline, nitrofurantoin, dantrolene, minocycline, pemoline, and the sulfonamides. **Metabolic diseases** can lead to chronic hepatitis, including α_1 -antitrypsin deficiency, inborn errors of bile acid biosynthesis, and Wilson disease. **Nonalcoholic steatohepatitis,** usually associated with obesity and insulin resistance, is another common cause of chronic hepatitis. It can progress to cirrhosis but responds to weight reduction. In many cases the cause of chronic hepatitis is unknown; in some, an autoimmune mechanism is suggested by the finding of serum antinuclear and anti–SMAs and by multisystem involvement (arthropathy, thyroiditis, rashes, Coombs-positive hemolytic anemia).

Table 389.1

Disorders Producing Chronic Hepatitis

- Chronic viral hepatitis
  - Hepatitis B
  - Hepatitis C
  - Hepatitis D
- Autoimmune hepatitis
  - Anti–actin antibody-positive
  - Anti–liver-kidney microsomal antibody-positive
  - Anti–soluble liver antigen antibody-positive
  - Others (includes antibodies to liver-specific lipoproteins or asialoglycoprotein)
  - Overlap syndrome with sclerosing cholangitis and autoantibodies
  - Systemic lupus erythematosus
  - Celiac disease
- Drug-induced hepatitis
- Metabolic disorders associated with chronic liver disease
  - Wilson disease
  - Nonalcoholic steatohepatitis
  - α_1 -Antitrypsin deficiency
  - Tyrosinemia
  - Niemann-Pick disease type 2
  - Glycogen storage disease type IV
  - Cystic fibrosis
  - Galactosemia
  - Bile acid biosynthetic abnormalities

Autoimmune hepatitis is a clinical constellation that suggests an immune-mediated process; it is responsive to immunosuppressive therapy (Table 389.2). Autoimmune hepatitis typically refers to a primarily hepatocyte-specific process, whereas autoimmune cholangiopathy and sclerosing cholangitis predominately involve intrahepatic and extrahepatic bile duct injury. Overlap of the process involving both hepatocyte and bile duct–directed injury may be more common in children. De novo hepatitis can be seen in a subset of liver transplant recipients whose initial disease was not autoimmune.

Table 389.2

Classification of Autoimmune Hepatitis

VARIABLE	TYPE 1 AUTOIMMUNE HEPATITIS	TYPE 2 AUTOIMMUNE HEPATITIS
Characteristic autoantibodies	Antinuclear antibody[*]	Antibody against liver-kidney microsome type 1[*]
	Smooth-muscle antibody[*]	
	Antiactin antibody [†]	Antibody against liver cytosol type 1[*]
	Autoantibodies against soluble liver antigen and liver-pancreas antigen [‡]	Antibody against liver-kidney microsomal type 3
	Atypical perinuclear antineutrophil cytoplasmic antibody	
Geographic variation	Worldwide	Worldwide; rare in North America
Age at presentation	Any age	Predominantly childhood and young adulthood
Gender of patients	Female in ~75% of cases	Female in ~95% of cases
Association with other autoimmune diseases	Common	Common [§]
Clinical severity	Broad range, variable	Generally severe
Histopathologic features at presentation	Broad range, mild disease to cirrhosis	Generally advanced
Treatment failure	Infrequent	Frequent
Relapse after drug withdrawal	Variable	Common
Need for long-term maintenance	Variable	~100%

[*] The conventional method of detection is immunofluorescence.

[†] Tests for this antibody are rarely available in commercial laboratories.

[‡] This antibody is detected by enzyme-linked immunosorbent assay.

[§] Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy is seen only in patients with type 2 disease.

Modified from Krawitt EL: Autoimmune hepatitis, *N Engl J Med* 354:54–66, 2006.

Etiology

T Lymphocytes

Autoimmune Regulator Gene

Autoimmune hepatitis arises in a genetically predisposed host after an unknown trigger leads to a T cell–mediated immune response targeting liver autoantigens. A dense portal mononuclear cell infiltrate invades the surrounding parenchyma and comprises T and B lymphocytes, macrophages, and plasma cells. The immunopathogenic mechanisms underlying autoimmune hepatitis are unsettled. Triggering factors can include molecular mimicry, infections, drugs, and the environment (toxins) in a genetically susceptible host. Several human leukocyte antigen class II molecules—particularly DR3, DR4, and DR7 isoforms—confer susceptibility to autoimmune hepatitis. Self-antigenic peptides are processed by populations of antigen-presenting cells and presented to CD4 and CD8 effector T cells. CD4+ T lymphocytes recognizing a self-antigenic liver peptide orchestrate liver injury. Cell-mediated injury by cytokines released by CD8+ cytotoxic T cells and/or antibody-mediated cytotoxicity can be operative. There is also evidence that regulatory T cells from patients with autoimmune hepatitis are impaired in their ability to control the proliferation of CD4 and CD8 effector cells. Cytochrome P450 2D6 is the main autoantigen in type 2 autoimmune hepatitis.

Antibody-coated hepatocytes may be lysed by complement or Fc-bearing natural killer lymphocytes. Heterozygous mutations in the **autoimmune regulator gene *(AIRE),*** which encodes a transcription factor controlling the negative selection of autoreactive thymocytes, can be found in some children with autoimmune hepatitis types 1 and 2. *AIRE* mutations also cause **autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy** (also called autoimmune polyendocrinopathy syndrome), in which autoimmune hepatitis occurs in approximately 20% of patients.

Pathology

The histologic features common to untreated cases include inflammatory infiltrates, consisting of lymphocytes and plasma cells that expand portal areas and often penetrate the lobule (interface hepatitis); moderate to severe piecemeal necrosis of hepatocytes extending outward from the limiting plate; variable necrosis, fibrosis, and zones of parenchymal collapse spanning neighboring portal triads or between a portal triad and central vein (bridging necrosis); and variable degrees of bile duct epithelial injury. Distortion of hepatic architecture can be severe; cirrhosis may be present in children at the time of diagnosis. Histologic features in acute liver failure may be obscured by massive necrosis and multilobular collapse. Other histologic features may suggest an alternative diagnosis: characteristic periodic acid–Schiff-positive, diastase-resistant granules are seen in α_1 -antitrypsin deficiency, and macrovesicular and microvesicular steatosis is found in nonalcoholic steatohepatitis and often in Wilson disease. Bile duct injury can suggest an autoimmune cholangiopathy or an overlap syndrome. Ultrastructural analysis might suggest distinct types of storage disorders.

Clinical Manifestations

The clinical features and course of autoimmune hepatitis are extremely variable. Signs and symptoms at the time of presentation comprise a wide spectrum of disease including a substantial number of asymptomatic patients and some who have an acute, even fulminant, onset. In 25–30% of patients with autoimmune hepatitis, particularly children, the illness mimics acute viral hepatitis. In most the onset is insidious. Patients can be asymptomatic or have fatigue, malaise, behavioral changes, anorexia, and amenorrhea, sometimes for many months before jaundice or stigmata of chronic liver disease are recognized. Extrahepatic manifestations can include arthritis, vasculitis, nephritis, thyroiditis, Coombs-positive anemia, and rash. Some patients' initial clinical features reflect cirrhosis (ascites, hypersplenism, bleeding esophageal varices, or hepatic encephalopathy).

There may be mild to moderate jaundice in severe cases. Spider telangiectasias and palmar erythema may be present. The liver may be tender and slightly enlarged but might not be felt in patients with cirrhosis. The spleen is commonly enlarged. Edema and ascites may be present in advanced cases.

Laboratory Findings

The findings are related to the severity of presentation. In many asymptomatic cases, serum aminotransferase ranges between 100 and 300 IU/L, whereas levels in excess of 1,000 IU/L can be seen in young symptomatic patients. Serum bilirubin concentrations may be normal in mild cases but are commonly 2-10 mg/dL in more severe cases. Serum alkaline phosphatase and γ-glutamyl transpeptidase activities are normal to slightly increased but may be more significantly elevated in autoimmune cholangiopathy or in the setting of overlap with sclerosing cholangitis. Serum γ-globulin levels can show marked polyclonal elevations. Hypoalbuminemia is common. The prothrombin time is prolonged, most often as a result of vitamin K deficiency but also as a reflection of impaired hepatocellular function. A normochromic normocytic anemia, leukopenia, and thrombocytopenia are present and become more severe with the development of portal hypertension and hypersplenism.

Most patients with autoimmune hepatitis have hypergammaglobulinemia. Serum immunoglobulin G levels usually exceed 16 g/L. Characteristic patterns of serum **autoantibodies** define distinct subgroups of autoimmune hepatitis (see Table 389.2). The most common pattern (type 1) is associated with the formation of non–organ-specific antibodies, such as **antiactin (smooth muscle)** and ANA. Approximately 50% of these patients are 10-20 yr of age. High titers of a **liver-kidney microsomal** antibody are detected in another form (type 2) that usually affects children 2-14 yr of age. A subgroup of primarily young women might demonstrate autoantibodies against a soluble liver antigen but not against nuclear or microsomal proteins. Antineutrophil cytoplasmic antibodies may be seen more commonly in autoimmune cholangiopathy. Autoantibodies are rare in healthy children, so that titers as low as 1 : 40 may be significant, although nonspecific elevation in autoantibodies can be observed in a variety of liver diseases. Up to 20% of patients with apparent autoimmune hepatitis might not have autoantibodies at presentation but have histological features and clinical course consistent with the disorder. Other, less common autoantibodies include rheumatoid factor, antiparietal cell antibodies, antithyroid antibodies, and anti–liver cytosol type 1 antibody (anti-LC-1). A Coombs-positive hemolytic anemia may be present.

Diagnosis

There is no specific test for autoimmune hepatitis; it is a clinical diagnosis based on certain diagnostic criteria. Diagnostic criteria with scoring systems have been developed for adults and modified slightly for children, although these scoring systems were developed as research rather than diagnostic tools. Important positive features include female gender, primary elevation in transaminases and not alkaline phosphatase (or GGT), elevated γ-globulin levels, the presence of autoantibodies (most commonly antinuclear, smooth muscle, or liver-kidney microsome), and characteristic histologic findings (Fig. 389.1). Important negative features include the absence of viral markers (hepatitides B, C, D) of infection, absence of a history of drug or blood product exposure, and negligible alcohol consumption.

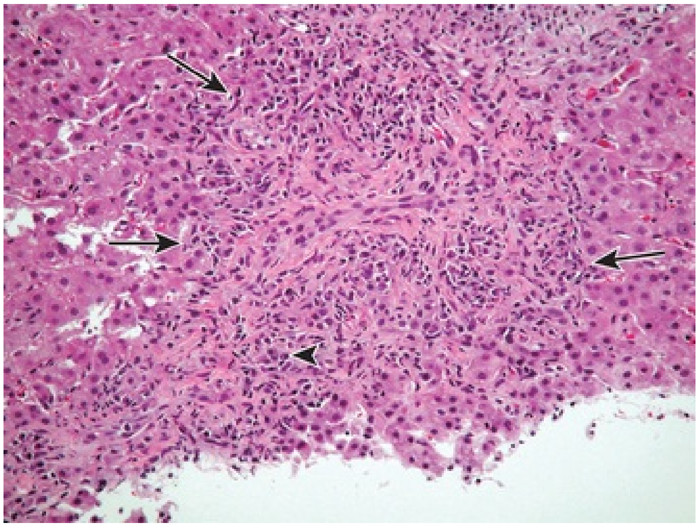

FIG. 389.1 **Autoimmune hepatitis. Liver biopsy showing fibrous expansion of the portal tracts with moderate portal lymphocytic infiltrates rich in plasma cells *(arrowhead).* There is extensive interface hepatitis *(arrows).* Original magnification ×20. (Courtesy Margret Magid, Mount Sinai School of Medicine.)**

Common conditions that might lead to chronic hepatitis should be excluded (see Table 389.1). The differential diagnosis includes α_1 -antitrypsin deficiency (see Chapter 357) and Wilson disease (see Chapter 357.2). The former disorder must be excluded by performing α_1 -antitrypsin phenotyping and the latter by measuring serum ceruloplasmin and 24-hr urinary copper excretion and/or hepatic copper levels. Chronic hepatitis may occur in patients with inflammatory bowel disease, but liver dysfunction in such patients is more commonly caused by pericholangitis or sclerosing cholangitis. Celiac disease (see Chapter 338) is associated with liver disease that is akin to autoimmune hepatitis, and appropriate serologic testing should be performed, including assays for anti–tissue transglutaminase antibodies or antiendomysial antibodies. An ultrasonogram should be done to identify a choledochal cyst or other structural disorders of the biliary system. Magnetic resonance (MR) cholangiography may be very useful for screening for evidence of sclerosing cholangitis. An overlap syndrome with features of primary sclerosing cholangitis and autoimmune hepatitis is being increasingly recognized with wider application of MR cholangiography (Table 389.3). Patients with primary sclerosing cholangitis can have elevated γ-globulin levels and autoantibodies; therefore liver biopsy findings in these children may be especially important. Dilated or obliterated veins on ultrasonography suggest the possibility of the Budd-Chiari syndrome. Diagnosis of autoimmune liver disease in the setting of acute liver failure is difficult and care should be taken in applying standardized approaches. “Seronegative” autoimmune hepatitis has been described, so absence of classic autoimmune markers does not exclude this diagnosis.

Table 389.3

Overlap Syndromes of Autoimmune Hepatitis

	AUTOIMMUNE HEPATITIS WITH OVERLAPPING FEATURES OF:		
	Primary Biliary Cholangitis[*]	**Primary Sclerosing Cholangitis**	**Cholestasis**
Clinical and laboratory features	AMA +	AMA −	AMA −
	Serum AP frequently > 2-fold ULN	Serum AP frequently > 2-fold ULN	Serum AP frequently > 2-fold ULN
		IBD common	No UC
		Abnormal cholangiogram (except in small-duct disease)	Normal cholangiogram
Histology	Destructive cholangitis	Ductopenia	Lymphoplasmacytic portal and acinar infiltrates
	Ductopenia	Cholangiolar proliferation	Lymphocytic destructive cholangitis
	Cholestasis	Swollen fibrotic portal tracts	Swollen hepatocytes
Treatment	Prednisone (10 mg daily) in combination with azathioprine (50 mg daily) if AP ≤ 2 × ULN	Prednisone (10 mg daily) in combination with azathioprine (50 mg daily) and low-dose UDCA (13-15 mg/kg daily)	Prednisone (10 mg daily) in combination with azathioprine (50 mg daily) and/or low-dose UDCA (13-15 mg/kg daily) depending on AP level and histologic features
	Prednisone (10 mg daily) in combination with azathioprine (50 mg daily) and low-dose UDCA (13-15 mg/kg daily) if AP > 2 × ULN and/or florid duct lesions		

[*] Primary biliary cholangitis formerly called primary biliary cirrhosis.

AMA , antimitochondrial antibodies; *AP* , alkaline phosphatase level; *UDCA* , ursodeoxycholic acid; *ULN* , upper limit of normal.

(Table 90.4).

Treatment

Prednisone, with or without azathioprine or 6-mercaptopurine, improves the clinical, biochemical, and histologic features in most patients with autoimmune hepatitis and prolongs survival in most patients with severe disease. The goal is to suppress or eliminate hepatic inflammation with minimal side effects. Prednisone at an initial dose of 1-2 mg/kg/24 hr is continued until aminotransferase values return to less than twice the upper limit of normal. The dose should then be lowered in 5-mg decrements over 2-4 mo until a maintenance dose of 0.1-0.3 mg/kg/24 hr is achieved. In patients who respond poorly, who experience severe side effects, or who cannot be maintained on low-dose steroids, azathioprine (1.5-2.0 mg/kg/24 hr, up to 100 mg/24 hr) can be added, with frequent monitoring for bone marrow suppression. Measurement of thiopurine methyltransferase activity should be done prior to beginning treatment with the thiopurine drugs azathioprine and 6-mercaptopurine. Patients with low activity (10% prevalence) or absent activity (prevalence 0.3%) are at risk for developing severe drug-induced myelotoxicity from accumulation of the unmetabolized drug. Measurement of the drug metabolites, 6-thioguanine nucleotide and 6-methylmercaptopurine, is useful in determining why a patient is not responding to a standard dose of a thiopurine drug and may help in avoiding myelosuppression and hepatotoxicity. Single-agent therapy with alternate-day corticosteroids should be used with great caution, although addition of azathioprine to alternate-day steroids can be an effective approach that minimizes corticosteroid-related toxicity. In patients with a mild and relatively asymptomatic presentation, some favor a lower starting dose of prednisone (10-20 mg) coupled with the simultaneous early administration of either 6-mercaptopurine (1.0-1.5 mg/kg/24 hr) or azathioprine (1.5-2.0 mg/kg/24 hr). Patients with primary sclerosing cholangitis/autoimmune hepatitis overlap syndrome respond similarly to immunosuppressive therapy. Precise diagnostic criteria for autoimmune disease in the setting of sclerosing cholangitis do not exist. Autoimmune markers and immunoglobulin levels are often elevated in children with sclerosing cholangitis and do not necessarily indicate a diagnosis of coincident autoimmune hepatitis. The choleretic agent, ursodeoxycholic acid, is often used in biliary tract disease, but trials in adults with primary sclerosing cholangitis have not shown efficacy, and patients have experienced toxicity at higher doses. There is a potential role for budesonide combined with azathioprine in treatment of noncirrhotic patients. Budesonide is a corticosteroid with high first-pass clearance by the liver and fewer systemic side effects including suppression of hypothalamic–pituitary axis. Cyclosporine, tacrolimus, mycophenolate mofetil, and sirolimus have been used in the management of cases refractory to standard therapy. Use of these agents should be reserved for practitioners with extensive experience in their administration, because the agents have a more restricted therapeutic to toxic ratio.

Histologic progress does not necessarily need to be assessed by sequential liver biopsies, although biochemical remission does not ensure histologic resolution. Follow-up liver biopsy is an important consideration in patients for whom consideration is given to discontinuing corticosteroid therapy. In patients with disappearance of symptoms and biochemical abnormalities and resolution of the necroinflammatory process on biopsy, an attempt at gradual discontinuation of medication is justified. There is a high rate of relapse after discontinuation of therapy.

Relapse can require reinstitution of induction dosing of immunosuppression to control disease relapse.

Prognosis

The initial response to therapy in autoimmune hepatitis is generally prompt, with a >75% rate of remission. Transaminases and bilirubin fall to near-normal levels, often in the first 1-3 months. When present, abnormalities in serum albumin and prothrombin time respond over a longer period (3-9 mo). In patients meeting the criteria for tapering and then withdrawal of treatment (25–40% of children), 50% are weaned from all medication; in the other 50%, relapse occurs after a variable period. Relapse usually responds to retreatment. Many children will not meet the criteria for an attempt at discontinuation of immunosuppression and should be maintained on the smallest dose of prednisone that minimizes biochemical activity of the disease. A careful balance of the risks of continued immunosuppression and ongoing hepatitis must be continually evaluated. This requires continual screening for complications of medical therapy (monitoring of linear growth velocity, ophthalmologic examination, bone density measurement, blood pressure monitoring). Intermittent flares of hepatitis can occur and can necessitate recycling of prednisone therapy.

Some children have a relatively steroid-resistant form of hepatitis. More extensive evaluations of the etiology of their hepatitis should be undertaken, directed particularly at reassessing for the presence of either sclerosing cholangitis or Wilson disease. Nonadherence to medical therapy is one of the most common causes of “resistance” to medical therapy. Progression to cirrhosis can occur in autoimmune hepatitis despite a good response to drug therapy and prolongation of life. Corticosteroid therapy in fulminant autoimmune disease may be useful, although it should be administered with caution, given the predisposition of these patients to systemic bacterial and fungal infections.

Liver transplantation has been successful in patients with end-stage or fulminant liver disease associated with autoimmune hepatitis (see Chapter 368). Disease recurs after transplantation in approximately 30% of patients and is associated with increased concentrations of serum autoantibodies and interface hepatitis on liver biopsy. Patients generally respond well to an increase in immunosuppression, particularly to the addition of azathioprine.

CHAPTER 390

Drug- and Toxin-Induced Liver Injury

Frederick J. Suchy, Amy G. Feldman

The liver is the main site of drug metabolism and is particularly susceptible to structural and functional injury after the ingestion, parenteral administration, or inhalation of chemical agents, drugs, plant derivatives (home remedies), herbal or nutritional supplements, or environmental toxins. The possibility of drug use or toxin exposure at home or in the parents' workplace should be explored for every child with liver dysfunction. The clinical spectrum of illness can vary from asymptomatic biochemical abnormalities of liver function to fulminant failure. Liver injury may be the only clinical feature of an adverse drug reaction or may be accompanied by systemic manifestations and damage to other organs. In hospitalized patients, clinical and laboratory findings may be confused with the underlying illness. After acetaminophen, antimicrobials, supplements, and central nervous system agents are the most commonly implicated drug classes causing liver injury in children.

There is growing concern about environmental hepatotoxins that are insidious in their effects. Many environmental toxins—including the plasticizers, biphenyl A, and the phthalates—are ligands for nuclear receptors that transcriptionally activate the promoters of many genes involved in xenobiotic and lipid metabolism and may contribute to obesity and nonalcoholic fatty liver disease. Some herbal, weight loss, and body building supplements have been associated with hepatic injury or even liver failure (Table 390.1) related to their intrinsic toxicity or because of contamination with fungal toxins, pesticides, or heavy metals.

Table 390.1

Hepatotoxic Herbal Remedies, Dietary Supplements, and Weight Loss Products

REMEDY	POPULAR USES	SOURCE	HEPATOTOXIC COMPONENT	TYPE OF LIVER INJURY
Ayurvedic herbal medicine	Multiple	Multiple	Uncertain (may contain heavy metal contaminants)	Hepatitis
Barakol	Anxiolytic	*Cassia siamea*	Uncertain	Reversible hepatitis or cholestasis
Black cohosh	Menopausal symptoms	*Cimicifuga racemosa*	Uncertain	Hepatitis (causality uncertain)
“Bush tea”	Fever	*Senecio, Heliotropium, Crotalaria* spp.	Pyrrolizidine alkaloids	SOS
Cascara	Laxative	*Cascara sagrada*	Anthracene glycoside	Cholestatic hepatitis
Chaparral leaf (greasewood, creosote bush)	“Liver tonic,” burn salve, weight loss	*Larrea tridenta*	Nordihydroguaiaretic acid	Acute and chronic hepatitis, FHF
Chaso/onshido	Weight loss	—	*N* -nitro-fenfluramine	Acute hepatitis, FHF
Chinese medicines (traditional)				
Jin bu huan	Sleep aid, analgesic	*Lycopodium serratum*	Levo-tetrahydropalmitine	Acute or chronic hepatitis or cholestasis, steatosis
Ma huang	Weight loss	*Ephedra* spp.	Ephedrine	Severe hepatitis, FHF
Shou-wu-pian	Anti-aging, neuroprotection, laxative	*Polygonum multiflorum* Thunb (fleeceflower root)	Anthraquinone	Acute hepatitis or cholestasis
Syo-saiko-to	Multiple	*Scutellaria* root	Diterpenoids	Hepatocellular necrosis, cholestasis, steatosis, granulomas
Comfrey	Herbal tea	*Symphytum* spp.	Pyrrolizidine alkaloid	Acute SOS, cirrhosis
Germander	Weight loss, fever	*Teucrium chamaedry, T. capitatum, T. polium*	Diterpenoids, epoxides	Acute and chronic hepatitis, FHF, autoimmune injury
Greater celandine	Gallstones, IBS	*Chelidonium majus*	Isoquinoline alkaloids	Cholestatic hepatitis, fibrosis
Green tea leaf extract	Multiple	*Camellia sinensis*	Catechins	Hepatitis (causality questioned)
Herbalife	Nutritional supplement, weight loss	—	Various; ephedra	Severe hepatitis, FHF
Hydroxycut	Weight loss	*Camellia sinensis* , among other constituents	Uncertain	Acute hepatitis, FHF
Impila	Multiple	*Callilepsis laureola*	Potassium atractylate	Hepatic necrosis
Kava	Anxiolytic	*Piper methysticum*	Kava lactone, pipermethystine	Acute hepatitis, cholestasis, FHF
Kombucha	Weight loss	Lichen alkaloid	Usnic acid	Acute hepatitis
Limbrel (Flavocoxid)	Osteoarthritis	Plant bioflavonoids	Baicalin, epicatechin	Acute mixed hepatocellular-cholestatic injury

Lipokinetix	Weight loss	Lichen alkaloid	Usnic acid	Acute hepatitis, jaundice, FHF
Mistletoe	Asthma, infertility	*Viscus album*	Uncertain	Hepatitis (in combination with skullcap)
Oil of cloves	Dental pain	Various foods, oils	Eugenol	Zonal necrosis
Pennyroyal (squawmint oil)	Abortifacient	*Hedeoma pulegoides, Mentha pulegium*	Pulegone, monoterpenes	Severe hepatocellular necrosis
Prostata	Prostatism	Multiple	Uncertain	Chronic cholestasis
Sassafras	Herbal tea	*Sassafras albidum*	Safrole	HCC (in animals)
Senna	Laxative	*Cassia angustifolia*	Sennoside alkaloids; anthrone	Acute hepatitis
Skullcap	Anxiolytic	*Scutellaria*	Diterpenoids	Hepatitis
Valerian	Sedative	*Valeriana officinalis*	Uncertain	Elevated liver enzymes

FHF, fulminant hepatic failure; *HCC,* hepatocellular carcinoma; *SOS,* sinusoidal obstruction syndrome.

From Lewis JH: Liver disease caused by anesthetics, chemicals, toxins, and herbal preparations. In Feldman M, Friedman LS, Brandt LJ, editors: *Sleisenger and Fordtran's gastrointestinal and liver disease* , ed 10, Philadelphia, 2016, Elsevier, (Table 89.6).

Hepatic metabolism of drugs and toxins is mediated by a sequence of enzymatic reactions that in large part transform hydrophobic, less-soluble molecules into more nontoxic, hydrophilic compounds that can be readily excreted in urine or bile (see Chapter 72). Relative liver size, liver blood flow, and extent of protein binding also influence drug metabolism. Phase 1 of the process involves enzymatic activation of the substrate to reactive intermediates containing a carboxyl, phenol, epoxide, or hydroxyl group. Mixed-function monooxygenase, cytochrome-*c* reductase, various hydrolases, and the cytochrome P450 (CYP) system are involved in this process. Nonspecific induction of these enzymatic pathways, which can occur during intercurrent viral infection, with starvation, and with the administration of certain drugs such as anticonvulsants, can alter drug metabolism and increase the potential for hepatotoxicity. A single agent can be metabolized by more than 1 biochemical reaction. The reactive intermediates that are potentially damaging to the cell are enzymatically conjugated in phase 2 reactions with glucuronic acid, sulfate, acetate, glycine, or glutathione. Some drugs may be directly metabolized by these conjugating reactions without first undergoing phase 1 activation. Phase 3 is the energy-dependent excretion of drug metabolites and their conjugates by an array of membrane transporters in the liver and kidney such as the multidrug resistant protein 1.

Pathways for biotransformation are expressed early in the fetus and infant, but many phase 1 and phase 2 enzymes are immature, particularly in the 1st yr of life. CYP3A4 is the primary hepatic CYP expressed postnatally and metabolizes more than 75 commonly used therapeutic drugs and several environmental pollutants and procarcinogens. Hepatic CYP3A4 activity is poorly expressed in the fetus but increases after birth to reach 30% of adult values by 1 mo and 50% of adult values between 6 and 12 mo of age. CYP3A4 can be induced by a number of drugs, including phenytoin, phenobarbital, and rifampin. Enhanced production of toxic metabolites can overwhelm the capacity of phase 2 reactions. Conversely, numerous inhibitors of CYP3A4 from several different drug classes, such as erythromycin and cimetidine, can lead to toxic accumulations of CYP3A4 substrates. By contrast, although CYP2D6 is also developmentally regulated (maturation by 10 yr of age), its activity depends more on genetic polymorphisms than on sensitivity to inducers and inhibitors because more than 70 allelic variants of CYP2D6 significantly influence the metabolism of many drugs. Uridine diphosphate glucuronosyltransferase 1A6, a phase 2 enzyme that glucuronidates acetaminophen, is also absent in the human fetus, increases slightly in the neonate, but does not reach adult levels until sometime after 10 yr of age. Mechanisms for the uptake and excretion of organic ions can also be deficient early in life. Impaired drug metabolism via phase 1 and phase 2 reactions present in the 1st few months of life is followed by a period of enhanced metabolism of many drugs in children through 10 yr of age compared with adults.

Genetic polymorphisms in genes encoding enzymes and transporters mediating phases 1, 2, and 3 reactions can also be associated with impaired drug metabolism and an increased risk of hepatotoxicity. Some cases of idiosyncratic hepatotoxicity can occur as a result of aberrations (polymorphisms) in phase 1 drug metabolism, producing intermediates of unusual hepatotoxic potential combined with developmental, acquired, or relative inefficiency of phase 2 conjugating reactions. Genome-wide association studies have identified HLA associations in certain cases of drug- and toxin-induced liver injury (**DILI**). Children may less susceptible than adults to hepatotoxic reactions; liver injury after the use of the anesthetic halothane is rare in children, and acetaminophen toxicity is less common in infants than in adolescents, whereas most cases of fatal hepatotoxicity associated with sodium valproate use have been reported in children. Excessive or prolonged therapeutic administration of acetaminophen combined with reductions in caloric or protein intake can produce hepatotoxicity in children. In this setting, acetaminophen metabolism may be impaired by reduced synthesis of sulfated and glucuronated metabolites and reduced stores of glutathione. Immaturity of hepatic drug metabolic pathways can prevent degradation of a toxic agent; under other circumstances, the same immaturity might limit the formation of toxic metabolites. Severe sodium valproate hepatotoxicity is often associated with an underlying inherited mitochondrial disorder (Alper syndrome).

Chemical hepatotoxicity can be predictable or idiosyncratic. Predictable hepatotoxicity implies a high incidence of hepatic injury in exposed persons depending on dose. It is understandable that only a few drugs in clinical use fall into this category. These agents might damage the hepatocyte directly through alteration of membrane lipids (peroxidation) or through denaturation of proteins; such agents include carbon tetrachloride and trichloroethylene. Indirect injury can occur through interference with metabolic pathways essential for cell integrity or through distortion of cellular constituents by covalent binding of a reactive metabolite; examples include the liver injury produced by acetaminophen or by antimetabolites such as methotrexate or 6-mercaptopurine.

Idiosyncratic hepatotoxicity is unpredictable and accounts for the majority of adverse reactions. In contrast to previous dogma that idiosyncratic reactions are independent of dose, there is new information that higher doses of drugs metabolized in the liver pose a greater risk for hepatotoxicity. Idiosyncratic drug reactions in certain patients can reflect aberrant pathways for drug metabolism, possibly related to genetic polymorphisms, with production of toxic intermediates (isoniazid and sodium valproate can cause liver damage through this mechanism). Duration of drug use before liver injury varies (weeks to ≥1 yr) and the response to reexposure may be delayed.

An idiosyncratic reaction can also be immunologically mediated as a result of prior sensitization (hypersensitivity); extrahepatic manifestations of hypersensitivity can include fever, rash, arthralgia, and eosinophilia. Duration of exposure before reaction is generally 1-4 wk, with prompt recurrence of injury on reexposure. Studies indicate that arene oxides, generated through oxidative (CYP) metabolism of aromatic anticonvulsants (phenytoin, phenobarbital, carbamazepine), can initiate the pathogenesis of some hypersensitivity reactions. Arene oxides, formed in vivo, can bind to cellular macromolecules, thus perturbing cell function and possibly initiating immunologic mechanisms of liver injury.

Although the generation of chemically reactive metabolites has received great attention in the pathogenesis of hepatoxicity, increasing evidence now exists for the multifactorial nature of the process, in particular the role played by the host immune system. Activation of liver nonparenchymal Kupffer cells and infiltration by neutrophils perpetuate toxic injury by many drugs by release of reactive oxygen and nitrogen species as well as cytokines. Stellate cells can also be activated, potentially leading to hepatic fibrosis and cirrhosis.

The pathologic spectrum of drug-induced liver disease is extremely wide, is rarely specific, and can mimic other liver diseases (Table 390.2). Predictable hepatotoxins, such as acetaminophen, produce centrilobular necrosis of hepatocytes. Steatosis is an important feature of tetracycline (microvesicular) and ethanol (macrovesicular) toxicities. A cholestatic hepatitis can be observed, with injury caused by erythromycin estolate and chlorpromazine. Cholestasis without inflammation may be a toxic effect of estrogens and anabolic steroids. Use of oral contraceptives and androgens has also been associated with benign and malignant liver tumors. Some idiosyncratic drug reactions can produce mixed patterns of injury, with diffuse cholestasis and cell necrosis. Chronic hepatitis has been associated with the use of methyldopa and nitrofurantoin.

Table 390.2

Patterns of Hepatic Drug Injury

DISEASE	DRUG
Centrilobular necrosis	Acetaminophen
	Carbon tetrachloride
	Cocaine
	Ecstasy
	Iron
	Halothane
Microvesicular steatosis	Valproic acid
	Tetracycline
	Toluene
	Methotrexate
Acute hepatitis	Isoniazid
	Anti–tumor necrosis factor agents
	Valproic acid
General hypersensitivity	Sulfonamides
	Phenytoin
	Minocycline
Fibrosis	Methotrexate
Cholestasis	Chlorpromazine
	Aniline
	Erythromycin
	Paraquat
	Estrogens
	Sertraline
Sinusoidal obstruction syndrome (venoocclusive disease)	Irradiation plus busulfan
	Arsenic

	Cyclophosphamide
Portal and hepatic vein thrombosis	Estrogens
	Androgens
Biliary sludge	Ceftriaxone
Hepatic adenoma or hepatocellular carcinoma	Oral contraceptives
	Anabolic steroids

Clinical manifestations can be mild and nonspecific, such as fever and malaise. Fever, rash, and arthralgia may be prominent in cases of hypersensitivity. In ill hospitalized patients, the signs and symptoms of hepatic drug toxicity may be difficult to separate from the underlying illness. The differential diagnosis should include acute and chronic viral hepatitis, biliary tract disease, septicemia, ischemic and hypoxic liver injury, malignant infiltration, and inherited metabolic liver disease.

The laboratory features of drug- or toxin-related liver disease are extremely variable. Hepatocyte damage can lead to elevations of serum aminotransferase activities and serum bilirubin levels and to impaired synthetic function as evidenced by decreased serum coagulation factors and albumin. Hyperammonemia can occur with liver failure or with selective inhibition of the urea cycle (sodium valproate). Toxicologic screening of blood and urine specimens can aid in the detecting drug or toxin exposure. Percutaneous liver biopsy may be necessary to distinguish drug injury from complications of an underlying disorder or from intercurrent infection. Vanishing bile duct syndrome can be seen in a small portion of patients with idiosyncratic DILI.

Slight elevation of serum aminotransferase activities (generally <2-3 times normal) can occur during therapy with drugs, particularly anticonvulsants, capable of inducing microsomal pathways for drug metabolism. Liver biopsy reveals proliferation of smooth endoplasmic reticulum but no significant liver injury. Liver test abnormalities often resolve with continued drug therapy.

Treatment

Treatment of drug- or toxin-related liver injury is mainly supportive. Contact with the offending agent should be avoided. Corticosteroids might have a role in immune-mediated disease. Treatment with *n* -acetylcysteine, by stimulating glutathione synthesis, is effective in preventing or attenuating hepatotoxicity when administered within 16 hr after an acute overdose of acetaminophen and appears to improve survival in patients with severe liver injury even up to 36 hr after ingestion (see Chapter 63). Intravenous L -carnitine may be of value in treating valproic acid–induced hepatotoxicity. Orthotopic liver transplantation may be required for treatment of drug- or toxin-induced hepatic failure.

Prognosis

The prognosis of DILI depends on its type and severity. Injury is usually completely reversible when the hepatotoxic factor is withdrawn. The mortality of submassive hepatic necrosis with fulminant liver failure can, however, exceeds 50%. Hyperbilirubinemia, coagulopathy, and elevated serum creatinine are associated with an increased risk of death or need for liver transplantation. With continued use of certain drugs, such as methotrexate, effects of hepatoxicity can proceed insidiously to cirrhosis, even with normal or near normal liver tests. Neoplasia can follow long-term androgen therapy. Rechallenge with a drug suspected of having caused previous liver injury is rarely justified and can result in fatal hepatic necrosis.

Prevention

The prevention of drug-induced liver injury remains a challenge. Monitoring of liver biochemical tests may be useful in some cases, but it can prove difficult to sustain for agents used for many years. Such testing may be particularly important in patients with preexisting liver disease. For drugs with hepatotoxic potential, even if episodes are infrequent in children, such as with the use of isoniazid, patients should be advised to immediately stop the medication with onset of nausea, vomiting, abdominal pain, and fatigue until liver damage is excluded. Obvious symptoms of liver disease such as jaundice and dark urine can lag behind severe hepatocellular injury. Monitoring for toxic metabolites and genotyping can be effective in preventing severe toxicity with the use of azathioprine. Advances in pharmacogenomics, such as the use of gene chips to detect variants in some of the CYP enzymes, hold promise of a personalized approach to prevent hepatotoxicity.

CHAPTER 391

Acute Hepatic Failure

Frederick J. Suchy, Amy G. Feldman

Acute liver failure is a clinical syndrome resulting from massive necrosis of hepatocytes or from severe functional impairment of hepatocytes. The synthetic, excretory, and detoxifying functions of the liver are all severely impaired. In adults, hepatic encephalopathy has been an essential diagnostic feature. However, in pediatrics, this narrow definition may be problematic, as early hepatic encephalopathy can be difficult to detect in infants and children, and some children in acute liver failure may not develop encephalopathy. The accepted definition in children includes biochemical evidence of acute liver injury (usually <8 wk duration); no evidence of chronic liver disease; and hepatic-based coagulopathy defined as a prothrombin time (PT) >15 sec or international normalized ratio (INR) >1.5 not corrected by vitamin K in the presence of clinical hepatic encephalopathy, or a PT >20 sec or INR >2 regardless of the presence of clinical hepatic encephalopathy.

Liver failure in the perinatal period can be associated with prenatal liver injury and even cirrhosis. Examples include gestational alloimmune liver disease (GALD), tyrosinemia, familial hemophagocytic lymphohistiocytosis (HLH), and some cases of congenital viral (herpes simplex virus [HSV]) infection. Liver disease may be noticed at birth or after several days of apparent well-being. Fulminant Wilson disease and fulminant autoimmune hepatitis also occurs in older children who were previously asymptomatic but, by definition, have preexisting liver disease. Other forms of acute-on-chronic liver failure can occur when a patient with an underlying liver disease such as biliary atresia develops hepatic decompensation after viral or drug-induced hepatic injury. In some cases of liver failure, particularly in the idiopathic form of acute hepatic failure, the onset of encephalopathy occurs later, from 8 to 28 wk after the onset of jaundice.

Etiology

Infection

Acute hepatic failure can be a complication of **viral hepatitis** (A, B, D, and rarely E), Epstein-Barr virus, herpes simplex virus, adenovirus, enterovirus, influenza A, cytomegalovirus, parvovirus B19, human herpesvirus-6, varicella zoster infection, parechovirus, and other respiratory illnesses. An unusually high rate of fulminant hepatic failure occurs in young people who have combined infections with the hepatitis B virus (HBV) and hepatitis D. Mutations in the precore and/or promoter region of HBV DNA are associated with fulminant and severe hepatitis. HBV is also responsible for some cases of fulminant liver failure in the absence of serologic markers of HBV infection but with HBV DNA found in the liver. Hepatitis E virus is an uncommon cause of fulminant hepatic failure in the United States, but can occur in pregnant women, in whom mortality rates rise dramatically to up to 25%. Patients with chronic hepatitis C are at risk if they have superinfection with hepatitis A virus.

Autoimmune Hepatitis

Acute hepatic failure is caused by **autoimmune hepatitis** in approximately 5% of cases. Patients have a positive autoimmune marker (e.g., antinuclear antibody, anti–smooth muscle antibody, liver-kidney microsomal antibody, or soluble liver antigen) and possibly an elevated serum immunoglobulin G level. If a biopsy can be performed, liver histology often demonstrates interface hepatitis and a plasma cell infiltrate.

Metabolic Diseases

Metabolic disorders associated with hepatic failure include Wilson disease, acute fatty liver of pregnancy, galactosemia, hereditary tyrosinemia, hereditary fructose intolerance, defects in β-oxidation of fatty acids, and deficiencies of mitochondrial electron transport, in particular mitochondrial DNA depletion disorders. Patients with Wilson disease who present in acute liver failure often have high bilirubin levels, *low* alkaline phosphatase levels, low uric acid levels, aspartate aminotransferase levels that are higher than alanine aminotransferase levels, and a Coombs-negative hemolytic anemia.

Neoplasm

Acute liver failure can occur with malignancies including leukemia, lymphoma, and **familial HLH** . Acute liver failure is a common feature of HLH caused by several gene defects, infections by mostly viruses of the herpes group, and a variety of other conditions including organ transplantation and malignancies. Impaired function of natural killer cells and cytotoxic T-lymphocyte cells with uncontrolled hemophagocytosis and cytokine overproduction is characteristic for genetic and acquired forms of HLH. Patients with HLH present with a combination of fever, splenomegaly, cytopenias, high triglyceride levels, very high ferritin levels, low natural killer cell activity, high soluble CD25 levels; they may also have hemophagocytosis on bone marrow or liver biopsy (see Chapter 534).

Gestational Alloimmune Liver Disease

GALD is the most common cause of acute liver failure in the neonate. In this alloimmune process, maternal immunoglobulin (Ig) G antibodies bind to fetal liver antigens and activate the terminal complement cascade resulting in hepatocyte injury and death. Infants with GALD present with low/normal aminotransferases that are out of proportion to their degree of liver failure. They may have significant hypoglycemia, jaundice, coagulopathy, and hypoalbuminemia. Alpha fetoprotein levels are typically high as are serum ferritin levels.

Drug-Induced Liver Injury

Various hepatotoxic drugs and chemicals can also cause drug-induced liver injury and acute hepatic failure. Predictable liver injury can occur after exposure to carbon tetrachloride, *Amanita phalloides* mushrooms or after acetaminophen overdose. Acetaminophen is the most common identifiable etiology of acute hepatic failure in children and adolescents in the United States and England. In addition to the acute intentional ingestion of a massive dose, a therapeutic misadventure leading to severe liver injury can also occur in ill children given doses of acetaminophen exceeding weight-based recommendations for many days. Such patients can have reduced stores of glutathione after a prolonged illness and a period of poor nutrition. Idiosyncratic damage can follow the use of drugs such as halothane, isoniazid, ecstasy, or sodium valproate. Herbal and weight loss supplements are additional causes of hepatic failure (see Chapter 390).

Vascular

Ischemia and hypoxia resulting from hepatic vascular occlusion, severe heart failure, cyanotic congenital heart disease, or circulatory shock can produce liver failure.

Idiopathic Acute Liver Failure

Idiopathic acute liver failure accounts for 40–50% of acute hepatic failure cases in children. The disease occurs sporadically and usually without the risk factors for common causes of viral hepatitis. It is likely that the etiology of these cases is heterogeneous, including unidentified or variant viruses, excessive immune activation, and undiagnosed genetic or metabolic disorders. There is increasing recognition of some children presenting with indeterminate acute hepatitis or acute liver failure who have evidence of immune activation including markedly elevated sIL-2R levels but never fulfilling diagnostic criteria for HLH.

Recurrent, acute liver failure has been reported with onset in infancy due to mutations of the neuroblastoma amplified sequence gene *(NBAS)* . Episodes are usually precipitated by fever and characterized by bouts of vomiting and lethargy. Massively elevated aminotransferase levels and coagulopathy are present. Microvesicular steatosis is prominent on liver biopsy. Most patients recovered with restoration of normal liver function after control of fever and maintenance of energy balance with the infusion of intravenous glucose. The function of NBAS protein remains uncertain but it appears to be involved in retrograde transport between the endoplasmic reticulum and Golgi apparatus.

Pathology

Liver biopsy usually reveals patchy or confluent massive necrosis of hepatocytes. Multilobular or bridging necrosis can be associated with collapse of the reticulin framework of the liver. There may be little or no regeneration of hepatocytes. A zonal pattern of necrosis may be observed with certain insults. Centrilobular damage is associated with acetaminophen hepatotoxicity or with circulatory shock. Evidence of severe hepatocyte dysfunction rather than cell necrosis is occasionally the predominant histologic finding (microvesicular fatty infiltrate of hepatocytes is observed in Reye syndrome, β-oxidation defects, and tetracycline toxicity).

Pathogenesis

The mechanisms that lead to acute hepatic failure are poorly understood. It is unknown why only approximately 1–2% of patients with viral hepatitis experience liver failure. Massive destruction of hepatocytes might represent both a direct cytotoxic effect of the virus and an immune response to the viral antigens. Of patients with HBV-induced liver failure, ⅓ – ½ become negative for serum hepatitis B surface antigen within a few days of presentation and often have no detectable HBV antigen or HBV DNA in serum. These findings suggest a hyperimmune response to the virus that underlies the massive liver necrosis. Formation of hepatotoxic metabolites that bind covalently to macromolecular cell constituents is involved in the liver injury produced by drugs such as acetaminophen and isoniazid; acute hepatic failure can follow depletion of intracellular substrates involved in detoxification, particularly glutathione. Whatever the initial cause of hepatocyte injury, various factors can contribute to the pathogenesis of liver failure, including impaired hepatocyte regeneration, altered parenchymal perfusion, endotoxemia, and decreased hepatic reticuloendothelial function.

Clinical Manifestations

Acute hepatic failure can be the presenting feature of liver disease or it can complicate previously known liver disease (acute-on-chronic liver failure). A history of developmental delay and/or neuromuscular dysfunction can indicate an underlying mitochondrial or β-oxidation defect. A child with acute hepatic failure has usually been previously healthy and most often has no risk factors for liver disease such as exposure to toxins or blood products. Progressive jaundice, fetor hepaticus, fever, anorexia, vomiting, and abdominal pain are common. A rapid decrease in liver size without clinical improvement is an ominous sign. A hemorrhagic diathesis and ascites can develop.

Patients should be closely observed for hepatic encephalopathy, which is initially characterized by minor disturbances of consciousness or motor function.

Irritability, poor feeding, and a change in sleep rhythm may be the only findings in infants; asterixis may be demonstrable in older children. Patients are often somnolent, confused, or combative on arousal and can eventually become responsive only to painful stimuli. Patients can rapidly progress to deeper stages of coma in which extensor responses and decerebrate and decorticate posturing appear. Respirations are usually increased early, but respiratory failure can occur in stage IV coma (Table 391.1). The pathogenesis of hepatic encephalopathy is likely related to increased serum levels of ammonia, false neurotransmitters, amines, increased γ-aminobutyric acid receptor activity, or increased circulating levels of endogenous benzodiazepine-like compounds. Decreased hepatic clearance of these substances can produce marked central nervous system dysfunction. The mechanisms responsible for cerebral edema and intracranial hypertension in acute liver failure (ALF) suggest both cytotoxic and vasogenic injury. There is increasing evidence for an inflammatory response (synthesis and release of inflammatory factors from activated microglia and endothelial cells) which acts in synergy with hyperammonemia to cause severe astrocyte swelling/brain edema.

Table 391.1

Stages of Hepatic Encephalopathy

	STAGES			
	I	**II**	**III**	**IV**
Symptoms	Periods of lethargy, euphoria; reversal of day-night sleeping; may be alert	Drowsiness, inappropriate behavior, agitation, wide mood swings, disorientation	Stupor but arousable; confused, incoherent speech	Coma: IVa responds to noxious stimuli; IVb no response
Signs	Trouble drawing figures, performing mental tasks	Asterixis, fetor hepaticus, incontinence	Asterixis, hyperreflexia, extensor reflexes, rigidity	Areflexia, no asterixis, flaccidity
Electroencephalogram	Normal	Generalized slowing, q waves	Markedly abnormal triphasic waves	Markedly abnormal bilateral slowing, d waves, electrocortical silence

Laboratory Findings

Serum direct and indirect bilirubin levels and serum aminotransferase activities may be markedly elevated. Serum aminotransferase activities do not correlate well with the severity of the illness and can decrease as a patient deteriorates. The blood ammonia concentration is usually increased, but hepatic coma can occur in patients with a normal blood ammonia level. PT and the INR are prolonged and often do not improve after parenteral administration of vitamin K. Hypoglycemia can occur, particularly in infants. Hypokalemia, hyponatremia, metabolic acidosis, or respiratory alkalosis can also develop.

Treatment

Specific therapies for identifiable causes of acute liver failure include *N* -acetylcysteine (acetaminophen), acyclovir (herpes simplex virus), penicillin (*Amanita* mushrooms), nucleos(t)ide analogs such as entecavir (hepatitis B virus [HBV]), and prednisone (autoimmune hepatitis). Immunosuppression with corticosteroids should also be considered in children with the indeterminate form of fulminant hepatic failure with immune activation to avoid progression to liver transplantation or death. However, controlled trials have shown a worse outcome in patients treated with corticosteroids in patients without an immune basis for liver injury. Treatment of GALD involves a combination of double-volume exchange transfusion to remove existing reactive antibody followed immediately by administration of high-dose intravenous immunoglobulin (IVIG) (1 g/kg) to block antibody induced complement activation. Management of other types of acute hepatic failure is supportive. No therapy is known to reverse hepatocyte injury or to promote hepatic regeneration.

An infant or child with acute hepatic failure should be cared for in an institution able to perform a liver transplantation if necessary and managed in an intensive care unit with continuous monitoring of vital functions. Endotracheal intubation may be required to prevent aspiration, to reduce cerebral edema by hyperventilation, and to facilitate pulmonary toilet. Mechanical ventilation and supplemental oxygen are often necessary in advanced coma. Sedatives should be avoided unless needed in the intubated patient because these agents can aggravate or precipitate encephalopathy. Opiates may be better tolerated than benzodiazepines. Prophylactic use of proton pump inhibitors should be considered because of the high risk of gastrointestinal bleeding.

Hypovolemia should be avoided and treated with cautious infusions of *isotonic* fluids and blood products. Renal dysfunction can result from dehydration, acute tubular necrosis, or functional renal failure (hepatorenal syndrome). Electrolyte and glucose solutions should be administered intravenously to maintain urine output, to correct or prevent hypoglycemia, and to maintain normal serum potassium concentrations. Hyponatremia is common and should be avoided; it is usually dilutional and not a result of sodium depletion. Parenteral supplementation with calcium, phosphorus, and magnesium may be required. Hypophosphatemia, probably a reflection of liver regeneration, and early phosphorus administration are associated with a better prognosis in acute liver failure, whereas hyperphosphatemia predicts a failure of spontaneous recovery. Coagulopathy should be treated with parenteral administration of vitamin K. Fresh-frozen plasma, cryoprecipitate, platelets, activated factor VII, or prothrombin complex concentrates can be used to treat clinically significant bleeding or can be given if an invasive procedure such as placement of a central line or an intracranial monitor needs to be performed. Plasmapheresis can permit temporary correction of the bleeding diathesis without resulting in volume overload. Continuous hemofiltration is useful for managing fluid overload, acute renal failure, and hyperammonemia.

Patients should be monitored closely for infection, including sepsis, pneumonia, peritonitis, and urinary tract infections. At least 50% of patients experience serious infection. Gram-positive organisms *(Staphylococcus aureus, Staphylococcus epidermidis)* are the most common pathogens, but Gram-negative and fungal infections are also observed.

Gastrointestinal hemorrhage, infection, constipation, sedatives, electrolyte imbalance, and hypovolemia can precipitate encephalopathy and should be identified and corrected. Protein intake should be initially restricted or eliminated, depending on the degree of encephalopathy. If encephalopathy or hyperammonemia develops, lactulose or rifaximin can be administered. *N*-acetylcysteine is not effective in improving the outcome of patients with acute liver failure not associated with acetaminophen.

Cerebral edema is an extremely serious complication of hepatic encephalopathy that responds poorly to measures such as corticosteroid administration and osmotic diuresis. Monitoring intracranial pressure can be useful in preventing severe cerebral edema, in maintaining cerebral perfusion pressure, and in establishing the suitability of a patient for liver transplantation.

Temporary liver support continues to be evaluated as a bridge for the patient with liver failure to liver transplantation or regeneration. Nonbiologic systems, essentially a form of liver dialysis with an albumin-containing dialysate, and biologic liver support devices that involve perfusion of the patient's blood through a cartridge containing liver cell lines or porcine hepatocytes can remove some toxins, improve serum biochemical abnormalities, and, in some cases, improve neurologic function, but there has been little evidence of improved survival, and few children have been treated.

Orthotopic liver transplantation can be lifesaving in patients who reach advanced stages (III, IV) of hepatic coma. Reduced-size allografts and living donor transplantation have been important advances in the treatment of infants with hepatic failure. Partial auxiliary orthotopic or heterotopic liver transplantation is successful in a small number of children, and in some cases it has allowed regeneration of the native liver and eventual withdrawal of immunosuppression. Orthotopic liver transplantation should not be done in patients with liver failure and neuromuscular dysfunction secondary to a mitochondrial disorder because progressive neurologic deterioration is likely to continue after transplantation.

Prognosis

Children with acute hepatic failure fare better than adults. Improved survival can be attributed to careful intensive care and if necessary liver transplantation. In the largest prospective study from the Pediatric Acute Liver Failure Study Group, 709 children were assessed at 21 days: 50.3% of patients survived with supportive care alone, 36.2% survived after liver transplantation, and 13.4% died. A scoring system based on peak values of total serum bilirubin, PT, and plasma ammonia concentration predicted transplant-free survival. Prognosis varies considerably with the cause of liver failure and stage of hepatic encephalopathy. Survival rates with supportive care may be as high as 90% in acetaminophen overdose and with fulminant hepatitis A. By contrast, spontaneous recovery can be expected in only approximately 40% of patients with liver failure caused by the idiopathic (indeterminate) form of acute liver failure or an acute onset of Wilson disease. Prognosis is also poor for spontaneous recovery in patients with mitochondrial deficits, hemophagocytic syndromes, herpes simplex disease, and idiosyncratic drug reactions. In patients who progress to stage IV coma (see Table 391.1), the prognosis is extremely poor. Brain stem herniation is the most common cause of death. Major complications such as sepsis, severe hemorrhage, or renal failure increase the mortality. The prognosis is particularly poor in patients with liver necrosis and multiorgan failure.

Age <1 yr, stage 4 encephalopathy, an INR >4, PT >90 sec, low factor V levels, and the need for dialysis before transplantation are associated with increased mortality. Pretransplantation serum bilirubin concentration or the height of hepatic enzymes is *not* predictive of posttransplantation survival. A plasma ammonia concentration >200 µmol/L is associated with a 5-fold increased risk of death. Children with acute hepatic failure are more likely to die while on the waiting list compared to children with other liver transplant requiring diagnoses. Owing to the severity of their illness, the 6 mo post–liver transplantation survival of approximately 75% for acute liver failure is significantly lower than the 90% achieved in children with chronic liver disease. Patients who recover from fulminant hepatic failure with only supportive care do not usually develop cirrhosis or chronic liver disease. Aplastic anemia occurs in approximately 10% of children with the idiopathic form of fulminant hepatic failure and is often fatal without bone marrow transplantation. Long-term survivors demonstrate average IQ and visual spatial ability but greater than expected impairments in motor skills, attention, executive function, and health-related quality of life.

CHAPTER 392

Cystic Diseases of the Biliary Tract and Liver

Frederick J. Suchy, Amy G. Feldman

Cystic lesions of liver may be initially recognized during infancy and childhood. Hepatic fibrosis can also occur as part of an associated developmental defect (Table 392.1). Cystic *renal* disease is usually associated and often determines the clinical presentation and prognosis. Virtually all proteins encoded by genes mutated in combined cystic diseases of the liver and kidney are at least partially localized to primary cilia in renal tubular cells and cholangiocytes.

Table 392.1

Syndromes Associated With Congenital Hepatic Fibrosis

DISORDER	ASSOCIATED FEATURES
Autosomal recessive polycystic kidney disease	Ductal plate malformation, Caroli syndrome
Autosomal dominant polycystic kidney disease	Ductal plate malformation, Caroli syndrome
Autosomal dominant polycystic liver disease	Rarely, congestive heart failure
Jeune syndrome	Asphyxiating thoracic dystrophy, with cystic renal tubular dysplasia, Caroli syndrome
Joubert syndrome	Central nervous system defects, cardiac malformations
COACH syndrome	*C* erebellar vermis hypoplasia, *o* ligophrenia, congenital *a* taxia, ocular *c* oloboma, *h* epatic fibrosis
Meckel-Gruber syndrome	Cystic renal dysplasia, abnormal bile duct development with fibrosis, posterior encephalocele, polydactyly
Carbohydrate-deficient glycoprotein syndrome type 1b	Phosphomannose isomerase 1 deficiency chronic diarrhea, protein-losing enteropathy
Ivemark syndrome type 2	Autosomal-recessive renal-hepatic-pancreatic dysplasia
Nephronophthisis type 3	Tapetoretinal degeneration
Bardet-Biedl syndrome	Retinal degeneration, obesity, limb deformities, hypogonadism
Oral-facial-digital syndrome type 1	Oral clefts, hamartomas or cysts of the tongue, digital anomalies pancreatic cysts

Miscellaneous syndromes	Intestinal lymphangiectasia, enterocolitis, cystic short rib (Beemer-Langer) syndrome, osteochondrodysplasia

After Suchy FJ, Sokol RJ, Balistreri WF, editors: *Liver disease in children,* ed 3, New York, 2014, Cambridge University Press, p. 713.

A solitary, congenital liver cyst (nonparasitic) can occur in childhood and has been identified in some cases on prenatal ultrasound. Abdominal distention and pain may be present, and a poorly defined right-upper-quadrant mass may be palpable. These benign lesions are best left undisturbed unless they compress adjacent structures or a complication occurs, such as hemorrhage into the cyst. Operative management is generally reserved for symptomatic patients and enlarging cysts.

Choledochal Cysts

Choledochal cysts are congenital dilatations of the common bile duct that can cause progressive biliary obstruction and biliary cirrhosis. Cylindrical (fusiform) and spherical (saccular) cysts of the extrahepatic ducts are the most common types (see Table 392.1). Choledochal cysts are classified according to the Todani method (Fig. 392.1). Type 1 choledochal cysts, the most common variant, involve a saccular or fusiform dilation of the common bile duct. Type II cysts are congenital diverticula protruding from the common bile duct. Type III cysts or choledochoceles involve a herniation of the intraduodenal segment of the common bile duct into the duodenum. Type IVa cysts or **Caroli disease** involve multiple intrahepatic and extrahepatic cysts. Type IVb cysts involve only the extrahepatic duct. Solitary liver cysts (type V) are very rare.

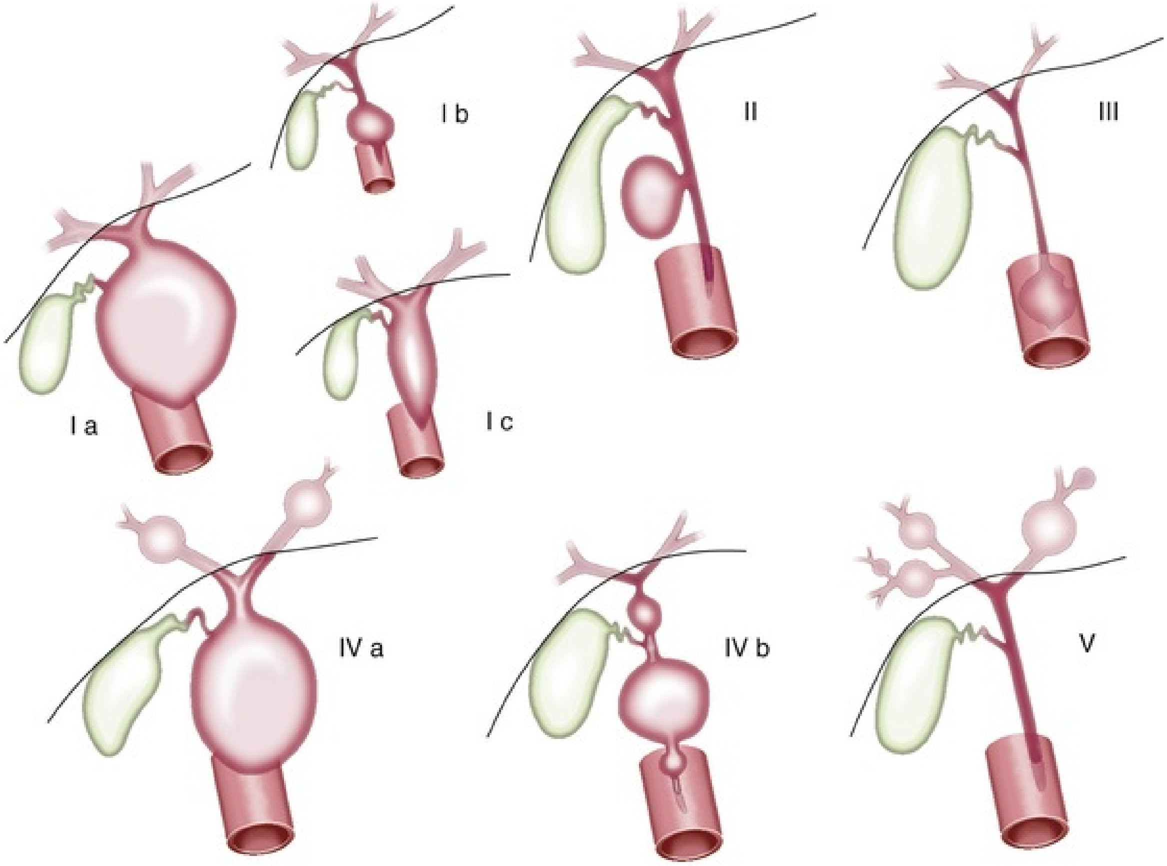

FIG. 392.1 **Classification of choledochal cysts according to Todani and colleagues. Ia, common type; Ib, segmental dilation; Ic, diffuse dilation; II, diverticulum; III, choledochocele; IVa, multiple cysts (intra- and extrahepatic); IVb, multiple cysts (extrahepatic); V, single or multiple dilations of the intrahepatic ducts (Caroli disease). (From Savader SJ, Benenati JF, Venbrux AC, et al. Choledochal cysts: Classification and cholangiographic appearance. AJR Am J Roentgenol 1991;156:327-31.)**

The pathogenesis of choledochal cysts remains uncertain. Some reports suggest that junction of the common bile duct and the pancreatic duct before their entry into the sphincter of Oddi might allow reflux of pancreatic enzymes into the common bile duct, causing inflammation, localized weakness, and dilation of the duct. It has also been proposed that a distal congenital stenotic segment of the biliary tree leads to increased intraluminal pressure and proximal biliary dilation. Other possibilities are that choledochal cysts represent malformations of the common duct or that they occur as part of the spectrum of an infectious disease that includes neonatal hepatitis and biliary atresia.

Approximately 75% of cases appear during childhood. The infant typically presents with cholestatic jaundice; severe liver dysfunction including ascites and coagulopathy can rapidly evolve if biliary obstruction is not relieved. An abdominal mass is rarely palpable. In an older child, the classic triad of abdominal pain, jaundice, and mass occurs in <33% of patients. Features of acute cholangitis (fever, right-upper-quadrant tenderness, jaundice, and leukocytosis) may be present. The diagnosis is made by ultrasonography; choledochal cysts have been identified prenatally using this technique. Magnetic resonance cholangiography is useful in the preoperative assessment of choledochal cyst anatomy.

Choledochal cysts have the potential to develop into cholangiocarcinoma; therefore the treatment of choice is primary excision of the cyst and a Roux-en-Y choledochojejunostomy. The postoperative course can be complicated by recurrent cholangitis or stricture at the anastomotic site. Long-term follow-up is necessary to ensure that no malignancy develops.

Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease (ARPKD) manifests predominantly in childhood (see Chapter 541.2). Bilateral enlargement of the kidneys is caused by a generalized dilation of the collecting tubules. The disorder is invariably associated with congenital hepatic fibrosis and various degrees of biliary ductal ectasia, discussed in detail later.

The polycystic kidney and hepatic disease 1 *(PKHD1)* gene, mutated in ARPKD, encodes a protein that is called fibrocystin/polyductin, which is localized to cilia on the apical domain of renal collecting cells and cholangiocytes. The primary defect in ARPKD may be ciliary dysfunction related to the abnormality in this protein. Fibrocystin/polyductin appears to have a role in the regulation of cellular adhesion, repulsion, and proliferation and/or the regulation and maintenance of renal collecting tubules and bile ducts, but its exact role in normal and cystic epithelia remains unknown. Kidney and liver disease are independent and variable in severity; they are not explainable by the type of *PKHD1* mutation. Phenotypic variability among affected siblings suggests the importance of modifier genes as well as possibly environmental influences.

In ARPKD, the cysts arise as ectatic expansions of the collecting tubules and bile ducts, which remain in continuity with their structures of origin. ARPKD normally presents in early life, often shortly after birth, and is generally more severe than autosomal dominant polycystic kidney disease (ADPKD). Fetal ultrasound may visualize large echogenic kidneys, also described as bright, with low or absent amniotic fluid (oligohydramnios). However, in many instances the features of ARPKD are not visualized on sonography until the 3rd trimester or after birth.

Patients with ARPKD can die in the perinatal period owing to renal failure or lung dysgenesis. The kidneys in these patients are usually markedly enlarged and dysfunctional. Respiratory failure can result from compression of the chest by grossly enlarged kidneys, from fluid retention, or from concomitant pulmonary hypoplasia. The clinical pathologic findings within a family tend to breed true, although there has been some variability in the severity of the disease and the time for presentation within the same family. In patients surviving infancy because of a milder renal phenotype, liver disease may be a prominent part of the disorder. The liver disease in ARPKD is related to congenital malformation of the liver with varying degrees of periportal fibrosis, bile ductular hyperplasia, ectasia, and dysgenesis. Initial symptoms are liver related in approximately 26% of patients. This can manifest clinically as variable cystic dilation of the intrahepatic biliary tree with congenital hepatic fibrosis. Congenital hepatic fibrosis and Caroli disease likely result from an abnormality in remodeling of the embryonic ductal plate of the liver. **Ductal plate malformation** refers to the persistence of excess embryonic bile duct structures in the portal tracts. ARPKD patients with recurrent cholangitis or complications of portal hypertension may require combined liver-kidney transplant.

Cystic Dilation of the Intrahepatic Bile Ducts (Caroli Disease/Caroli Syndrome)

In Caroli disease there is isolated ectasia or nonobstructing segmental dilatation of the larger intrahepatic ducts. Caroli syndrome is the more common variant, in which malformations of small bile ducts are associated with congenital hepatic fibrosis. Congenital saccular dilation can affect several segments of the intrahepatic bile ducts; the dilated ducts are lined by cuboidal epithelium and are in continuity with the main duct system, which is usually normal. Choledochal cysts have also been associated with Caroli disease. Bile duct dilation leads to stagnation of bile and formation of biliary sludge and intraductal lithiasis. There is a marked predisposition to ascending cholangitis, which may be exacerbated by calculus formation within the abnormal bile ducts.

Affected patients usually experience symptoms of acute cholangitis as children or young adults. Fever, abdominal pain, mild jaundice, and pruritus occur, and a slightly enlarged, tender liver is palpable. Elevated alkaline phosphatase activity, direct-reacting bilirubin levels, and leukocytosis may be observed during episodes of acute infection. In patients with Caroli disease, clinical features may be the result of a combination of recurring bouts of cholangitis, reflecting the intrahepatic ductal abnormalities and portal hypertensive bleeding resulting from hepatic fibrosis. Ultrasonography shows the dilated intrahepatic ducts, but definitive diagnosis and extent of disease must be determined by percutaneous transhepatic, endoscopic, or magnetic resonance cholangiography.

Cholangitis and sepsis should be treated with appropriate antibiotics. Calculi can require surgery. Partial hepatectomy may be curative in rare cases in which cystic disease is confined to a single lobe. The prognosis is otherwise guarded, largely owing to difficulties in controlling cholangitis and biliary lithiasis and to a significant risk for developing cholangiocarcinoma.

Congenital Hepatic Fibrosis

Congenital hepatic fibrosis is usually associated with ARPKD and is characterized pathologically by diffuse periportal and perilobular fibrosis in broad bands that contain distorted bile duct–like structures and that often compress or incorporate central or sublobular veins (see Table 392.1). Irregularly shaped islands of liver parenchyma contain normal-appearing hepatocytes. Caroli disease and choledochal cysts are associated. Most patients have renal disease, mostly autosomal recessive polycystic renal disease and rarely nephronophthisis. Congenital hepatic fibrosis also occurs as part of the COACH syndrome (cerebellar vermis hypoplasia, oligophrenia, congenital ataxia, coloboma, and hepatic fibrosis). Congenital hepatic fibrosis has been described in children with a congenital disorder of glycosylation caused by mutations in the gene encoding phosphomannose isomerase (see Chapter 105.6).

Several different forms of congenital hepatic fibrosis have been defined clinically: portal hypertensive (most common) cholangitic, mixed, and latent. The disorder usually has its onset in childhood, with hepatosplenomegaly or with bleeding secondary to portal hypertension. In a recent study, splenomegaly, as a marker for portal hypertension, developed early in life and was present in 60% of children younger than 5 yr of age.

Cholangitis can occur in these patients, as they have abnormal biliary tracts even without Caroli disease. Hepatocellular function is usually well preserved. Serum aminotransferase activities and bilirubin levels are usually normal in the absence of cholangitis and choledocholithiasis; serum alkaline phosphatase activity may be slightly elevated. The serum albumin level and prothrombin time are normal. Liver biopsy is rarely required for diagnosis, particularly in patients with obvious renal disease.

Treatment of this disorder should focus on control of bleeding from esophageal varices and aggressive antibiotic treatment of cholangitis. Infrequent mild bleeding episodes may be managed by endoscopic sclerotherapy or band ligation of the varices. After more severe hemorrhage, portacaval anastomosis can relieve portal hypertension. The prognosis may be greatly improved by a shunting procedure, but survival in some patients may be limited by renal failure.

Autosomal Dominant Polycystic Kidney Disease

ADPKD (see Chapter 541.3), the most commonly inherited cystic kidney disease, affects 1 in 1,000 live births. It is characterized by progressive renal cyst development and cyst enlargement and an array of extrarenal manifestations. There is a high degree of intrafamilial and interfamilial variability in the clinical expression of the disease.

ADPKD is caused by mutation in 1 of 2 genes, *PKD1* or *PKD2* , which account for 85–90% and 10–15% of cases, respectively. The proteins encoded by these genes, polycystin-1 and polycystin-2, are expressed in renal tubule cells and in cholangiocytes. Polycystin-1 functions as a mechanosensor in cilia, detecting the movement of fluid through tubules and transmitting the signal through polycystin-2, which acts as a calcium channel.

Dilated noncommunicating cysts are most commonly observed. Other hepatic lesions are rarely associated with ADPKD, including the ductal plate malformation, congenital hepatic fibrosis, and biliary microhamartomas (the von Meyenburg complexes). Approximately 50% of patients with renal failure have demonstrable hepatic cysts that are derived from the biliary tract but not in continuity with it. The hepatic cysts increase with age. In one study the prevalence of hepatic cysts was 58% in patients 15-24 yr old. Hepatic cystogenesis appears to be influenced by estrogens. Although the frequency of cysts is similar in males and females, the development of large hepatic cysts is mainly a complication in females. Hepatic cysts are often asymptomatic but can cause pain and are occasionally complicated by hemorrhage, infection, jaundice from bile duct compression, portal hypertension with variceal bleeding, or hepatic venous outflow obstruction from mechanical compression of hepatic veins, resulting in tender hepatomegaly and exudative ascites. Cholangiocarcinoma can occur. Subarachnoid hemorrhage can result from the associated cerebral arterial aneurysms.

Selected patients with severe symptomatic polycystic liver disease and favorable anatomy benefit from liver resection or fenestration. Combined liver-kidney transplantation may be required. There is considerable evidence for a role of cyclic adenosine monophosphate in epithelial proliferation and fluid secretion in experimental renal and hepatic cystic disease. Several clinical trials in adults have shown that somatostatin analogs can blunt hepatic cyst expansion by blocking secretin-induced cyclic adenosine monophosphate generation and fluid secretion by cholangiocytes.

Autosomal Dominant Polycystic Liver Disease

Autosomal dominant polycystic liver disease is a distinct clinical and genetic identity in which multiple cysts develop and are unassociated with cystic kidney disease. Liver cysts arise from but are not in continuity with the biliary tract. Girls are more commonly affected than boys, and the cysts often enlarge during pregnancy. Cysts are rarely identified in children. Cyst complications are related to effects of local compression, infection, hemorrhage, or rupture. The genes associated with autosomal dominant polycystic liver disease are *PRKCSH* and *SEC63* , which encode hepatocystin and Sec63, respectively. Hepatocystin is a protein kinase C substrate adK-H, which is involved in the proper folding and maturation of glycoproteins. It has been localized to the endoplasmic reticulum. *SEC63* encodes the protein SEC63P, which is a component of the protein translocation machinery in the endoplasmic reticulum.

CHAPTER 393

Diseases of the Gallbladder

Frederick J. Suchy, Amy G. Feldman

The incidence of gallbladder disease, particularly cholelithiasis and biliary dyskinesia, has been increasing in children, and has been associated with a rise in the number of cholecystectomies.

Anomalies

The gallbladder is congenitally absent in approximately 0.1% of the population. Hypoplasia or absence of the gallbladder can be associated with extrahepatic biliary atresia or cystic fibrosis. Duplication of the gallbladder occurs rarely. Gallbladder ectopia may occur with a transverse, intrahepatic, left-sided, or retroplaced location. Multiseptate gallbladder, characterized by the presence of multiple septa dividing the gallbladder lumen, is another rare congenital anomaly of the gallbladder.

Acute Hydrops

Table 393.1 lists the conditions associated with hydrops of the gallbladder.

Table 393.1

Conditions Associated With Hydrops of the Gallbladder

Cholelithiasis Cholecystitis Kawasaki disease Streptococcal pharyngitis Staphylococcal infection Leptospirosis

Ascariasis
Threadworm
Sickle cell crisis
Typhoid fever
Thalassemia
Total parenteral nutrition
Prolonged fasting
Viral hepatitis
Sepsis
Henoch-Schönlein purpura
Mesenteric adenitis
Necrotizing enterocolitis

Acute noncalculous, noninflammatory distention of the gallbladder can occur in infants and children. It is defined by the absence of calculi, bacterial infection, or congenital anomalies of the biliary system. The disorder may complicate acute infections and Kawasaki disease, but the cause is often not identified. Hydrops of the gallbladder may also develop in patients receiving long-term parenteral nutrition, presumably because of gallbladder stasis during the period of enteral fasting. Hydrops is distinguished from acalculous cholecystitis by the absence of a significant inflammatory process and is a generally benign prognosis.

Affected patients usually have right upper quadrant pain with a palpable mass. Fever, vomiting, and jaundice may be present and are usually associated with a systemic illness such as streptococcal infection. Ultrasonography shows a markedly distended echo-free gallbladder, without dilation of the biliary tree. Acute hydrops is usually treated conservatively with a focus on supportive care and managing the intercurrent illness; cholecystostomy and drainage are rarely needed. Spontaneous resolution and return of normal gallbladder function usually occur over a period of several weeks. If a laparotomy is required, a large edematous gallbladder is found to contain white, yellow, or green bile. Obstruction of the cystic duct by mesenteric adenopathy is occasionally observed. Cholecystectomy is required if the gallbladder is gangrenous. Pathologic examination of the gallbladder wall shows edema and mild inflammation. Cultures of bile are usually sterile.

Cholecystitis and Cholelithiasis

Acute acalculous cholecystitis is uncommon in children and is usually caused by infection. Pathogens include streptococci (groups A and B), Gram-negative organisms—particularly *Salmonella* and *Leptospira interrogans* —and a number of viral infections (hepatitis A, Epstein-Barr [EB] virus, and cytomegalovirus). Parasitic infestation with *Ascaris* or *Giardia lamblia* may be found. Acalculous cholecystitis may be associated with abdominal trauma or burn injury or with a severe systemic illness such as leukemia, end-stage liver disease, and systemic vasculitis.

Clinical features include right upper quadrant or epigastric pain, nausea, vomiting, fever, and jaundice. Right upper quadrant guarding and tenderness are present. Ultrasonography discloses an enlarged, thick-walled gallbladder without calculi. Serum alkaline phosphatase activity and direct-reacting bilirubin levels are elevated. Leukocytosis is usual.

Patients may recover with treatment of systemic and biliary infection. Because the gallbladder can become gangrenous, daily ultrasonography is useful in monitoring gallbladder distention and wall thickness. Cholecystectomy is required in patients who fail to improve with conservative management. Cholecystostomy drainage is an alternative approach in a critically ill patient.

Cholelithiasis is relatively rare in otherwise healthy children, occurring more commonly in patients with various predisposing disorders (Table 393.2). Gallstones are rarely detected by ultrasonography in the fetus, but generally remain asymptomatic and resolve spontaneously during the 1st yr of life. In an ultrasonographic survey of 1570 children (ages 6-19 yr) the overall prevalence of gallstone disease was 0.13% (0.27% in female subjects). Older reports consistently found that >70% of gallstones were the pigment type, 15–20% were cholesterol stones, and the remainder were composed of a mixture of cholesterol, organic matrix, and calcium bilirubinate. Black pigment gallstones, composed mostly of calcium bilirubinate and glycoprotein matrix, are a frequent complication of chronic hemolytic anemias. However, because of obesity, cholesterol gallstones predominate in children, while the number of patients with hemolytic anemia-associated gallstones have remained stable.

Table 393.2

Conditions Associated With Cholelithiasis

Chronic hemolytic disease (sickle cell anemia, spherocytosis, thalassemia, Gilbert disease)
Ileal resection or disease
Cystic fibrosis
Cirrhosis
Cholestasis
Crohn disease
Obesity

Insulin resistance
Prolonged parenteral nutrition
Prematurity with complicated medical or surgical course
Prolonged fasting or rapid weight reduction
Treatment of childhood cancer
Abdominal surgery
Pregnancy
Sepsis
Genetic *(ABCB4, ABCG5/G8)* progressive familial intrahepatic cholestasis
Cephalosporins

Brown pigment stones form mostly in infants as a result of biliary tract infection. Unconjugated bilirubin is the predominant component, formed by the high β-glucuronidase activity of infected bile. Cholesterol gallstones are composed purely of cholesterol or contain >50% cholesterol along with a mucin glycoprotein matrix and calcium bilirubinate. Calcium carbonate stones have also been described in children.

Patients with hemolytic disease (including sickle cell anemia, the thalassemias, and red blood cell enzymopathies) and Wilson disease are at increased risk for black pigment cholelithiasis. In sickle cell disease, pigment gallstones can develop before age 4 yr and have been reported in 17–33% of patients 2-18 yr of age. Genetic variation in the promoter of uridine diphosphate-glucuronosyltransferase 1A1 (the [TA]7/[TA]7 and [TA]7/[TA]8 genotypes) underlies **Gilbert syndrome** , a relatively common, chronic form of unconjugated hyperbilirubinemia, and is a risk factor for pigment gallstone formation in sickle cell disease.

Cirrhosis and chronic cholestasis also increase the risk for pigment gallstones. Sick premature infants may also have gallstones; their treatment is often complicated by such factors as bowel resection, necrotizing enterocolitis, prolonged parenteral nutrition without enteral feeding, cholestasis, frequent blood transfusions, and use of diuretics. Cholelithiasis in premature infants is often asymptomatic and may resolve spontaneously. Brown pigment stones are found in infants with obstructive jaundice and infected intra- and extrahepatic bile ducts. These stones are usually radiolucent, owing to a lower content of calcium phosphate and carbonate and a higher amount of cholesterol than in black pigment stones. MDR3 deficiency caused by *ABCB4* mutations is a cholestatic syndrome related to impaired biliary phospholipid excretion. It is associated with symptomatic and recurring cholelithiasis. Patients may show intrahepatic lithiasis, sludge, or microlithiasis along the biliary tree.

Obesity has assumed an increasingly important role as a risk factor for cholesterol cholelithiasis in children, particularly in adolescent girls. Cholesterol gallstones are also found in children with disturbances of the enterohepatic circulation of bile acids, including patients with ileal disease and bile acid malabsorption, such as those with ileal resection, ileal Crohn disease, and cystic fibrosis. Pigment stones can also occur in these patients.

Cholesterol gallstone formation results from an excess of cholesterol in relation to the cholesterol-carrying capacity of micelles in bile. Supersaturation of bile with cholesterol, leading to crystal and stone formation, could result from decreased bile acid or from an increased cholesterol concentration in bile. Other initiating factors that may be important in stone formation include gallbladder stasis or the presence in bile of abnormal mucoproteins or bile pigments that may serve as a nidus for cholesterol crystallization.

Prolonged use of high-dose ceftriaxone, a 3rd-generation cephalosporin, has been associated with the formation of calcium-ceftriaxone salt precipitates *(biliary pseudolithiasis)* in the gallbladder. Biliary sludge or cholelithiasis can be detected in >40% of children who are treated with ceftriaxone for at least 10 days. In rare cases, children become jaundiced and develop abdominal pain; precipitates usually resolve spontaneously within several months after discontinuation of the drug.

Acute or chronic cholecystitis is often associated with gallstones. The acute form may be precipitated by impaction of a stone in the cystic duct. Proliferation of bacteria within the obstructed gallbladder lumen can contribute to the process and lead to biliary sepsis. Chronic calculous cholecystitis is more common. It can develop insidiously or follow several attacks of acute cholecystitis. The gallbladder epithelium commonly becomes ulcerated and scarred.

More than 50% of patients with gallstones have symptoms, and 18% present with a complication as the first indication of cholelithiasis, such as pancreatitis, choledocholithiasis or acute calculous cholecystitis. The most important clinical feature of cholelithiasis is recurrent abdominal pain, which is often colicky and localized to the right upper quadrant. An older child may have intolerance for fatty foods. Acute cholecystitis is characterized by fever, pain in the right upper quadrant, and often a palpable mass. Jaundice occurs more commonly in children than adults. Pain may radiate to an area just below the right scapula. A plain x-ray of the abdomen may reveal opaque calculi, but radiolucent (cholesterol) stones are not visualized. Accordingly, ultrasonography is the method of choice for gallstone detection. Hepatobiliary scintigraphy is a valuable adjunct in that failure to visualize the gallbladder provides evidence of cholecystitis.

Laboratory evaluation may reveal elevated aminotransferase levels, leukocytosis, and mild hyperbilirubinemia. Marked elevations of the direct bilirubin, alkaline phosphatase, or GGT levels should prompt evaluation for choledocholithiasis.

Patients with cholecystitis and persistent fever or concern for obstruction should be hospitalized and started on antibiotics. Cholecystectomy is curative. Laparoscopic cholecystectomy is routinely performed in symptomatic infants and children with cholelithiasis. Common bile duct stones are unusual in children, occurring in 2–6% of cases with cholelithiasis, often in association with obstructive jaundice and pancreatitis. Operative cholangiography should be done at the time of surgery, however, to detect unsuspected common duct calculi. Endoscopic retrograde cholangiography with extraction of common duct stones is an option before laparoscopic cholecystectomy in older children and adolescents.

Asymptomatic patients with cholelithiasis pose a more difficult management problem. Studies in adults indicate a lag time of more than a decade between initial formation of a gallstone and development of symptoms. Spontaneous resolution of cholelithiasis has been reported in infants and children. However, if surgery is deferred for any patient, parents should be counseled about signs and symptoms consistent with cholecystitis or obstruction of the common bile duct by a gallstone. In patients with chronic hemolysis or ileal disease, cholecystectomy can be carried out at the same time as another surgical procedure. Because laparoscopic surgery can safely be performed in children with sickle cell disease, elective cholecystectomy is being done more frequently at the time of gallstone diagnosis, before symptoms or complications develop. In cases associated with liver disease, severe obesity, or cystic fibrosis, the surgical risk of cholecystectomy may be substantial so that the risks and benefits of the operation need to be carefully considered.

Biliary Dyskinesia

Biliary dyskinesia is a motility disorder of the biliary tract that may cause biliary colic in children, often in association with nausea and fatty food intolerance, but symptoms may overlap with functional abdominal pain. There are no gallstones on imaging. Sphincter of Oddi dysfunction may be a variant that can present with chronic abdominal pain and recurrent pancreatitis. The diagnosis is based on a cholecystokinin–diisopropyl iminodiacetic acid scan or an ultrasound done with a fatty meal demonstrating a gallbladder ejection fraction of <35%. Reproduction of pain on cholecystokinin administration may also be seen, as well as the absence of gallbladder filling on an otherwise normal ultrasound examination. Although laparoscopic cholecystectomy is performed for many patients with this disorder, short-term and long-term symptomatic improvement is highly variable.

CHAPTER 394

Portal Hypertension and Varices

Amy G. Feldman, Frederick J. Suchy

Portal hypertension, defined as an elevation of portal pressure >10-12 mm Hg or a hepatic venous pressure gradient >4 mm Hg, is a major cause of morbidity and mortality in children with liver disease. Portal hypertension occurs when there is increased portal resistance or increased blood flow through the portal system. When portal hypertension occurs, children can develop varices, splenomegaly, ascites, and gastrointestinal bleeding.

Etiology

Portal hypertension can result from obstruction to portal blood flow anywhere along the course of the portal venous system (prehepatic, intrahepatic, or posthepatic). Table 394.1 outlines the various disorders associated with portal hypertension.

Table 394.1

Causes of Portal Hypertension

EXTRAHEPATIC PORTAL HYPERTENSION
Portal vein agenesis, atresia, stenosis
Portal vein thrombosis or cavernous transformation
Splenic vein thrombosis
Increased portal flow
Arteriovenous fistula
INTRAHEPATIC PORTAL HYPERTENSION
Hepatocellular disease
Acute and chronic viral hepatitis
Cirrhosis
Congenital hepatic fibrosis
Wilson disease

α_1 -Antitrypsin deficiency
Glycogen storage disease type IV
Hepatotoxicity
Methotrexate
Parenteral nutrition
Biliary tract disease
Extrahepatic biliary atresia
Cystic fibrosis
Choledochal cyst
Sclerosing cholangitis
Intrahepatic bile duct paucity
Idiopathic portal hypertension
Postsinusoidal obstruction
Budd-Chiari syndrome
Venoocclusive disease

Portal vein thrombosis is the most common cause of extrahepatic portal hypertension. The obstruction can occur at any level of the portal vein. In neonates, portal vein thrombosis can occur from umbilical infection (omphalitis) with or without a history of catheterization of the umbilical vein, dehydration, and/or sepsis. Rare developmental anomalies producing extrahepatic portal hypertension include agenesis, atresia, stenosis, or a web of the portal vein. In older children, portal vein thrombosis can occur with intraabdominal infection (appendicitis, peritonitis, pancreatitis), inflammatory bowel disease, primary sclerosing cholangitis, or biliary infection. Portal vein thrombosis is also associated with hypercoagulable states, such as deficiencies of factor V Leiden, protein C, or protein S. The portal vein can be replaced by a fibrous remnant or contain an organized thrombus. At least half of reported cases have no defined cause. Uncommonly, presinusoidal hypertension can be caused by increased flow through the portal system as a result of a congenital or acquired arteriovenous fistula.

The intrahepatic causes of portal hypertension are numerous. The most common cause of portal hypertension in children is **cirrhosis.** The numerous causes of cirrhosis include recognized disorders such as biliary atresia, autoimmune hepatitis, chronic viral hepatitis, and metabolic liver disease such as α_1 -antitrypsin deficiency, Wilson disease, glycogen storage disease type IV, hereditary fructose intolerance, and cystic fibrosis.

Portal infiltration with malignant cells or granulomas can also contribute. An idiopathic form of portal hypertension characterized by splenomegaly, hypersplenism, and portal hypertension without occlusion of portal or splenic veins and with no obvious disease in the liver has been described. In some patients, noncirrhotic portal fibrosis has been observed.

Postsinusoidal causes of portal hypertension are also observed in childhood. **Budd-Chiari syndrome** occurs with obstruction to hepatic veins anywhere between the efferent hepatic veins and the entry of the inferior vena cava into the right atrium. In most cases, no specific cause can be found, but thrombosis can occur from inherited and acquired hypercoagulable states (antithrombin III deficiency, protein C or S deficiency, factor V Leiden or prothrombin mutations, paroxysmal nocturnal hemoglobinemia, pregnancy, oral contraceptives) and can complicate hepatic or metastatic neoplasms, collagen vascular disease, infection, and trauma. Additional causes of the Budd-Chiari syndrome include Behçet syndrome, inflammatory bowel disease, aspergillosis, dacarbazine therapy, autoinflammatory-recurrent fever syndromes, and inferior vena cava webs.

Sinusoidal obstruction syndrome (venoocclusive disease) is the most common cause of hepatic vein obstruction in children. In this disorder, occlusion of the centrilobular venules or sublobular hepatic veins occurs. The disorder most frequently occurs in bone marrow transplant recipients after total body irradiation with or without cytotoxic drug therapy, but can also be seen in patients on azathioprine, mercaptopurine, thioguanine, and those taking herbal remedies that contain pyrrolizidine alkaloids.

Pathophysiology

The primary hemodynamic abnormality in portal hypertension is increased resistance to portal blood flow. This is the case whether the resistance to portal flow has an intrahepatic cause such as cirrhosis or is due to portal vein obstruction. Portosystemic shunting should decompress the portal system and thus significantly lower portal pressures. However, despite the development of significant collaterals deviating portal blood into systemic veins, portal hypertension is maintained by an overall increase in portal venous flow and thus maintenance of portal hypertension. A hyperdynamic circulation is achieved by tachycardia, an increase in cardiac output, decreased systemic vascular resistance, and increased splanchnic dilation. Overall, the increase in portal flow likely contributes to an increase in variceal transmural pressure. The increase in portal blood flow is related to the contribution of hepatic and collateral flow; the actual portal blood flow reaching the liver is reduced. It is also likely that hepatocellular dysfunction and portosystemic shunting lead to the generation of various humoral factors that cause vasodilation and an increase in plasma volume.

Many complications of portal hypertension can be accounted for by the development of a remarkable collateral circulation. Collateral vessels can form prominently in areas in which absorptive epithelium joins stratified epithelium, particularly in the esophagus or anorectal region. The superficial submucosal collaterals, especially those in the esophagus and stomach, and to a lesser extent, those in the duodenum, colon, or rectum, are prone to rupture and bleeding under increased pressure. In portal hypertension, the vascularity of the stomach is also abnormal and demonstrates prominent submucosal arteriovenous communications between the muscularis mucosa and dilated precapillaries and veins. The resulting lesion, a vascular ectasia, has been called *congestive gastropathy* and contributes to a significant risk of bleeding from the stomach.

Clinical Manifestations

Bleeding is the most common presentation of portal hypertension in children. In large series of children with portal hypertension, two thirds presented with hematemesis or melena, most commonly from rupture of an esophageal varix. Less commonly, patients bleed from portal gastropathy, gastric antral ectasia, or stomal, intestinal, or anorectal varices. The risk of a first bleed in children with cirrhosis is 22%, but rises to 38% in children with known varices over a 5-yr period. In children with biliary atresia, 15–25% have bleeding on long-term follow-up. The age of first bleed is dependent on the underlying etiology of portal hypertension. Hemorrhage, particularly in children with portal vein obstruction, can be precipitated by minor febrile, intercurrent illness. The mechanism is often unclear; aspirin or other nonsteroidal antiinflammatory drugs may be a contributing factor by damaging the integrity of a congested gastric mucosa or interfering with platelet function. Coughing during a respiratory illness can also increase intravariceal pressure.

Splenomegaly is the second most common finding in children with portal hypertension and may be initially recognized on routine physical examination. As more than half of patients in many series with portal vein obstruction do not experience bleeding until after 6 yr of age, underlying liver disease should be considered in any child with splenomegaly, especially if there is concurrent cytopenias. Most children with splenomegaly are asymptomatic.

Ascites is the presenting sign of portal hypertension in 7–21% of children. Ascites can develop at any time with cirrhosis or if there is new onset portal vein obstruction. Children with portal hypertension can also suffer from growth impairment, minimal hepatic encephalopathy, and impaired quality of life. Some develop **portal hypertensive biliopathy** , where portal vein obstruction occurs as a result of external compression of the bile ducts by cavernous transformation of the portal vein.

Children with portal hypertension may also develop pulmonary complications, including **hepatopulmonary syndrome** (HPS) and **portopulmonary hypertension** (PP-HTN). HPS is defined as an arterial oxygenation defect induced by intrapulmonary microvascular dilation, resulting from release of a number of endogenous vasoactive molecules, including endothelin-1 and nitric oxide into the venous circulation. HPS develops in ≥10% of patients with portal hypertension. Patients with HPS may present with dyspnea, cyanosis, clubbing, and spider nevi. PP-HTN is defined by a pulmonary arterial pressure greater than 25 mm Hg at rest or a left-ventricular end-diastolic pressure of less than 15 mm Hg. Patients with PP-HTN most commonly present with exertional dyspnea. Histologically, these patients have pulmonary arteriopathy with laminar intimal fibrosis.

Diagnosis

In patients with established chronic liver disease or in those in whom portal vein obstruction is suspected, an experienced ultrasonographer should be able to demonstrate the patency of the portal vein, and Doppler flow ultrasonography can demonstrate the direction of flow within the portal system. The pattern of flow correlates with the severity of cirrhosis and encephalopathy. Reversal of portal vein blood flow (hepatofugal flow) is more likely to be associated with variceal bleeding. Ultrasonography is also effective in detecting the presence of esophageal varices. Another important feature of extrahepatic portal vein obstruction is cavernous transformation of the portal vein, in which an extensive complex of small collateral vessels forms in the paracholedochal and epicholedochal venous system to bypass the obstruction. Other imaging techniques also contribute to further definition of the portal vein anatomy but are required less often; contrast-enhanced CT and magnetic resonance angiography provide information similar to ultrasonography. Selective arteriography of the celiac axis, superior mesenteric artery, and splenic vein may be useful in precise mapping of the extrahepatic vascular anatomy. This is not required to establish a diagnosis but can prove valuable in planning surgical decompression of portal hypertension. The platelet count, spleen length measured by ultrasonography, and serum albumin are the best noninvasive predictors of portal hypertension in children.

In a patient with hypoxia (HPS), intrapulmonary microvascular dilation is demonstrated with contrast-enhanced bubble echocardiography that shows delayed appearance in the left heart of microbubbles from a saline bolus injected into a peripheral vein.

Endoscopy is the most reliable method for detecting esophageal varices and for identifying the source of gastrointestinal bleeding. Although bleeding from esophageal or gastric varices is most common in children with portal hypertension, up to one third of patients, particularly those with cirrhosis, have bleeding from some other source, such as portal hypertensive gastropathy or gastric or duodenal ulcerations. There is a strong correlation between variceal size as assessed endoscopically and the probability of hemorrhage. Red spots apparent over varices at the time of endoscopy are a strong predictor of imminent hemorrhage.

Treatment

The therapy of portal hypertension can be divided into emergency treatment of potentially life-threatening hemorrhage and prophylaxis directed at prevention of initial or subsequent bleeding. It must be emphasized that the use of many therapies is based on experience in adults with portal hypertension; there are few randomized trials of therapies for portal hypertension in the pediatric population.

Treatment of patients with acute variceal hemorrhage must focus on stabilization of the patient. Fluid resuscitation should be administered, initially in the form of crystalloid infusion, followed by the replacement of red blood cells. Care should be taken to avoid overtransfusing children with portal hypertension-induced bleeding, as this can result in overfilling the intravascular space and increasing portal pressure. A reasonable goal hemoglobin level after variceal bleed is between 7 and 9 g/dL. Correction of coagulopathy by administration of vitamin K and/or infusion of platelets or fresh-frozen plasma may be required. A nasogastric tube should be placed to document the presence of blood within the stomach and to monitor for ongoing bleeding. An H_2 -receptor blocker or proton pump inhibitor should be given intravenously to reduce the risk of bleeding from gastric erosions. Intravenous antibiotics should be considered, as there is high risk of infectious complications during variceal bleeding.

Pharmacologic therapy to decrease portal pressure should be initiated in patients with continued bleeding. Vasopressin or one of its analogs is commonly used and is thought to act by increasing splanchnic vascular tone and thus decreasing portal blood flow. Vasopressin is administered initially with a bolus of 0.33 units/kg over 20 min, followed by a continued infusion of the same dose on an hourly basis or a continuous infusion of 0.2 units/1.73 m^2 /min. The drug has a half-life of approximately 30 min. Its use may be limited by the side effects of vasoconstriction, which can impair cardiac function and perfusion to the heart, bowel, and kidneys and can also, as a result, exacerbate fluid retention. More commonly, the somatostatin analog, octreotide, is used, as it decreases splanchnic blood flow with few side effects. Octreotide is initially administered with a bolus of 1 µg/kg followed by a continuous intravenous infusion of 1.0-5.0 µg/kg/hr. A total of 15% of children with a portal hypertensive bleed will have persistent hemorrhage despite initiation of some form of splanchnic vasoconstriction.

After an episode of variceal hemorrhage or in patients in whom bleeding cannot be controlled with pharmacologic therapy, endoscopy with variceal band ligation or variceal sclerotherapy should be performed. Endoscopic band ligation is preferred, as it has been shown in adults to be more effective and has fewer side effects. For smaller children in whom the banding device cannot be used, sclerosants can be injected either intra- or paravariceal until bleeding has stopped. Sclerotherapy treatments may be associated with bleeding, bacteremia, esophageal ulceration, and stricture formation. After band ligation or sclerosis, repeat endoscopy should be performed until varices are obliterated.

In patients who continue to bleed despite pharmacologic and endoscopic methods to control hemorrhage, a Sengstaken-Blakemore tube may be emergently placed to stop hemorrhage by mechanically compressing esophageal and gastric varices. The device is rarely used now, but it may be the only option to control life-threatening hemorrhage until a more definite procedure can be performed. It carries a significant rate of complications and a high rate of bleeding when the device is removed, and it poses a particularly high risk for pulmonary aspiration. The tube is not well tolerated in children without significant sedation and intubation.

Various surgical procedures have been devised to divert portal blood flow and to decrease portal pressure. A portacaval shunt diverts nearly all of the portal blood flow into the subhepatic inferior right vena cava. Although portal pressure is significantly reduced, because of the significant diversion of blood from the liver, patients with parenchymal liver disease have a marked risk for hepatic encephalopathy. Even mild hepatic encephalopathy can impair cognitive function, including school performance. More selective shunting procedures, such as mesocaval or distal splenorenal shunt, can effectively decompress the portal system while allowing a greater amount of portal blood flow to the liver. The small size of the vessels makes these operations technically challenging in infants and small children, and there is a significant risk of failure as a result of shunt thrombosis. A shunt may be good option for a child with relatively well-preserved liver function, as sometimes occurs in patients with biliary atresia, congenital hepatic fibrosis, or cystic fibrosis. For children with an extrahepatic portal vein thrombosis, a Meso-Rex shunt (superior mesenteric vein to left portal vein bypass) may successfully restore physiologic portal blood flow and inflow of hepatotrophic factors. In one large single-center experience, 84% of children with idiopathic extrahepatic portal vein thrombosis were successfully treated with a Meso-Rex shunt. Growth and cognitive function improve after this procedure.

A transjugular intrahepatic portosystemic shunt, in which a stent is placed by an interventional radiologist between the right hepatic vein and the right or left branch of the portal vein, can aid in the management of portal hypertension in children, especially in those needing temporary relief before liver transplantation. The transjugular intrahepatic portosystemic shunt procedure can precipitate hepatic encephalopathy and is prone to thrombosis.

Orthotopic liver transplantation represents a much better therapy for portal hypertension resulting from intrahepatic disease and cirrhosis. A prior portosystemic shunting operation does not preclude a successful liver transplantation but makes the operation technically more difficult.

Long-term treatment with nonspecific β-blockers, such as propranolol, has been used extensively in adults with portal hypertension. These agents might act by lowering cardiac output and inducing splanchnic vasoconstriction. Evidence in adult patients shows that β-blockers can reduce the incidence of variceal hemorrhage and improve long-term survival. A therapeutic effect is thought to result when the pulse rate is reduced by ≥25%. There is limited published experience with the use of this therapy in children.

Prognosis

Portal hypertension secondary to intrahepatic disease has a poor prognosis.

Portal hypertension is usually progressive in these patients and is often associated with deteriorating liver function. Efforts should be directed toward prompt treatment of acute bleeding and prevention of recurrent hemorrhage with available methods. Patients with progressive liver disease and significant esophageal varices ultimately require orthotopic liver transplantation. Liver transplantation is the only effective therapy for HPS and should also be considered for patients with portal hypertension secondary to hepatic vein obstruction or resulting from severe venoocclusive disease.

CHAPTER 395

Liver Transplantation

Jorge D. Reyes, Evelyn Hsu

Survival rates for pediatric liver transplantation are now >90% in the United States, in large part to refinements made in the critical care management of children with liver failure and advances in perioperative care and immunosuppression management. Protocols for immune suppression withdrawal enhancing tolerance have introduced the possibility of transplantation without the need for long-term immunosuppression. In the United States, a national allocation system matches donor organs with wait-list candidates (the Organ Procurement and Transplantation Network and the United Network for Organ Sharing [UNOS]); this organization has been given the responsibility of allocating scarce organs to the neediest patients and has undergone continuous revisions with this goal in mind—the most significant in 2002, with the adoption of the Pediatric End-Stage Liver Disease and Medical End-Stage Liver Disease (for adolescents) illness severity scoring system.

Indications

The diseases for which liver transplantation is indicated can be categorized into the following groups:

- *Obstructive biliary tract disease:* biliary atresia, sclerosing cholangitis, traumatic or postsurgical injury
- *Metabolic disorders with liver parenchymal disease:* α_1 -antitrypsin deficiency, tyrosinemia type I, glycogen storage disease type IV, Wilson disease,

gestational alloimmune liver disease (GALD, previously known as neonatal hemochromatosis), cystic fibrosis

◆ *Metabolic disorders without liver parenchymal disease:* Crigler-Najjar type I, familial hypercholesterolemia, primary oxalosis (with kidney), organic acidemia, urea cycle defects

◆ *Acute hepatitis:* fulminant hepatic failure, viral, toxin, or drug-induced

◆ *Chronic hepatitis with cirrhosis:* hepatitis B or C, autoimmune

◆ *Intrahepatic cholestasis:* idiopathic neonatal hepatitis, Alagille syndrome, progressive familial intrahepatic cholestasis, bile acid synthetic disorders

◆ *Primary liver tumors:* benign tumors (hamartomas, hemangioendothelioma), unresectable hepatoblastoma, and hepatocellular carcinoma

◆ *Miscellaneous:* cryptogenic cirrhosis, congenital hepatic fibrosis, Caroli disease, polycystic kidney and liver disease, cirrhosis induced by total parenteral nutrition

◆ *Emerging indications:* graft-versus-host disease (a complication of bone marrow transplantation), hemophilia, and portosystemic shunts

Biliary atresia is the most common indication for liver transplantation in children, accounting for more than half of all pediatric liver transplants performed in the United States, followed by metabolic liver disease and inborn errors of metabolism, autoimmune and familial cholestatic disorders, and acute hepatic necrosis. Biliary atresia may present with 2 clinical patterns: an acquired form for which there may be nonrandom clustering of potential etiologies (80% of cases), and a syndromic/embryonic form that includes other anomalies, such as polysplenia preduodenal portal vein, intestinal malrotation, situs anomalies, and absence of the retrohepatic vena cava. Hepatoportoenterostomy benefits survival if performed within the first 60 days of life; however, some patients with successful drainage later develop cirrhosis with portal hypertension (variceal bleeding and ascites). Children with biliary atresia (or any other obstructive biliary disorder) who do not achieve successful drainage will experience continued decline and end-stage liver disease, usually requiring liver transplantation within the 1st yr of life.

Inborn errors of metabolism result from a single enzyme deficiency that results in alteration of synthesis, breakdown, transport, or function of carbohydrate, fat, or protein. These disorders can be grouped into those diseases that cause liver parenchymal disease and eventual cirrhosis with end-stage liver disease, as well as liver cancer (i.e., α_1 -antitrypsin deficiency, Wilson disease, cystic fibrosis, progressive familial intrahepatic cholestasis), and those inborn errors that manifest principally by their hepatic enzyme deficiency with no hepatocellular injury; complications occur in “satellite” systems such as the brain (hyperammonemic conditions), the kidney (hyperoxaluria type 1), or heart (familial hypercholesterolemia). Some metabolic disorders place patients at risk for decompensation throughout their entire lives, and others manifest principally after adolescence. Liver transplantation is a form of enzyme replacement; the value and risk benefit of doing so in the absence of cirrhosis has prompted the pursuit of gene therapy and hepatocyte transplantation as possible alternatives, but the therapeutic benefit of these modalities of treatment is as yet equivocal.

Although a proportion of children with **acute hepatic necrosis** will survive without transplant, it accounts for approximately 13% of pediatric liver transplantation and requires the most intense concentration of multimodal management/support yet devised. This diagnosis lacks clear etiology in the majority of cases, and posttransplantation survival varies but is worse than the general population, likely due to multifactorial issues related to comorbidities and listing/transplantation graft option availability.

Primary hepatic malignancies in children are rare (<2% of all pediatric malignancies) and account for a fewer than 5% of pediatric transplants. Hepatoblastoma accounts for the majority of cases (75% of primary liver tumors in childhood) and usually presents in an advanced stage; adjuvant chemotherapy and total hepatectomy with transplantation provide cure and long-term survival for the majority of these children. Survival of >85% has been reported by the International Society of Pediatric Oncology and several American centers.

The impact of chronic liver disease and its impact on growth, development, and quality of life of children can be devastating. Liver transplantation is a valid therapy and cure. The allocation of deceased donor livers in the United States follows guidelines based on severity of liver disease as reflected in the Pediatric End-Stage Liver Disease/Model for End-Stage Liver Disease (PELD/MELD) scoring system implemented in 2002, which is calculated from the measurable values of bilirubin, albumin or creatinine (depending upon age), and international normalization ratio. The PELD scoring system was initially modeled from a cohort of 884 children on the pediatric liver transplant wait list, and is intended to predict death, decompensation, or transplantation within 3 mo. Since 2002 the number of liver transplants performed in children in the United States has remained relatively stable, while the number of liver transplants performed in adults has steadily increased by approximately 10% per year. Due to an allocation algorithm that prioritizes local adults over critically ill children nationally, a significant proportion of livers from pediatric deceased donors have been transplanted into adults without ever being offered to a child. This and other issues highlight the importance of advocacy on behalf of children in this growing field.

Contraindications to liver transplantation include uncontrolled infection of extrahepatic origin, extrahepatic malignancies, and severely disabling and uncorrectable disease in other organ systems, principally the brain, heart, and lungs. Although combined liver and heart or lung transplantation has been performed in adults and children, such cases require special consideration and centers dedicated to the complexities of posttransplantation management.

Technical Innovations

There are no limitations on age or weight for liver transplantation; to enhance the availability of liver grafts to children and optimize the timing of transplantation, techniques allowing the use of reduced-size or segmental grafts (a right or left lobe of liver, or the left lateral segment of the left lobe) were developed; this allows a liver from a larger donor to be implanted into a child, overcoming the barrier of size mismatch. In the same era, techniques were developed for the use of segments from living donors (usually the left lateral segment for small pediatric recipients), and then split-liver grafts from deceased donors where the left lateral segment is transplanted into a child and the remaining segments of right lobe and medial segment of left lobe transplanted into an adult, allowing increased utilization of deceased donor grafts without affecting adult wait-list mortality. Reduction of a liver graft is performed ex vivo (i.e., outside of the body); split-liver procurement surgery can be performed either ex vivo or in situ (in the hemodynamically stable brain-dead donor). Donors suitable for aforementioned graft variants should ideally be young (younger than 45 yr of age), healthy, and nonobese; however, variations are guided by the severity of illness and urgency for transplantation of the recipient. Not all centers have the degree of surgical expertise required to perform these more complex surgeries; thus options may be limited for children at centers that only accept size-matched organs.

The implantation of a liver (either whole organ or segment) involves removal of the native liver and encompasses 4 anastomoses: the suprahepatic vena cava, the portal vein, the hepatic artery, and the bile duct. Modifications of the procedure generally involve retaining (or not) of the retrohepatic vena cava, the performance (or not) of a temporary portocaval shunt to decompress the splanchnic venous system during the anhepatic phase, and the use of vascular homografts of donor iliac vein or artery to replace the native inflow (guided by the presence of recipient anomalies or thrombosis of native vessels). The donor bile duct may be connected to a loop of recipient intestine (Roux-en-Y limb) or the native bile duct. UNOS reported outcomes analyzing graft types, and outcomes have shown improved graft survival in children younger than 3 yr of age for live donor grafts when compared with deceased donor whole, split, and reduced grafts. After the 1st yr, however, patient and allograft survivals were similar, independent of graft type.

Immunosuppression

The long-term goal of effective clinical immunosuppression after solid-organ transplantation is to inhibit antigen-induced T-lymphocyte activation and cytokine production, and to interrupt alloimmune–major histocompatibility complex recognition. To prevent weakening the host response to infection, this goal should be achieved while preserving host immunocompetence. A major emphasis is on the prevention of acute and chronic rejection and preserving the ability to reverse refractory acute rejection. These efforts have been successful; the challenge for the future of pediatric liver transplantation is achieving long-term survival and improved quality of life; this inherently involves strategies to minimize the long-term toxicity of immunosuppressive drug therapy, which can include renal failure, cardiovascular complications, and infections. Strategies of drug minimization, steroid free therapy, and complete withdrawal of drugs have been accomplished in select patients and under careful medical supervision.

Immediately peri- or posttransplantation induction immunosuppressive therapy can involve antilymphocyte antibody induction with depleting antibodies (monoclonal or polyclonal), such as antithymocyte globulin antibody, or the use of a chimeric mouse–human antibody that blocks the interleukin-2 receptor of the T cell, thus preventing activation and replication of antigen-selected T cells. Corticosteroids act through the suppression of antibody production and cytokine synthesis (interleukin-2, and interferon-γ), decreasing proliferation of T cells (helper, suppressor, and cytotoxic), B cells, and neutrophils. Maintenance immunosuppression is achieved by using calcineurin phosphatase inhibitor (cyclosporine or tacrolimus); these drugs interfere with the production and release of interleukin-2, a critical factor in the cytotoxic T-cell response. Calcineurin phosphatase inhibitors are most effectively directed toward inhibiting T-cell–mediated acute cellular rejection. Tacrolimus is the mainstay of most immunosuppressive regimens, and its ability to progress or initiate maintenance immunosuppression in the absence of corticosteroids is of particular benefit in the children. Adjuvant immunosuppression, such as azathioprine or mycophenolate mofetil, which inhibits the synthesis of purine nucleosides and subsequently the proliferation of T and B lymphocytes as well as antibody formation, may be added to enhance the antirejection profile, allow for decrease in the calcineurin dosage, or manage chronic rejection. Rapamycin, a macrolide that binds its molecular target of mammalian target of rapamycin receptor, decreases interleukin-2 production, and in turn T- and B-cell activation and proliferation.

Complications

Posttransplantation complications can be related to the pretransplantation condition of the recipient and the donor match and type, immunologic responses to the graft and the need for enhanced immunosuppressive drug therapy, and toxicity effects of these drugs or infections from over-immunosuppression.

Posttransplant complications can occur at varying specific frequencies over a fairly well-defined time course (early, late, remote).

The most anticipated early complications involve those inherent to the transplantation operation: primary nonfunction of the graft, hepatic artery thrombosis, portal/hepatic venous strictures or occlusions, and biliary strictures. Primary nonfunction of the graft is rare in pediatric recipients given the selection criteria of potential donors. Hepatic artery thrombosis is the most frequent and early vascular complication; it occurs in 5–10% of recipients and can have devastating consequences on the graft (acute necrosis and gangrene, biliary leaks/stricture/bilomas) and may require urgent retransplantation. Portal vein or hepatic vein strictures/occlusions are rare and generally occur later posttransplantation. Biliary strictures are the most frequent surgical complication (10–30%) after liver transplantation and should be included in the differential diagnosis of any posttransplantation liver allograft dysfunction. Management of these complications varies and may include interventional radiologic procedures, reoperation, or retransplantation. Advancements in interventional radiology technique have allowed for a less invasive and equally efficacious approach to resolving these complications.

Rejection usually occurs after the first 2 wk after transplantation, with the highest incidence (30–60%) within the first 90 days. Diagnosis of rejection is suspected based on abnormal liver function studies; rarely are there systemic signs such as fever, abdominal pain, new-onset ascites, or hydrothorax. Diagnosing rejection requires biopsy confirmation; treatment algorithms include high doses of corticosteroids and antilymphocyte antibodies. Chronic rejection is less frequent (5–10%) and is characterized by progressive damage and loss of bile ductules with consequent cholestasis; treatment involves long-term enhancement of maintenance immunosuppression with corticosteroids and other agents.

The need to treat rejection can place the patient at a higher risk of drug toxicity or infection. The most common transplantation-related infections are cytomegalovirus and Epstein-Barr virus infections, for which there are well-developed algorithms of prophylaxis and screening. Epstein-Barr virus–induced **posttransplant lymphoproliferative disease** (PTLD) represents a unique complication of over-immunosuppression and infection occurring in approximately 10% of patients. It is managed primarily by withdrawal of immunosuppression and antiviral therapy; some patients require chemotherapy.

Outcomes

The clinical, surgical, and immunosuppressive drug therapy advances since the 1990s have dramatically improved survival of liver transplantation in children. UNOS data reveal a 1 yr patient and graft survival for biliary atresia of 95% and 87%, respectively. Examination of 461 5-yr survivors of pediatric liver transplantation in a North American registry found a 1st graft survival of 88%, with 12% requiring a 2nd graft and 2% requiring a 3rd transplant. The same investigators published a study of 167 10-yr survivors and found that only 30% of the group had an “ideal outcome” of normal liver-associated enzymes, no retransplant, and no evidence of PTLD, chronic rejection, hypertension, or renal disease. Longer-term survival is inherently dependent on adequacy of long term immunosuppression management, adherence to care protocols, and prevention of infection/toxicities/chronic rejection.

Pediatric liver recipients have excellent and sustained survival following childhood transplantation. With improved survival, the new frontier of care needs to battle the issues of growth, patient loss with a functioning graft, cognitive functioning, and quality of life. The goals of the field have been reset to discovery of the induction protocols and long-term strategies that can foster minimization of drug therapy, and even the induction of tolerance and a life free of the burden of immunosuppression.

Chapter 397 Ascites

Chapter 398 Peritonitis

Chapter 399 Epigastric Hernia

CHAPTER 396

Peritoneal Malformations

Asim Maqbool, Chris A. Liacouras

Congenital peritoneal bands represent anatomically unabsorbed portions of omentum and mesentery, and most commonly occur in the regions of the duodenum, duodenojejunal flexure, ileocecal junction, and ascending colon. Although usually benign, they may be responsible for intestinal obstruction or midgut volvulus and resulting intestinal necrosis. Intraabdominal herniations infrequently occur through ringlike formations produced by anomalous peritoneal bands. Numerous other anomalies can occur in the course of the development of the peritoneum but are rarely of clinical importance. Absence of the omentum or its duplication occurs rarely. Omental cysts arise in obstructed lymphatic channels within the omentum. They may be congenital or can result from trauma and are usually asymptomatic. Abdominal pain or partial small bowel obstruction can result from compression or torsion of the small bowel from traction on the omentum.

Mesenteric cysts are also rare and may co-exist with omental cysts. They may arise from the retroperitoneum, the small bowel mesentery, or even the sigmoid colon. Mesenteric cysts involve the small bowel most frequently but are also reported in association with the colon. Cysts can be single or multiple and are often large. Presentation varies, but most frequently involves abdominal pain and appreciation of an abdominal mass on examination. Gastrointestinal symptoms may also include nausea, emesis, constipation, or loose stools. Mesenteric cysts are mostly benign lesions but may act as lead points for torsion and intussusception. Cysts are usually well defined and identified on imaging via ultrasound or CT scan. Treatment is with simple excision, which can be performed laparoscopically in most cases, with excellent results and generally good prognosis.

CHAPTER 397

Ascites

Asim Maqbool, Jessica W. Wen, Chris A. Liacouras

Ascites is the pathologic accumulation of fluid within the peritoneal cavity. Multiple causes of ascites have been described in different age groups (Tables 397.1 to 397.3). In children, hepatic and renal disease are the most common causes, but ascites can also be caused by cardiac disease, trauma, infection, or neoplasia.

Table 397.1

Causes of Fetal Ascites

- Gastrointestinal disorders
  - Meconium peritonitis
  - Intestinal malrotation
  - Small intestinal or colonic atresia
  - Intussusception
  - Volvulus
  - Cystic fibrosis
  - Biliary atresia
  - Portal venous malformations
- Infection
  - Parvovirus
  - Syphilis
  - Cytomegalovirus
  - Toxoplasmosis
  - Acute maternal hepatitis
- Genitourinary disorders
  - Hydronephrosis
  - Polycystic kidney disease
  - Urinary obstruction
  - Ovarian cyst
  - Persistent cloaca
- Chylous ascites
- Cardiac disorders
  - Arrhythmia
  - Heart failure

- Chromosomal abnormalities
  - Trisomy
  - Turner syndrome
- Neoplasm
- Hematologic
  - Hemolytic anemia
  - Neonatal hemochromatosis
- Metabolic disease
  - Niemann-Pick type C
  - Congenital disorders of glycosylation
  - Wolman disease
  - Lysosomal storage disease
- Other
  - Maternal/fetal abuse
  - Idiopathic

  - Chronic granulomatous disease
  - Nonaccidental trauma
  - Protein losing enteropathy
  - Idiopathic

Modified from Giefer MJ, Murray KF, Colletti RB: Pathophysiology, diagnosis, and management of pediatric ascites, *J Pediatr Gastroenterol Nutr* 52(5):503–513, 2011 (Table 3).

The clinical hallmark of ascites is abdominal distention. Early satiety and dyspnea can occur with a moderate amount of ascites. Considerable intraperitoneal fluid can accumulate before ascites is detectable by the classic physical signs: bulging flanks, dullness to percussion, shifting dullness, a fluid wave, and the *puddle sign* (percussion of a supine person's abdomen over the umbilicus becomes dull as the patient is moved to a prone position and ascitic fluid puddles in dependent regions). Umbilical herniation can be associated with tense ascites. Ultrasound examination is useful for detecting small amounts of ascites.

Abdominal paracentesis can provide symptomatic relief and may be diagnostic of the cause of the ascites. Determining the serum-ascites albumin gradient can help determine the cause of ascites. A gradient greater than 1.1 g/dL (high-gradient ascites) is consistent with ascites caused by portal hypertension, whereas a gradient <1.1 g/dL (low-gradient ascites) indicates ascites of non-portal-hypertensive etiology.

The course, prognosis, and treatment of ascites depend entirely on the cause. For most patients, treatment consists of dietary sodium restriction and diuretic therapy with spironolactone, with the addition of furosemide in more severe cases. Supplemental albumin can also aid in ascitic fluid mobilization. Refractory cases may require large volume paracentesis or transjugular intrahepatic portosystemic shunting. Patients with any type of ascites are at increased risk for spontaneous bacterial peritonitis.

397.1

Chylous Ascites

Asim Maqbool, Jessica W. Wen, Chris A. Liacouras

Chylous ascites refers to peritoneal fluid that contains lymphatic drainage with a characteristic milky appearance that is rich in triglycerides. Chylous ascites can result from congenital anomaly, injury, or obstruction of the intraabdominal portion of the thoracic duct. Although uncommon, it can occur at any age. In the pediatric population, the most common cause is lymphatic malformation (lymphangiectasia). Other causes include surgical injury to the lymphatics, trauma, cirrhosis, peritoneal bands, generalized lymphangiomatosis, chronic inflammatory processes of the bowel, and mycobacterial infection. Malignancy is a common cause in the adult population but uncommon in pediatrics. Congenital anomalies of the lymphatic system can be associated with Turner, Noonan, yellow nail, and Klippel-Trenaunay-Weber syndromes. Other etiologies include nephrotic syndrome, familial visceral myopathy, sarcoidosis, intestinal malrotation and volvulus, pancreatitis, constrictive pericarditis, Behcet disease, and after appendectomy.

The most common presentation is painless abdominal distention, and it may be accompanied by poor weight gain and loose stools. Peripheral edema is common. Massive chylous ascites can result in scrotal edema, inguinal and umbilical herniation, and respiratory difficulties.

Diagnosis of chylous ascites depends on the demonstration of milky ascitic fluid obtained via paracentesis after a fat-containing feeding. Ascites fluid analysis reveals high protein content, elevated triglycerides, and lymphocytosis. If the patient has had nothing by mouth, the fluid may appear serous. Hypoalbuminemia, hypogammaglobulinemia, and lymphopenia are common in these patients.

Treatment includes a high-protein, low-fat diet supplemented with medium-chain triglycerides that are absorbed directly into the portal circulation and decrease lymph production. Parenteral alimentation may be necessary if nutrition remains impaired on oral feedings; this may also significantly decrease lymph flow and facilitate sealing at the point of lymph leakage. Octreotide, a somatostatin analog, has been used subcutaneously in chylous ascites. The mechanism is not clearly understood; however, it decreases intestinal blood flow, leading to decreased portal pressure, and it also inhibits lymphatic secretion through somatostatin receptors in the intestinal wall. Paracentesis should be repeated only if abdominal distention causes respiratory distress. Lymphangiography with adjunctive embolization may be very successful in treating chylous ascites with identified site of leakage. Finally, laparotomy may be indicated if conservative management has been unsuccessful for potential surgical ligation of lymphatics.

CHAPTER 398

Peritonitis

Asim Maqbool, Jessica W. Wen, Chris A. Liacouras

Inflammation of the peritoneal lining of the abdominal cavity can result from infectious, autoimmune, neoplastic, and chemical processes. Infectious peritonitis is usually defined as primary (spontaneous) or secondary. In primary peritonitis, the source of infection originates outside the abdomen and seeds the peritoneal cavity via hematogenous, lymphatic, or transmural spread. Secondary peritonitis arises from the abdominal cavity itself through extension from or rupture of an intraabdominal viscus or an abscess within an organ. Tertiary peritonitis refers to recurrent diffuse or localized disease and is associated with poorer outcomes than secondary peritonitis.

Clinically, patients have abdominal pain, abdominal tenderness, and rigidity on exam. Peritonitis can result from rupture of a hollow viscus, such as the appendix or a Meckel diverticulum; disruption of the peritoneum from trauma or peritoneal dialysis catheter; chemical peritonitis from other bodily fluid, including bile and urine; and infection. Meconium peritonitis is described in Chapter 123.1 . Peritonitis is considered a surgical emergency and requires exploration and lavage of the abdomen, except in spontaneous bacterial peritonitis.
